Underground Water.—The discussion of State laws under the heading, "Underground Water Law in General", indicates that there has been little legislation on underground water and that administrative control has been attempted in few jurisdictions. Under the headings, "Percolation Through Basins", "Underflow Which May Support a Surface Stream", "Artesian Areas or Basins", "Alluvium Supplied by Deep Percolation from Irrigation", and "Alluvium or Glacial Till Supplied by Rainfall", several typical situations were described in which underground water is of commercial importance. Consider the situation in San Gabriel Valley. No administrative control of the use of underground water is exercised in California, and all underground water rights are correlative one with another and with rights in the surface stream of the system. Consider the present condition had the surface rights at the lower end of the valley been empowered to enjoin the use of underground water at up-stream points in order that the surface flow might be maintained, as such rights probably are empowered in all appropriative doctrine States, or will be if the two systems of law are welded. In 1912, 32 000 acres were irrigated in the valley at up-stream points, whereas, in 1934, there were 97 000 acres, but there is no indication of long-time deficiency in supply in spite of the increase. This increase could not have occurred had such power existed. Had this additional draft not taken place the water-table would now be higher than it is; the capacity of the underground basin above the water-table would have been smaller than it is at present; and the amount of percolation from floods would have been much less. In short, unless these paramount rights had been extinguished, development would now be much less than it is and the water now percolating in flood time into the underground reservoir would be wasting into the ocean. On the other hand, those having surface water rights would secure it at less cost than they now do, as they have been forced to resort to pumping to secure part of their supply. The result of the existing law has been a more complete development and the greater unit cost which is generally incurred by recent developers has been spread more or less evenly over all users.

Consider the Roswell Basin: The water which supplies the artesian area of the Basin, in part at least, flowed through, or out of, the region as sustained flow usable for irrigation; but surface users have now been deprived of this water. In part, there may be recharge now from floods which was formerly wasted. If the paramount consideration had been to preserve the surface flow to satisfy rights therein, the Basin, in all probability, could not have been developed as it now is, and the irrigated area served by the stream would be less unless surface reservoir capacity had been substituted. If this is true, development of the Basin has gone forward because of lack of administrative control.

Consider the South Platte: The control of underground water has existed through Court decree, and encroachment upon surface rights has been

inhibited. Some, but no great percentage of, stream discharge is now wasted and most of this water could be captured were pumping allowed in the river bottom and were more acreage developed. Additional cost would be incurred by all users down stream from the location of pumping and the cost of new development would have been spread to some of the prior users; but to conserve this water by surface reservoirs would also cost money, which would be furnished by the direct beneficiaries, and perhaps construction of a reservoir would not be financially feasible for them.

The foregoing examples suffice to illustrate the results of administrative control under the concepts now existing. Clearly, development now exists which would not exist had control been in effect, yet, in many cases, in spite of this greater development, draft does not exceed supply. Whether this added development, with its attendant increased costs to early water users, is more desirable than a smaller development and lower costs is a question that need not be discussed in this paper, but where draft does exceed supply there can be little argument that the condition which exists is desirable.

Although control of surface waters is not simple, the administrator charged with the control of underground water finds himself involved in a vastly more complicated situation than he who administers only surface streams. He may be faced with the necessity of re-examining his concepts of what constitutes a water right. His decision must enter the field of economics from which he has been free in the administration of surface streams. Practically, no extensive use of underground water can be made in the West without diminishing the normal summer flow of surface streams below it where such flow exists and as these streams in most cases are appropriated the precedent of decisions will incline the Courts to protect the user of surface rights against depletion by underground-water users. If this is the case, administrative control merely means complete inhibition of pumping where surface streams are involved unless pumping occurs so far from the stream that the depressed water-table has no effect on the summer flow.

The Court of Idaho has already indicated by decisions, previously cited, that it considers that the first underground-water user has a right to compensation against later pumpers in the same basin, whose draft would lower the water-table. The Court of Arizona (Pima Farms *v.* Proctor, 245 P. 369) has adopted the same attitude as to water in a definite underground stream. Pumping cannot be done without lowering the water-table, and each additional draft causes additional lowering. Consequently, even without reference to surface rights, these rulings constitute absolute prohibition of the development of underground water in these jurisdictions, except in similar situations. Statutes embodying control by the water authority merely make it easier to accomplish the same result if the administrator either voluntarily adopts the same view, or is forced to do so by the Courts.

Administration of a surface stream involves only matter which is in plain sight on which, as compared to underground water, only a small amount of study is required. The problem is solved largely in the field and a set rule is followed if only priorities are considered. Administration of under-

ground water involves gathering and studying data. The work is in the office, and decision is not so easy. The cost of obtaining sufficient information to provide a basis for intelligent decision is considerable and this cost would not be justified where economic conditions do not permit extensive use of underground water and, from the same consideration, administrative control would not be justified.

If funds are sufficient for study, administrative control should lead to greater knowledge of hydrology and the education of engineers and Courts so that water law can be modified logically. If such changes are to be constructive the powers of the administrator must not be too hampered, and his function must at least be quasi-judicial. The increased responsibility requires greater power than ordinarily lies in the water administrator's office. Above all, it requires power to deny applications.

Summary, Discussion, and Conclusions

1.—The use of underground water in the United States is increasing continually. In humid regions this use is principally for municipalities, but in arid regions the draft is for both municipalities and for irrigation. In the East it is only in the vicinity of very large or very numerous municipalities that the draft is sufficient to be of concern and in the West it is only where physical and climatic conditions are favorable. There has been very little use of underground water in the Northwestern States; and there is no conceivable prospect for increase except in the arid or semi-arid portion of those Northern States favored by the Pacific slope climate.

2.—An underground basin contains a body of water that is moving; but, at the same time, it is a reservoir because it is moving very slowly and it may take several years for a unit of water to pass through it. Withdrawal of water from the underground reservoir decreases the quantity that must be disposed of by Nature unless conditions are such that the quantity pumped is replenished by percolation from stream beds, or by deep percolation from rainfall, neither of which would have occurred had not underground space been created by pumping. This replenishment, if it occurs, does so as Nature sees fit and is not under the control of Man. If the underground water is tributary to a stream, the stream flow will be decreased by a draft on the underground basin. This decrease may be either in the period of low water or of high water, or both, and its time is non-controllable.

3.—In humid regions there are few statutory enactments as to rights to use water. The body of Court decisions rules. Both the English and American rules exist for underground water, but the trend is toward the American rule in which ownership of the water is not vested absolutely with ownership of the surface. This is not on the same basis as the riparian doctrine in surface stream flow, but satisfies the requirement in most cases, as does also the English rule, apparently, where it prevails.

4.—All the arid States of the Union have instituted more or less far-reaching administrative control of surface waters in order to obviate the chaotic conditions which generally result without such control. Such legis-

lation was adopted by many very soon after Statehood was granted and, at that early period, the use of underground water was nil, or practically so. Probably, as a consequence of this condition, reference to underground water in the statutes of many of the States is lacking, inadequate, or must be inferred by the all-embracing wording of the statutes. In California, because of the clear-cut doctrine developed by the Court prior to the enactment of statutes regarding surface waters vesting the rights to underground water in overlying lands, reference to it was omitted from these statutes.

5.—In California, which is the only jurisdiction in the United States recognizing the riparian doctrine where the law of underground water has been fully harmonized with surface water law, each land owner having access to the usable water of the stream system, whether it is on the surface, or underground, has a right to a reasonable use of the water. If the owner whose land overlies an underground basin, in exerting his right, infringes upon a surface-water user's supply the latter has no recourse if the infringement is not excessive and he may be deprived of his surface right entirely if he can secure water by pumping. He is thus deprived only as the result of the exercise of another right equally as good, vested in all who have access.

On the other hand, in Colorado, which recognizes the appropriative doctrine instead of the riparian doctrine, and in which State the law of underground water appears to have been more fully correlated with the law of surface waters than in any other State except California, the owner whose land overlies a body of underground water is prohibited from using that water if such use would decrease the surface flow necessary to supply the appropriative rights of surface users.

The result of the legal doctrine recognized in California has been so far to give a free hand in the development of underground water. The result of the legal doctrine recognized in Colorado is practically complete prohibition of such development where rights to diversion from surface streams are involved, because the surface streams were used in most cases prior to the time that the use of underground water began.

6.—In the absence of definite statutory enactments the Courts have adopted diverse views as to the doctrine of law applying to underground water and in many jurisdictions even in the West the doctrine as enunciated by the Courts is not compatible with the doctrine of law prevailing for surface waters. There is a long line of decisions in the United States which vests with the owner of the surface the right to use water under his property although the right is not absolute but rather relative in most jurisdictions and the tendency is toward the relative doctrine. This right to use underground water seems a natural one and the Courts tend to promulgate it, but in a State where the theory of the appropriative doctrine prevails (State ownership of water), underground water should be regarded as belonging to the State if the law of underground water is to be compatible with that of surface water.

7.—It is notable that, in California and Colorado, the two States in which use of water for irrigation is largest (see Table 1), underground water and surface water are in the same system of law. In other words, the fact

that they are part of the same stream system is recognized. It seems entirely probable that this same development of law will come about in other States whether or not statutes enacted for the control of underground water ignore the interdependence. It would be convenient in many cases if this did not occur, but to continue to ignore, legally, the interconnection while at the same time putting administrative control of underground water into effect would seem to be an impossibility. The following Conclusions assume that the two classes of water will come under the same system of law.

8.—The appropriative doctrine (Conclusion 6) rejects the right of each individual to pump commercial quantities of water from his own land, and makes it necessary to secure a permit from the State to do so. In any effective administration the permit would be granted only after a survey of the entire situation and, since the appropriative doctrine seeks to preserve to prior users the full measure of their water right, would lead to rejection if the investigation disclosed that use of underground water would cause decrease in the water to which they are adjudged to have a right provided the concept prevails, that a water right on a surface stream cannot be satisfied by pumping from underflow.

9.—No doubt legislation on underground water in States recognizing the appropriative doctrine would be a powerful influence in future Court decisions, but if the legislation should be contrary to the doctrine of underground-water rights laid down by the Courts in sufficient previous decisions to make it well grounded, it might be declared unconstitutional in certain jurisdictions inasmuch as the existence of previous decisions means that development exists under the doctrine of law adopted by the Court.

10.—It is improbable, but not impossible, that legislation on underground water—even in some States recognizing the appropriative doctrine—might recognize that a right to use such water exists in the ownership of the overlying land, in which case prior use in surface streams fed by underground water would not constitute a right which could be exercised against the users of such water. Much more probable legislation, however, would place all water, whether surfac or underground, on the same basis and under the control of the water authority.

11.—The water authorities of the arid States generally grant a permit to an applicant for the use of surface waters. This can be done because the streams are patrolled. If the project is constructed the diversion works can be closed when the surface flow is not sufficient for all prior rights; but when an underground supply feeds a surface stream it will be impractical to follow the same course on application for rights to pump from the underground basin because the evidence of the effect of the draft on underground water is so long delayed, and because the time at which the effect will occur is uncontrollable. Action by the authorities (if it is intelligent) must have behind it the knowledge gained by a thorough investigation and if, in those States where the law of underground water is, or becomes, compatible with the surface-water law, this leads to the conclusion that the use of underground water will reduce the supply available to surface-water users, a permit would be denied if the surface right is paramount. There is no half-way point. At

present, practically all surface streams are fully used in the late summer and, on many of them, reservoirs have been constructed which impound all the flood flows in ordinary years.

12.—In isolated basins with no surface stream outlet the problem is less complicated by traditional concepts of what constitutes a water right. The average recharge and draft can be estimated with reasonable accuracy after thorough study. At first thought, it would seem that a simple solution would be to issue permits up to the amount of recharge as a greater draft which may be sustained for a period would only necessitate a future decrease. However, decrease in draft most often occurs because cost of pumping from a lowered water-table becomes too great for some users and not because the water has become physically unavailable. The recharge during a long period of years may be deficient due to vagaries of the climate. Even though pumping draft is less than the long-time average recharge the water-table will drop during such periods, and excessive pumping costs will occur so that some users quit. The result is different only in degree from that which would be the case with actual long-time overdraft. Obviously, the administrator is faced with consideration of water costs to determine the safe yield in such situations and this, instead of merely quantity of water available, may guide his decision.

13.—The administrator will also be faced with another situation not discussed in the body of this paper and pertinent only to the economic questions which are potentially present in the intensive use of almost all streams, but particularly so in the intensive use of underground water. The use and re-use of water increase the content of dissolved solids. Some of the salts held in suspension appear to be actively poisonous to plant growth whereas others merely decrease the growth by partial smothering. Still others destroy the soil and make it unworkable. Theoretically, the use of water from an underground basin can be developed to equal the average recharge, but this would result in a slowly cumulative concentration of solids possibly to the point at which all agricultural values would be destroyed. A certain percentage of the supply must be wasted to carry off the salts. This fact must be considered in any intelligent administrative control of underground water.

14.—The foregoing sections refer to natural underground supply. When water is diverted from a stream it passes into the possession of the appropriator. As more water than can be consumed is almost always diverted and placed on the land the surplus percolates to the water-table, and, unless pumped out, finally reaches the stream. The law differs between States; in some States the water which has percolated, is deemed the property of the diverter until it reaches a natural channel, and hence it can be pumped and used on additional land under his control without interference with other users down stream. In other States the diversion is deemed to be applicable for use on the land which it will serve directly. The use is deemed completed when the water in the surface conduit is exhausted, and deep percolation is regarded as belonging to the stream system. In such cases, it cannot be pumped without a permit, which would not be given in most cases for reasons previously stated.

15.—The decisions of the Idaho Court (Silkey *v.* Trego, 5 P. 2d, 1049, 1931; and Noli *v.* Stonen, 26 P., 1112, 1933) prohibited additional pumping from an underground basin because it lowered the water-table and thereby increased the pumping cost for a prior user. The decisions of the Arizona Court cited previously follow the same reasoning, but in this case the underground water is regarded as being in a definite channel, although several miles wide. As underground water cannot be used without lowering the water-table, this reasoning, if persisted in, means inhibition of the further development of underground water in these jurisdictions. The fact that considerable underground water is used in these States is no criterion of the future. This use has created a body of water users who will unite behind these decisions to enjoin additional use.

16.—In any State having the appropriative doctrine it should not be difficult to enact a statute that will clearly put underground water under the control of the water authority, or to frame rules and regulations in those States in which the status is already clear. If the doctrine of the statute is compatible with the appropriative doctrine it clearly means prohibition of further underground-water development when the water authority takes control of an underground basin which contributes to a surface stream for reasons before stated.

In States recognizing a different administration of water law than the appropriative doctrine, statutes regulating the use of underground water, if enacted, must rest on police power. In a State wherein the water law is as well developed as is the case in California, such a statute would probably extend only to prohibition in the case of overdraft and would not have the effect noted in the preceding paragraph.

17.—Lack of administrative control leads to the fullest development of underground water but, at the same time it leads to excess development. A statute creating control, such as those adopted by New Mexico, Oregon, and Utah, apparently permits the water authority to declare control at his option. This permits a thorough investigation of the situation prior to taking control and is a flexible arrangement which may guard against the evils of too much and too little control.

18.—Perhaps future development, particularly in cases where the regulation of underground water is involved, will bring sharply to the fore a trend toward modification of water laws applicable to smaller units than those involved in such agreements as the Colorado River Compact.

19.—To summarize: Administrative control of underground water, to be intelligent, requires much research and investigation, which, in turn, requires large legislative appropriations. When administrative control is initiated it may well result in the prohibition of underground water development in States following the appropriative doctrine, in most basins tributary to surface streams, and plunge the administrator into the question of economics in isolated basins. On the other hand, control will stop over-development and thus becomes desirable at some stage no matter what the legal doctrine of the jurisdiction. If the fullest development of the water resources of a State are desired, administrative control of underground water should

not be adopted until overdraft threatens, and then only in particular areas. Conditions probably would never warrant administrative control in the arid States having a cool climate or in most of the humid States.

20.—All the foregoing comments lead to a re-statement of the paramount conclusion that, as control of underground water becomes necessary in the various jurisdictions, the complexities of the situation can be dealt with only by lodging greater power in the water authority than is now given in most jurisdictions. However, a step at a time may be the safest course.

ACKNOWLEDGMENTS

The writer expresses his appreciation of the authorities cited in this paper and acknowledges his debt in the preparation of the résumé of the law given herein. In addition, he expresses his appreciation of the corrections and criticisms offered by the members of the Committee of the Irrigation Division on the Conservation of Water.

DISCUSSION

JOSEPH JACOBS,[7] M. AM. SOC. C. E. (by letter).—This exceptionally able paper deals with the subject of the administrative control of underground water—a consideration of steadily increasing importance in the economic development, not only of the semi-arid sections of the West, but of the entire country. In his reference to irrigation in Oregon and Washington, the author inadvertantly states that "west of the Cascade Mountains irrigation is not practiced, but east of these mountains both States are arid." The writer desires to offer a correction of that statement.

As to the sections east of the Cascades it would be more accurate to state that they would, in general, be classed as semi-arid although there are considerable areas along the eastern border of Washington, and to some extent in Northeastern Oregon, that have sufficient rainfall for successful agriculture without irrigation. The status of irrigation west of the Cascades is portrayed in the following quotation from a paper prepared by the writer for the Pacific Northwest Regional Planning Commission and which appeared, in abstract, in a report published in 1936 by the National Resources Committee:

"There has, as yet, been but limited irrigation development west of the Cascades. A relatively high annual precipitation, and a relatively high humidity, even in summer, have served to discourage such development. However, despite the rather substantial annual precipitation, its 3 inches or less of summer rainfall, when water is most needed by the crops, is less than that of many irrigated sections on the east side. The cost of west-side irrigation should, in general, be much less than that of the east side due to the shorter irrigation season, the less amount of water required, and the more readily available water supplies. Unquestionably, the agricultural output would be increased by such irrigation and unquestionably, too, the expense involved would, in many instances, be fully justified economically. About 12 000 acres are now irrigated in western Washington and 65 000 acres in western Oregon, of which about 10 000 acres are in the Willamette Valley. A recent study made by the Oregon State Planning Board, reports 1 140 000 acres of irrigable land in that valley. A more detailed investigation of the valley is now being made by the Corps of Engineers, United States Army. It is easily conceivable that west-side irrigation may ultimately amount to as much as 1 500 000 acres."

W. D. FAUCETTE[8] AND J. E. WILLOUGHBY,[9] MEMBERS, AM. SOC. C. E. (by letter).—In view of the prevailing lack of administrative control of the ground-waters and the reckless destruction of those waters by interests having other objects in view, this paper is particularly timely. There is now (1936) a determined effort, well-financed, to obtain the excavation of a sea-level ship canal by the Federal Government across the underground flow in the peninsula of Florida, which has aroused the apprehension of the many people whose farming and fruit-growing industry is dependent on that flow. The physical

[9] Chf. Engr., A. C. L. R. R., Wilmington, N. C.

conditions in Florida make a résumé thereof an item of interest in connection with Mr. Conkling's paper.

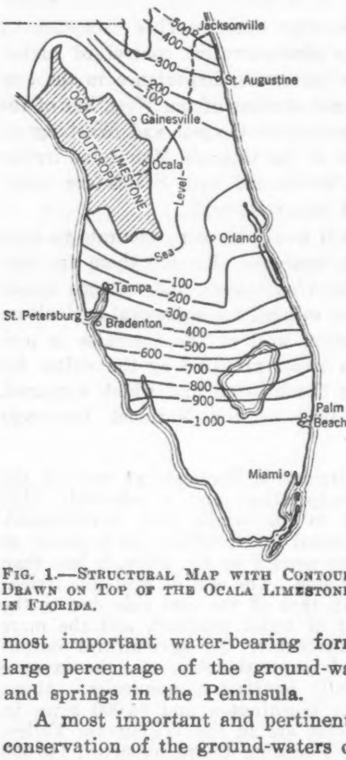

FIG. 1.—STRUCTURAL MAP WITH CONTOUR DRAWN ON TOP OF THE OCALA LIMESTONE IN FLORIDA.

The author discusses conditions that obtain in the arid West; in Florida, the rainfall is generous, and the geological relationships are different from any mentioned in his paper. Artesian water in Florida is not found in structural basins, but it moves outward and downward in a great dome of Ocala limestone. This limestone (which is a porous, soft, cavernous material through which ground-water moves freely) lies at or near the surface in the area from about Webster and Bushnell on the south, to Silver Springs on the east, and Gainesville, High Springs, and Mayo on the north, and extends to the Gulf of Mexico (see Fig. 1)[10]. The flanks of this limestone outcrop are covered with younger and often more impervious formations. The Ocala limestone outcrop area forms a great catchment basin. Copious rainfall thereon percolating outward and downward through this formation which underlies the entire State of Florida and is the most important water-bearing formation in the State, is the source of a large percentage of the ground-water supply available through deep wells and springs in the Peninsula.

A most important and pertinent question raised by the advocates for the conservation of the ground-waters of Florida is the effect of a 200-mile ditch cut 30 ft below sea level, across the catchment area that supplies the greater part of the artesian water of Florida. Would such a ditch so intercept, contaminate, and pollute the ground-waters of the Florida Peninsula as to destroy much of the beauty and charm of the great winter playground of the Nation, and, at the same time, ruin its groves, farms, and its market gardens? Would the canal bring about a situation whereby the residents of Florida could no longer depend upon ground-water supplies for industrial, municipal, agricultural, and domestic uses?

For several years, in co-operation with the U. S. Geological Survey, the Florida State Geological Survey has been making a study of the ground-waters of the State. Realizing the danger of promiscuous borings for artesian water and of contamination by drainage wells, the State Geologist has advocated a very careful supervision and conservation of ground-water supplies,

[10] Twenty-First and Twenty-Second Annual Repts., Florida Geological Survey, Fig. 8, p. 50.

and laws have been passed to that end. In spite of these recommendations, certain engineers and geologists have made superficial investigations and recommended the building of the canal, without giving due consideration to its effect upon ground-waters.

To the present time the weight of scientific evidence as to the effect of a canal on the geological problems involved, has been against, rather than for, the building of the canal. The geologists who have reported favorably on the canal admit the possibility of grave danger to such scenic features as Silver Springs and Blue Springs, but state that this danger may be minimized or entirely prevented by proper engineering precautions. However, lowering the water-table to 40 ft below the present level of Silver Springs and Blue Springs, and the lower courses of the Withlacoochee and Ocklawaha Rivers, will undoubtedly destroy these springs. That is what an effective drainage ditch will always do—drain. It is difficult to imagine any engineering precaution that can be taken to prevent it. The author points out that springs in the vicinity of Roswell, N. Mex., no longer exist, because the water formerly issuing from them has been diverted, and the area of artesian flow within that region has shrunk from 663 sq miles to 425 sq miles, because of depressed piezometric head.

In regard to the effect of salting artesian wells, the geologists favoring the canal frankly admit that they do not know what will be the result, if the canal is constructed. However, Dr. Herman Gunter, Florida State Geologist, specifically states that such salting is greatly to be feared, especially in that area where highly mineralized water is present at moderate depths. Any lowering of head due to excessive drainage in the Ocala catchment area may cause further encroachment of salting in those areas where there already exists a delicate balance between fresh water and salt water. This condition is already faced by some vegetable growers in the Sanford Section. Less than normal rainfall on the catchment basin over a period of several years has reduced the quantity of ground-water available in the Ocala formation, and this, together with the attendant necessity of heavy draft on flowing artesian wells for the irrigation of crops, has resulted in some wells in the Sanford District ceasing to flow, and the waters in others showing high salinity. The construction of the proposed canal could accentuate and make permanent these conditions, not only in the Sanford area but also in other important vegetable and fruit-producing districts of the State. Growers in the Sanford District, having experienced the disastrous effects on their crops of depleted ground-water supplies, have arisen *en masse* protesting the construction of the canal, fearing that it would completely destroy their livelihood. It is also true in certain areas, such as Sanford, that any diminution of head would necessitate the pumping of wells where they now flow freely. This would greatly increase the cost to the growers of water used for irrigation.

Geologists and engineers who have favored building the canal have definitely stated that the pursuit of agriculture and the growth of vegetation will not be affected; that the progress of agriculture and the growth of vegetation in general are only remotely related to the water-table. These are strong state-

ments when it is remembered that three-fifths of the rainfall of Florida is in June, July, August, and September (which is the non-growing season, as Florida farmers produce their crops during the winter months for the Northern markets), and evaporation is so great that probably less than 20 of the 50 in. that fall as rain sinks into the soil. The control of water through irrigation and drainage is rapidly becoming a limiting factor in successful crop production in all areas of the United States. Areas in Florida that are not irrigated, and where the water-table is 60 to 100 ft below the surface, are adapted, only under exceptional conditions, to a highly developed agriculture. Florida growers are beginning to realize the necessity for more precise control of water in crop production if the State is to maintain its horticultural prominence. In that State, with the exception of the Everglades, irrigation is mostly from the underground water supply. Vast producing districts have been established in many parts of the Peninsula where perishable crops are grown under intensive methods based on irrigation from deep wells. This shows that Florida farmers realize that they cannot depend entirely on rainfall for the production of their crops. Like many areas in the West, noted by the author, Florida is using more and more artesian water for irrigation, and for municipal, industrial, and domestic purposes; and there is, therefore, a constantly increasing drain on underground supplies.

The statement has been made that although the water-table at the edge of the canal would be lowered to sea level, normal water-table slopes would be approached 10 to 15 miles from the canal. Unfortunately, the areas used in calculating these slopes were not taken in the Ocala limestone, but were in the Tampa and Hawthorne formations, which are younger and more impervious. As the Ocala material has a mean porosity of 30.6%, and as the canal would cross "the ramifying system of ground-water drains which has been developing over a period of millions of years", discharge from this area would be very rapid and the water-table slopes in such a formation much more gentle than those used in the calculations previously cited.

Over a large area in Central Florida the water-table stands between 40 and 50 ft above sea level. With more complete drainage established by cutting into the Ocala limestone, the water-table will fall to sea level over approximately the same area with the following results: (1) Decrease of head will cause salt water to rise in artesian wells approximately 40 ft for every foot the head is reduced; (2) lowering the water-table will remove supports from cavern roofs and walls, and there will be a progressive formation of sink holes from the canal, both to the north and south; and (3), the areas of high water-tables (the piezometric surface), both north and south of the canal, will be lowered, whereas high water-tables have a beneficial effect on temperature during cold waves.

Amplifying Result (2), perched lakes and swamps will be drained. It is interesting to note that many of the lakes of Florida may be of this character. A notable example of a lake of this type existed at Payne's Prairie, near Gainesville, Fla. Payne's Prarie has an area of 18 to 20 sq miles. In the summer of 1790, William Bartram visited this section and found a vast savanna that afforded pasturage to large herds of horses and cattle belonging

to the Alachua tribe of Indians. When visited by James Pearce, in 1824, this basin was still dry land. About 1871, Alachua sink became clogged, and the body of water thus formed was known as Alachua Lake, which is reported to have been navigable for small steamers. This lake continued until the summer of 1891, when it was drained through a sink. Since that time the lake bed has remained dry land, with the exception of temporary overflows, and is known as Payne's Prairie, one of the best cattle-grazing areas in the State.

As the author points out, the use of ground-water in the United States as a whole is constantly increasing, and it is important that this valuable natural resource be conserved. Ground-water is the very life blood of Florida; and in view of this fact one can readily understand the concern which many localities in that State, south of the route of the proposed canal, have shown with regard to the conservation of their most important natural resource. It is the hope of the writers that the present agitation in Florida will lead to more effective administrative control, and to the development in the mind of engineers and of the public of a greater sense of responsibility to the future of preserving the ground-water resources throughout the Nation

R. E. SAVAGE,[11] Assoc. M. Am. Soc. C. E. (by letter).—A complete review of a new and important subject is presented in this paper. Mr. Conkling has handled the legal background of water legislation and Court decisions in an able manner. The paper points out some of the implications of public control of ground-water, assuming that such control will be exercised by the States in a wise and inclusive manner, in places where there is an economic justification and need for such a program.

The extreme variation in topographical, geological, and climatic conditions in the United States present a wide basis for the application of remedial legislation and governmental control of ground-water. In addition, there is the differing laws, customs, and application of laws by Civil Courts, resulting in the building up of a complicated structure. The author has emphasized all these phases and has shown the need for future control of underground water through the growing use of it for beneficial purposes.

The increase in population and the decreasing water supplies have brought the need of conservation of water to the fore. There is an ever-increasing demand for large supplies of water of relatively high standards of quality for industrial purposes in the centers of population in the United States. Large metropolitan areas have striven heroically to meet this demand by the construction of aqueducts bearing the supplies of mountain water-sheds a great distance. It is evident, however, that the economic and physical limit of these distant supplies is in sight. In the past few years engineers have witnessed a heightened discussion of the climatic cycles and their relation to the quantity of run-off water available for storage, irrigation, and domestic use, and the studies presented have been of absorbing interest. There is an increasing efficiency and excellence in the design of pumping machinery and motor-power equipment for the utilization of ground-water. There should be a correspond-

[11] Asst. Engr., California Railroad Comm., San Francisco, Calif.

ing advance in regulation and protection and in making the existing ground-water supplies available.

The writer has been greatly impressed by the need of regulation, by law, of the loss of wells in basins subject to harmful encroachment from salt water from adjacent coast lines and inlets, and also the need of eliminating the waste from virgin artesian supplies due to careless and destructive methods. There is no doubt that much benefit would result from the co-ordinated control of ground-water by public authority. After reading the paper, one is more than impressed with the need of distinct legislation for the various phases of water-supply control, wisely and skilfully drafted.

Any student of ground-water resources realizes the necessity of collecting information concerning the geologic nature, the history, and the yield of wells. In the private development of ground-water much of this information is lost, and these data can be collected and made available by future regulation.

In this comment on the physical aspects the writer has endeavored to keep in mind the difficulties besetting the progress of any comprehensive program of public control of ground-water, because of the diversity of the legal treatment of property relations in the ownership of water in the various States and political subdivisions. Mr. Conkling has ably clarified this phase of the situation. As stated under the heading, "Conclusion", it is incomprehensible that the control should be taken from the State, due to complex and extensive legal framework that has been constructed in the past as a means of controlling the surface waters.

H. J. F. GOURLEY,[12] M. AM. SOC. C. E. (by letter).—The subject-matter of this paper is of great interest, if only as an indication of the variation in the practice in different parts of the United States, and forms a valuable record. To complete the picture, the following notes of the position in England are submitted.[13]

In 1859, the highest legal tribunal—the House of Lords—established the principle that the rights of riparian owners, in respect of water flowing in visible surface streams or in known and defined channels, do not apply to underground water which simply percolates into and through the ground and has neither certain course nor defined limits. Subsequent cases decided in 1881, 1886, and 1902, made it clear that a "defined" channel is one which is definitely contracted and bounded, although the actual course of a channel may be undefined by human knowledge, and, furthermore, that a defined subterranean channel must be "known" not by excavation but by reasonable inference from observations on the surface of the ground.

By these decisions an owner claiming riparian rights in the flow of water in a subterranean channel must prove the existence of such a channel without recourse to excavation, and as recently as 1932 this statement of the legal position was affirmed by the Court. The general position, therefore, is that there is no property right in underground water, and nothing to prevent the sinking of a well on land adjacent to the site of an existing well, to the possible detriment of that well.

[12] Civ. Engr. (Binnie, Deacon & Gourley), Westminster, London, England.

[13] "Some Recent Developments in British Waterworks Practice", by H. J. F. Gourley, *Journal*, New England Water Works Assoc., December, 1936, p. 345.

As between neighboring industrial concerns using underground water, the principal effect of the existing law has been that when "Peter" robbed "Paul" by sinking to, and pumping from, a greater depth than "Paul", the latter's only remedy was to deepen his own well and pump from still greater depths, and the only people who gained were the well sinkers.

Until comparatively recently an industrial concern using more than 100 000 gal of water per day from an underground source was the exception; within the past decade, artificial silk and other specialized works have been established, and these, by drawing on underground resources to the extent of several million gallons per day in some cases, have so depleted (over-pumped) the area in which the works happen to be, as to affect adversely the yield of public wells upon which the community relies for all or part of its supply.

It will have been appreciated that a private individual or manufacturing concern has only to buy land in order to have the indisputable right to obtain such water from underground sources as the strata are capable of yielding.

When, however, a public authority or statutory water undertaker[14] contemplates the augmentation of its resources by an underground supply, the position is not so simple, since the authority of Parliament or of the Ministry of Health must be obtained first. Parliamentary plans are then deposited in both Houses (that is, the House of Lords and the House of Commons), in other specified places, and with Government departments. A Bill is prepared describing the "works" for which powers are sought, and among its other provisions is a so-called "protective clause." At the same time, by notices published in the newspapers, all persons or interests likely to be concerned are made aware of the proposals of the Bill, which is, in due course, the subject of inquiry, in turn, by a committee of each House. The promoters and the various opposing interests are represented by counsel and supported by engineers, and other technical witnesses, and, in the sequel, the Bill emerges as an Act upon receiving the Royal Assent, although, generally, with amendments put upon the promoters by one or other committee or inserted by agreement with opponents. It is by such an Act that a public authority is empowered to purchase land by condemnation, if agreement is not possible, and to sink a well or wells, and to build other structures, on it. For less important works and where there is no opposition, a simpler and less expensive procedure is available, for the Minister of Health has authority to grant a Provisional Order, which must subsequently be confirmed, if not then opposed, by Parliament.

For thirty years or more most private Acts involving the construction of wells have included the protective section previously mentioned. Under this section, the owner of any well or spring (and, sometimes, pond) within a specified radius, used at the date of the Act as a source of water supply, who can prove that his supply has been diminished as a consequence of the pumping at the authorized well, is entitled to compensation in water, or otherwise. The radius of protection varies with the geological formation and in special

[14] Throughout this discussion the term, "undertaker", means, according to the context, a municipal authority or a public utility company empowered by statutory authority to construct and operate works for supplying water within a specified area.

circumstances, but it is usually 1 mile for wells in chalk and 2 miles for wells in Triassic sandstone. It also sometimes happens that, having regard to representations made during the Parliamentary proceedings on behalf of opposing statutory water undertakers, a limit is put on the quantity that may be pumped in any day.

Thus, it will be seen that, whereas private individuals have been unfettered in their exploitation of underground water resources, those charged with the duty of affording supplies to the community have, by precedent and practice, been restricted as it were outside the general law; and until 1936 there was no case of reciprocal protection being given to the public authority and nothing in law to prevent an industrial concern, with the knowledge that an authorized well had proved the presence of a large supply, from sinking its well immediately adjacent to the authorized well and developing it so as seriously and adversely to affect the yield of the authorized well.

Partly to meet the growing needs of its area of supply and partly because one of its authorized wells had had its yield reduced from 1 500 000 to 700 000 gal per day in the course of eight years, the Wolverhampton Corporation sought Parliamentary powers this year (1936) to sink additional wells at some distance from the Borough. The reduction in yield was attributed to the pumping of increasingly large quantities (now about 2 000 000 gal per day) from the same Triassic formation by an industrial concern the works of which are within the Borough and less than a mile from the well; and evidence was given to the effect that, in the course of a few more years, the yield of that well would become so small as not to be worth pumping by the Corporation.

Although the Bill, which included the usual protective clause with a radius of 2 miles, was opposed, it emerged with a reciprocal clause by which, after the date of the Royal Assent, no land-owner within the same radius could sink a well or otherwise abstract underground water, except by consent of the Corporation, except for the domestic supply of persons on his land, for the watering of stock, or for other purposes of an agricultural nature connected with the product of that land. It was not the intention of the Corporation to impose undue restrictions on the normal development of the lands within the 2-mile radius, and the clause was definitely directed to preventing the incursion of large industrial works. The clause provided that on refusal by the Corporation of consent to sink a well, the land-owner may require the Corporation to afford a supply at cost price to the Corporation, although there is no obligation if by so doing there is likely to be interference with the Corporation's ability to maintain either the supply for domestic purposes within its statutory limits of supply, or with existing trade supplies; nor if the aggregate of such supplies, together with what water was necessary to compensate owners of existing sources within the radius of protection, exceeds the yield of the authorized well.

Having regard to the extent to which underground resources were being exploited without control, water-works undertakers for many years have been pressing for general legislation to control the development of under-

ground sources, and advocating a system of licensing by which regard would be had to the limits of potential yield of particular underground basins; and during the past two or three years the Institution of Water Engineers of Great Britain, acting jointly with other associations representing water-works interests, has made representations to the Minister of Health which were supported by him in a memorandum placed before a Joint Committee of both Houses of Parliament which sat at intervals during 1935 and 1936. This Committee reported on July 29, 1936, and, after referring to the anomalous position of water supply undertakers as compared with private individuals (as previously described), states that "it would be more equitable and more in the public interest if property owners were treated in the same way as water undertakers in any project where the former may wish either to sink wells below a certain depth or extract more than a certain quantity of water from them except for their own agricultural or domestic purposes." It remains to be seen how far general legislation follows this recommendation; it is sufficient to observe that the Wolverhampton Act is in advance of the general law as it now stands, and since, in the absence of general legislation, Parliamentary Committees on Private Bills are more often than not guided by precedent, this Act will serve as an argument in favor of similar provisions in future Bills.

So far as regional considerations affect underground-water resources and supplies, the problem is by no means as simple and as capable of reasonably clear-cut limitations as in the case of surface supplies. To appraise with any reasonable and approximate degree of accuracy the limits of a particular underground basin, its rate of replenishment, its storage capacity, and its potential yield, is a difficult and often involved undertaking. In most cases it is only after years of exploitation that it becomes apparent, on an investigation and consideration of ground-water levels, on the character of the water yielded, or on a combination of these factors, that water is being extracted in excess of replenishment. Often, particularly in areas adjacent to the sea, it is too late to remedy a partial or complete spoilation of an otherwise potable supply which has resulted from over-pumping in such circumstances.

What has been stated herein, indicates that there is now a tendency in England toward what the author describes as the "American rule" and also to what may be considered as a measure of State control. In so complicated a matter, the step-by-step approach, as the author observes, is probably the safest line and one which will allow of re-orientation in the light of experience.

O. J. Baldwin,[15] Jun. Am. Soc. C. E. (by letter).—The able manner in which this paper has been presented is a subject for congratulation. The value of administrative control of underground waters is well emphasized and a careful study of the paper would be of great value to all concerned with the utilization and conservation of this natural resource.

There are other aspects of the use of underground water, not mentioned by Mr. Conkling, which are of major importance in many States, particularly in

[15] Chf. Engr., The Iowa State Planning Board, Ames, Iowa.

the humid sections in the Mid-Western and Eastern United States where irrigation is not an important water use. In this region the demands of business and industry upon underground water for air-conditioning and industrial use have placed drafts of such magnitude on small areas that static levels are being, and have been, seriously lowered. The continued exploitation of underground waters will result in conditions which, undoubtedly, will produce a fifth doctrine of law, or a modification of the fourth doctrine discussed by the author.

Specifically, the point that must be decided by the Courts, or written into future legislation, concerns the proposed use of the water. Shall the municipal or domestic consumption of underground waters be considered a more basic or fundamental use than those of industry (manufacturing), refrigeration, and air-conditioning? If so, what shall be the priority of use, and shall a prior claim on the underground waters be subject to condemnation proceedings to meet the needs of a more fundamental use, as is the case with surface waters in some States? Inasmuch as air-conditioning and refrigeration may be obtained by other, although more expensive, means it would appear that the development of sub-surface waters for these purposes should be definitely controlled by legislative action.

Legislative control of air-conditioning and cooling usage should not be construed as a prohibition of such usage. Where the cooling effect is obtained by circulation through a closed system, the water may be returned to the source, through recharge wells, without changing the mineral or bacterial content. This method of maintaining the static level has already been used successfully in some of the Eastern metropolitan areas.

The use of a recharge well at a point removed from the supply well is more expensive to the individual user than wasting the water into sanitary sewers. On the other hand, the overloading of the sanitary sewerage system and the sewage disposal plant of a municipality with waste water from air-conditioning plants will greatly increase the cost of operation and maintenance. Already, some cities have found legislative action necessary to force the operators of air-conditioning plants to cease overloading sanitary sewers by connecting to the storm sewers. It is not unlikely that a continued development of sub-surface waters (provided the supply is not exhausted) may lead to an overloading of storm sewers also. Even if the storm sewers prove adequate to carry the flow, the wasteful use of artesian water is not halted. Viewed in the light of conserving the underground waters, any reasonable increase in expense, incurred in returning the waste water from closed-circuit air-conditioning plants to the ground, can be justified.

The use of a recharge well presents certain problems aside from those of expense. Foremost of these are the questions of minimum spacing between wells to prevent recirculating the returned water, and the temperature rise to the return of the heated water. The interval between recharge and supply wells must be determined by studies of the individual cases, giving due weight to the porosity of the aquifer, the movements of the artesian stream, the location of adjacent wells, and other factors peculiar to the site.

A rise of only a few degrees in the temperature can materially lower the efficiency of a refrigerating or air-conditioning system. To offset the temperature rise, it seems entirely possible, from the practical aspects, to utilize a closed system with a recharge well both as a cooling system in the summer and a heating plant in the winter. With an underground water temperature of 50 to 60° it would be possible to use the cooling system as a heating plant probably 20% of the year. A temperature differential of only a few degrees would permit a material saving in fuel costs in heating fresh air brought into the building, whereas warehouses might be completely heated to a satisfactory temperature.

Temperature differences of 75° would be quite common for short periods in the Northern United States. Under such conditions it is possible that sufficient "cold" could be stored in the sub-surface formations to eliminate the temperature rise of the following summer. It is quite likely that an actual economy could be effected, over a yearly operation of individual heating and air-conditioning plants, that would more than offset the added expense of a closed system. Regardless of the comparative cost, however, a less wasteful usage of sub-surface water resources will be one of the conservation problems of major importance in the near future.

The need of wisely drafted legislation, based on a thorough study of the water resources, is most urgent. The Engineering Profession is perhaps as responsible as any one group for the uncontrolled exploitation of this natural resource. It is now its responsibility to encourage the conservation of artesian waters and to lend its support to obtaining legislative appropriations for studies of the many problems relating to sub-surface waters. The tempo of the present development calls for an immediate study of extensive proportions in order that control measures may be adopted before depletion of the underground supply occurs. The writer is in accord with the conclusions that the control of underground water should be retained in the State. The complex situations existing in the various States make legislative control sufficiently difficult even within the State. Only in special situations where the interest of more than one State is involved, should there be any attempt at regulation by higher authority.

G. E. P. Smith,[16] M. Am. Soc. C. E. (by letter).—This very valuable paper is more comprehensive than its title indicates. It is a rather thorough treatment of the entire subject of ground-water law, but with special emphasis on the control of ground-water by the State. If the following discussion appears to be critical, it does not follow that the writer is unappreciative of the high value of the author's timely analysis of an intricate subject.

A great handicap in the development of ground-water law is that legislators and advocates in the Courts usually have little conception of the hydrology of ground-waters. Fortunately, this has led to an avoidance of the issues in many States, and questions which might have been settled wrongly are still open. Progress is being made in the understanding of ground-water regimen and hydrologic records are being accumulated, but it

[16] Prof. of Irrig. Eng., Univ. of Arizona, Tucson, Ariz.

may be long before ground-water law becomes fully crystallized. Although uniformity in the seventeen Western States might be desirable, it can scarcely be hoped for; even in the use of terminology, the various State Courts are not in agreement at present. Hydrologists should have an active part in the development of the law, both statutory and judicial, and administrative control should be in the hands of engineers whose training includes hydrology.

The most notable pioneering advance in recent years is the legislation in New Mexico, enacted in 1931, placing underground streams and bodies of ground-water the boundaries of which "can be reasonably ascertained" under the effective control of the State Engineer. The excellent administrative control that has been established has solved the difficult problem of a seriously decreasing water supply and has even made a significant further advance in the use of public funds, in part, in shutting off the loss of water from abandoned and leaky wells.

The author has described and contrasted the various systems of law relating to surface waters and ground-waters. The riparian doctrine, as modified and developed by the Courts in California, is so different from the original riparian theory introduced into this country from the English law that it ought to be given a new name for the sake of clarity. Among its disadvantages in an arid region should be mentioned that, in theory at least, it may lead to the spreading out of the water supply, in dry years, into a thin irrigation over too great an area, so that on no field is there a profitable crop. Furthermore, since all ditches will be wetted, the proportion of the water lost in the canal system will be high; and, if a real attempt were made by a State administrative body to prorate the waters from day to day through a drought period, the task would be found well-nigh impossible. It is understood that the irrigation interests in California have had to tolerate the riparian doctrine, but have not relished it.

In his comparisons of laws relating to ground-water the author has tended to minimize the disadvantages of the American and California systems, which are, first, the almost certain over-development of the supply to the injury of all the water users; second, the insecurity as to the future of a developed supply and the insecurity attending the 5-yr probationary period; and, third, the likelihood of ultimate scattered small patches of irrigated land instead of more compact areas. Under the appropriative doctrine a water user at least knows where he stands, assuming that the determination of the existing rights has been made by the State's administrative officer.

The writer questions the statement that the rule of law promulgated in the Katz *v.* Walkinshaw case was adopted in other States. The one exception was the Utah Oil Refining Company case, in which the Court adopted the correlative rule, but permitted export; and more recently Utah, by statute, has placed all ground-waters under the full appropriative rule.

In an Arizona case, involving a small seepage of water, the query was as to just what constitutes a spring. The Court added considerable dicta, and indicated a leaning toward the correlative rule, but such tendency should not be considered as adoption. When the issue arises directly in a case, the American or the California rule may possibly be followed. In a case in

the State of Washington, where a hillside well had been drained by reason of a new railway cut, the chief issue was damages, and the references to the correlative doctrine were of little moment. Judges often wander afield in the preparation of decisions.

The author points out clearly that the doctrine of correlative rights is incompatible with the doctrine of priority of appropriation. By reason of that incompatibility the correlative rights theory should be rejected in arid States other than California, at least with regard to "commercial" supplies of water.

The author's analysis of the terminology of rules of law is timely. The term, correlative, has been used in decisions with several different meanings. He might well have emphasized that a number of States have a dual system of law—the American system for "diffused percolating waters" and the appropriative system for underground streams flowing in definite channels. The division is not along the same lines as that between non-commercial and commercial supplies. New Mexico, Arizona, Nevada, Oregon, and Washington have the dual system. A recent case in point is that of Evans *v.* City of Seattle (47 Pac. (2d) 984).

Normally, the best pumping supplies are located in the Quaternary valley fill. If they are controlled under the appropriative system of law, it may be assumed that domestic supplies will be made available under the rule of preferential rights. If meager supplies are obtainable from Tertiary formations (at least in Arizona), it may be best to leave them under the rule of reasonable use, the American rule; rarely, if ever, will the effect of such use on the Quaternary supplies be of any considerable importance.

The writer agrees that the extension of the right of priority to the means of diversion, requiring that the water level at the well of the prior appropriator be not disturbed, is absurd. For the rule respecting means of diversion of surface water, the case of Salt Lake City *v.* Gardner (114 Pac. 147) is a leading one and was followed in the case of Pima Farms Co. *v.* Proctor, cited by the author. In the few cases where this rule has been upheld, it is not unlikely that sooner or later the Courts will reverse themselves, and will adopt the rule of reasonableness; even now in those jurisdictions the rule is ignored in practice.

The future success of administrative control over ground-waters will depend to a large extent on the right to reject applications when development has reached a safe limit. It will be simpler to prevent drilling of wells than to exercise constant control over surplus wells. A private communication from the State Engineer indicates that the attitude in Wyoming as to rejections is that "if an individual wishes to proceed * * * he is the one who must bear the burden of costs and should satisfy himself as to the chance of securing water for his appropriation in accordance with its date of priority." It is understood that, in California, despite frequent strong opposition, the Division of Water Rights refuses applications to appropriate when there is no unappropriated water, "getting away with it when they can."

A State administrative office has all the data on vested and initiated rights and on stream flow and storage, and is in a better position to determine when

a water supply is fully appropriated than any other agency. Surely an "individual" in an isolated location with limited finances cannot be expected to go into the question thoroughly; nor can a promotional company do it. It does not promote the public welfare when great sums are invested in irrigation works and in clearing land, building homes, and planting orchards, subdividing land, and luring settlers, only to find later that the water supply is inadequate or undependable. The attitude in Wyoming seems to be to evade the responsibility; this is lamentable because engineers most favorable to State administration of water supplies consider Wyoming's record of administration as the ideal one.

The author states that there are no statutes on underground water in Arizona. On the contrary, the State Water Code includes water "in definite underground channels, whether perennial or intermittent", and also springs, among the waters that belong to the public and are subject to appropriation. This statutory provision is far-reaching, and has been recognized in Court decisions. It remains now to establish just what constitutes a definite underground channel, and much thought is being given that problem. In the Southwest Cotton Company case (4 Pac. 2d, 369), the Court in its decision suggested a test which hydrologists agree is impractical. When another case comes before the Court, or by statute, both definition and test should be settled definitely.

The author states, also, that in the case of Pima Farms Co. *v.* Proctor (245 Pac. 369), the Court ruled that the ground-water beneath the inner valley of the Santa Cruz River is in a definite under-ground channel. No technical data or competent evidence on that point was presented to the Court. The litigants stipulated that it was a definite channel, and the Court stated, "it is assumed or conceded throughout that this body of water is a known independent subterranean stream." How the Court would "rule" on this point if the evidence were presented, cannot be known. The status of ground-water law in Arizona is one of uncertainty.

In no Western State has the final word been said; ground-water law is still in the making. There will be refinements, especially in border-line cases, and there will be some reversals. In the further development of the law and of administrative control of ground-waters, it should be kept in mind that the interests of the public are an important factor. On some points, property rights may be modified or may give way entirely. The public is interested primarily in having the limited water supplies fully utilized. Furthermore, in the future, it may be emphasized that, in cases of conflict, the most important uses must prevail over those less vital to the general welfare.

David G. Thompson,[17] Esq. (by letter).—In this paper Mr. Conkling discusses a problem of great importance in planning the efficient development of one of the country's valuable natural resources, namely, the underground water or, as it is commonly called, the ground-water. In some States almost all public and domestic supplies are derived from ground-water, and large indus-

[17] Senior Geologist, Div. of Ground-Water, U. S. Geological Survey, Washington, D. C. Published with permission of the Director, U. S. Geological Survey.

tries and thousands of acres of irrigated land are dependent upon this source of water supply. There is abundant evidence that, in many areas, the supply of ground-water is not sufficient to meet the needs or demands of all who desire to use it.

The paper is written largely from the viewpoint of problems in the Western States where much water is used for irrigation. It is the aim of this discussion to raise for consideration certain viewpoints arising from a study of ground-water conditions in many parts of the United States, but most particularly in certain of the humid States. The writer has delved assiduously into the laws of many of the States and of numerous Court decisions relating to ground-waters, but he must emphasize the fact that his viewpoint is that of one not versed in the principles of law. His approach is primarily from the viewpoint of a ground-water hydrologist whose duty has been to advise in the development of the country's ground-water resources.

Mr. Conkling has stated that, in his paper, he has not considered the phase of control of ground-water relating to waste. He is concerned primarily with the orderly development of the available supply to the greatest possible extent without exceeding the safe yield of the source. Meinzer[18] has pointed out that the problem of legal control of artesian water relates: (1) To the proper construction and operation of wells to prevent waste; and (2) to the equitable distribution of the water. It is the writer's belief that laws relating to control of the use of ground-water should not avoid consideration of the phase of prevention of waste. As a matter of fact, a definite requirement in the statutes of most of the States that have sought to establish a property right in either surface or ground-water, makes such a right dependent upon a "reasonable use" of the water. As a result of its quantitative studies of ground-waters in many parts of the country the Division of Ground Water of the U. S. Geological Survey now defines the safe yield of an aquifer somewhat as follows: "The safe yield is the rate at which water may be drawn perennially from the formation * * * without depletion of the supply or impairment of its quality to such an extent that withdrawal at this rate is no longer economically feasible." In other words, safe yield involves not merely the elements of quantity of water, time, and cost of pumping, but also the element of quality of the water; for example, the controlling factor in the maximum use of water from beds along a sea coast may be the rate at which water can be withdrawn without drawing in salt water. Elsewhere, the usefulness of fresh water-bearing beds may be impaired by improper well construction in oil fields, or in other areas where salt water is present, by disposal of waste in industrial areas, or by pollution when wells are used for drainage. Any law seeking to bring about a reasonable development of ground-water must recognize these dangers and give authority to control them just as much as it gives authority to limit quantity of withdrawal. However, this discussion is confined to the phase of equitable distribution or limitation of the use of ground-water.

---

[18] "Progress in the Control of Artesian Water Supplies", by O. E. Meinzer, *Engineering News-Record*, Vol. 113, pp. 167-169, 1934.

Under "Extent of Underground Water Use" Mr. Conkling has stated that "in humid regions (that is, in regions of the United States east of the 98th Meridian) underground water is exploited to the point where far-reaching effects are produced only to secure supplies for metropolitan areas." However, in Table 1, the two States following California, in second and third rank (namely, Louisiana and Arkansas), and a large part of the irrigated area in Texas, are in the humid part of the country.

It is doubtless true that the problem of the control of ground-water has been most urgent in the arid Western States. There is evidence, however, that increasing attention must be given to the problem in other States. In a most interesting discussion of problems of legal control in England, H. J. F. Gourley[19], M. Am. Soc. C. E., shows some of the legal difficulties encountered in an area that certainly is as humid as most of the United States. Within recent years the need for some kind of legal control has been recognized by State geologists and other officials in several Eastern and Central States, and legislation has been drafted in some States. In the last two or three years special impetus has been given to the consideration of projects for irrigation by ground-water in drought-affected areas. There have been numerous developments of ground-water for municipal supply and for private industrial use. Particularly has there been a great increase in the use of ground-water for air-conditioning, and this use is certain to increase. In all too few instances in the actual and proposed developments has adequate consideration been given to the safe yield of the source aquifers, and control of development becomes increasingly desirable. A few instances may be cited to supplement, for the Eastern States, Mr. Conkling's excellent summary of the present status of control in the Western States, and to show the further need for, and problems of, control.

Stated briefly, the writer's thesis is as follows: Much of the classification of ground-waters adopted in many Court decisions and by writers of legal textbooks is not consistent with scientific principles of ground-water hydrology. Efforts frequently have been made to distinguish between "percolating water" and water moving in "known and defined subterranean channels or watercourses", where geologic and hydrologic conditions do not warrant such distinctions. The rule adopted in some Courts to apportion the ground-water among land owners in accordance with the doctrine of correlative rights will not provide a universally satisfactory solution because in many localities the supply of ground-water available is inadequate to fulfill the reasonable needs of all land owners and, especially in industrial areas, there may be no relation between the actual reasonable needs of different individual land owners and the area of lands owned by them, respectively. If this doctrine were interpreted in such a way as to limit each user to no more than his *pro rata* share of the ground-water on a basis of area of land owned, in some localities such share would be so small that no ground-water development would be practicable; and this great economic resource would largely go unused. Therefore, if the ground-water resources are to be utilized most beneficially it is believed to be essential that a doctrine of appropriation

[19] "English Law Does not Control Ground-Water Draft", by H. J. F. Gourley, *Water Works Engineering*, Vol. 89, pp. 1294–1297, September 30, 1936.

and beneficial use sufficiently flexible to be adaptable to the conditions of each locality is the only practicable solution. It is realized that adoption of this doctrine in some States will encounter divergences of opinion and conflicts of interests among various groups which must be most carefully and sympathetically reconciled, but it is not believed that any insurmountable obstacles exist.

Attempts at, or Lack of, Control in Eastern States.—In the Grand Prairie region of Arkansas for about 20 yr from 100 000 to 160 000 acres of rice land has been irrigated with water from wells[30]. Since 1927, the water level in observation wells has dropped to lower and lower levels in successive years and the evidence seems indisputable that the safe yield of the beds has been exceeded. The area of land that is suitable for irrigation is much larger than that actually irrigated in any season, and conceivably at some future time, with conditions of price and other factors favorable to the rice farmer, there may be a great increase in the use of ground-water for irrigation in the Grand Prairie region.

Arkansas has no law providing for the control of ground-water, and so far as the writer knows, there have been no Court decisions upon the subject within the State. The available scientific facts disclose that limitation of the use of ground-water in the Grand Prairie region is desirable if not necessary to protect an important agricultural development. With conditions as they now exist in the region, undoubtedly it would be necessary to recognize the rights for water already developed, and if these rights exceed the safe yield of the aquifers, to require a proportionate decrease in use by present water users to bring the total consumption within the safe yield.

Within a radius of 25 miles of Houston, Tex., at least 80 000 000 gal of water per day is used for public supply and industrial purposes and irrigation. It is believed that the pumpage has not yet exceeded the safe yield of the aquifers, but there may be larger future development of ground-water, which (at least as far as mechanical problems are concerned) can be obtained from properly constructed wells. In this region, as in other areas in Texas, to protect the large investments already made, regulation of the use of ground-water is desirable.

There has been great lowering of artesian head in a large area around Chicago, Ill.[31]. Less severe drops have been reported from other parts of Illinois. It would seem that some control in this area would also be desirable.

Ground-water is used for irrigation in several areas of the Florida Peninsula and in certain areas some wells already yield salt water. There is reason to believe that any considerable increase in draft will cause further contamination. In an attempt to give some protection to the Gulf Coast area, the Florida Legislature in 1929 passed a law relating solely to Sanford, Manatee, and Charlotte Counties[32]. An effort has been made, but is as yet (1936)

[31] "The Artesian Waters of Northeastern Illinois", by Carl B. Anderson, *Bulletin 34*, Ill. State Geological Survey, pp. 93-95, Fig. 3, and Pl. IV, 1919.

[32] The text of the law is printed in "Ground-Water Resources of Sarasota County, Fla.," by V. T. Stringfield, Twenty-third and Twenty-fourth Annual Repts., Florida State Geological Survey, pp. 179-181, 1933. (This paper is also printed separately.)

unsuccessful, to pass a law applying to the entire State. The present law defines waste from wells, sets up provisions for the prevention of waste, and violation of these provisions is a misdemeanor subject to the penalties prescribed by law. It also makes provision for inspection and supervision by the State Geologist of drilling operations in order to prevent leakage of water, known in some places to be salty, from one aquifer to another. The law further states that,

"Should the underground-water supply of any district become so depleted by heavy draft as to endanger the water supply of such district by saline contamination, the State Geologist, his assistants, or duly authorized representative, shall be empowered to regulate the draft upon all wells in such district so that the water resources can be protected and preserved."

This provision, however, relates only to the prevention of salt-water contamination. There is no provision of funds to enforce the law, nor for bond or other insurance that a well owner or driller will properly plug or otherwise control a leaking or flowing salt-water well. The prevention of leakage from one formation to another or of flow around the outside of wells has been difficult and costly, and laws should definitely require a bond by the driller or owner to assure proper protection of other well owners in areas where these difficulties are likely to be encountered.

In New Jersey there has been a partial control of ground-water by the State since 1907. This has been accomplished by laws which provide that new or additional developments of water, either surface or underground, for public supply, by municipalities or privately owned water supply companies, can not be made until the supervising commission (at present (1936), the State Water Policy Commission) has approved the plans for such development.

In the State of New York there is a control of public water supply systems exercised by the State Water Power and Control Commission, very similar to that in New Jersey. The power seems to be limited to an approval of plans and not to the granting of water rights. In 1933, the New York Legislature amended the law to provide that,

"* * * no person, firm, or corporation shall hereafter install or operate any new or additional wells in the counties of Kings, Queens, Nassau and Suffolk to withdraw water from underground sources for manufacturing or industrial purposes or for use in manufacture or industry where the capacity of such well or wells singly or in the aggregate is in excess of one hundred thousand gallons a day without first obtaining the approval of the Commission. * * * The provisions of this act shall not apply to the use of water for agricultural purposes."

The four counties mentioned constitute all of Long Island. The first section of the law, after referring to reports by State and Federal agencies in regard to depletion of the underground waters of Long Island and the danger of encroachment of salt water, states that "this enactment is made in the exercise of the police power of the State and its purposes generally are to protect public health and public welfare in conserving the supply of water for domestic consumption."

Parenthetically, it may be noted, in contrast, that an Hawaiian Court expressed the opinion that the police powers of the Territory "cannot be

deemed to justify, under the showing made in this case, the prohibition of the appellant's proposed well while at the same time permitting all existing wells to continue to be operated without diminution"; but it did recognize that the Territory could exercise the police power to the extent of regulating the exercise of "private rights to the end that the health and safety of the community may be preserved and that the right of co-owners may not be violated." (City Mill Co., Ltd. *v.* Honolulu Sewer and Water Commission, 30 Haw. 912.)

In both New Jersey and New York favorable action by the controlling commission apparently does not constitute a grant of any right to use the water, but merely an approval of plans, etc. Nevertheless, the laws in these States have had the effect of controlling to some extent the development of ground-water supplies in certain areas where there is danger of the safe yield being exceeded, either by actual refusal of approval, or by modifying provisions as to location of wells or quantity to be withdrawn.

In both New Jersey and New York, except Long Island, the law does not apply to diversions of water by industries or others using the water for purposes other than public supply systems. This distinction has brought about a peculiar situation in that upon showing that a proposed development for municipal supply may injure an existing private supply the controlling commission may refuse, and (at least in New Jersey) has refused, to approve the public development; but, on the other hand, after a municipal development has been completed, a private development may be made which may greatly reduce the capacity of the wells of the public system or perhaps even destroy its usefulness. A similar situation in England has been cited by Mr. Gourley[19].

Confusion in Classification of Ground-Waters.—There is considerable inconsistency or confusion in thinking concerning certain phases of the situation of control, or lack of control, of the use of ground-water as it now exists. These conditions are largely the cause of the present mixed, and to large extent unsatisfactory, status of legal control. This situation doubtless is due in part to the fact that the legal principles were established before there had been developed an adequate knowledge of the geologic and hydrologic conditions that govern the occurrence of ground-water; but even after these conditions have become better known, the hydrologists have, perhaps, not presented them clearly to the Courts and legislative bodies. It may be said that some progress is being made, but there is still room for more enlightment.

An outstanding confusion of ideas exists in the distinctions or classes into which underground waters have been divided from a legal viewpoint. In many cases the question arises as to whether the water under consideration is ground-water or part of a surface stream. From the viewpoint of many hydrologists this is a starting point of ambiguity and uncertainty. In his discussion of ground-water law, Mr. C. S. Kinney divides underground waters into three general classes, namely, "subterranean water courses or streams", "artesian waters", and "percolating waters."[20] The first class is subdivided

[20] "A Treatise on the Law of Irrigation and Water Rights and the Arid Region Doctrine of Appropriation of Water Rights", by C. S. Kinney, Bender-Moss Co., San Francisco, Calif., Second Edition, p. 2095, 1912.

into water flowing in "known and defined channels or water courses", or in "undefined and unknown" courses. Artesian waters apparently were originally placed in the class of "percolating waters", but as their characteristics became better known a separate class was made for them. Percolating waters have been subdivided into: Diffused percolations or percolating waters; percolating waters tributary to surface watercourses or other bodies of surface waters; percolating waters tributary to underground reservoirs or other bodies of underground waters; and, finally, seepage waters. Other subdivisions include "underflow dependent on surface streams", "percolating waters tributary to springs", and "percolating waters supplying surface wells" (as distinguished from waters supplying artesian wells).

There is no doubt that, at the mention of the term, "known and defined subterranean channels or water courses", most geologists visualize streams flowing in channels with definitely identifiable banks, such as are found principally in solutional channels in limestone caverns (for example, the Echo River in the Mammoth Cave of Kentucky); or of so-called tunnels in lava flows, or in smaller openings with definite walls such as crevices, rather than minute interstices in sand and gravel, even if the water-bearing beds are beneath a definitely recognizable surface stream. On the other hand, the geologist would consider the water flowing in alluvium beneath a stream bed to be percolation just as much as water moving in an artesian aquifer, or ground-water tributary to surface streams or underground reservoirs is percolating water. (The Standard Dictionary defines "percolate" as to cause, as a liquid, to pass through fine interstices; filter; strain. It then defines "percolation" as the act of percolating or passing through small interstices; infiltration. Furthermore, the Standard Dictionary defines "channel" as: (1) The bed of a long body of water, especially the hollowed course of a stream; (2) the deep part of a river, harbor, straight, or estuary where the current or tide is strongest; etc. It defines "watercourse" as: (*a*) A stream of water; river; brook, especially, in law, a stream usually flowing (although not necessarily running all the time) in a definite channel, having a bed and banks; (*b*) the course or channel of a stream of water. The definition in Webster's Unabridged Dictionary is in essentially similar language.)

Further difficulties arise when one attempts to discover the distinction, for example, between underflow, percolation, and artesian water. In many localities, where a stream flows over a considerable thickness of permeable alluvium confined in a rock-walled canyon, most, if not all, Court decisions recognize underflow as part of the surface stream. The question becomes more complicated where the stream flows across a wide alluvial plain of essentially homogeneous material, so that the stream is continuous with the water-table beneath the plain for many miles on either side of it, the stream being at about the lowest part of the water-table. Perhaps there would be no question as to the portion of the ground-water body directly beneath the stream, provided the course of the stream is fairly straight; but what would be the determination where the stream, instead of flowing in a reasonably straight line, meanders in large ox-bow curves several miles in diameter across a wide

plain as does the Mississippi River, and other rivers in wide alluvial filled valleys? In this case the movement of water in the lowest part—the thalweg[24] of the water-table—may be expected to be in a rather straight line toward the mouth of the stream and not parallel to and beneath the meanders of the stream. Thus, although certain drops of water may at one place be directly beneath the stream bed and, therefore, might be called underflow, upon reaching and passing down stream beyond a sharp sideward meander of the stream, they apparently cease to be "underflow" in the sense of water flowing beneath a stream bed, and become "percolating water" which, in its journey to the sea, may reach a point several miles from the river before again passing under it.

In both the foregoing cases there is a question as to where boundaries shall be drawn to divide the underflow from the "percolating" water beneath the plains on either side of the river. In many localities this is hydrologically impossible because, at least in part, percolation laterally from the plains to the river maintains the underflow and at different seasonal periods or in different sections of the river system, this direction of movement may be reversed. In some localities it can be demonstrated both by studies of the geological history of the regions in question and by hydrological data, that the underflow is derived largely, if not wholly, from such lateral percolation, and not from the surface stream as is stated by Mr Kinney to be the legal presumption both under the common law doctrine and under the doctrine of appropriation[25]. In fact, the usual geological and hydrological conception of the relations between a permanent surface stream and the ground-water is that the stream comes into existence only after erosion has cut a channel deep enough to intersect the top of the zone of saturation or water-table. This view is in agreement with Mr. Conkling (see "Introduction") who uses the title of "underflow which may support a surface stream." The theory stated by Mr. Kinney that the stream supplies the underflow can be demonstrated completely only where the stream is influent; that is, where the water-table is some distance below the bottom of the stream and water percolates from it downward to the ground-water body. In this case it might be well argued that the person who diverted the surface water was taking water that would otherwise naturally supply the ground-water reservoir of percolating water.

Mr. Conkling has described certain conditions under the headings of "Definite Underground Channels" and "Percolation Through Basins." Presumably, these conditions comply with those described by Kinney as waters flowing in subterranean streams or watercourses and percolating waters, respectively. It will be noted that Mr. Conkling states ("Definite Underground Channels"): "If the underflow of a stream * * * is regarded as a definite underground stream, it may be said that such streams, usable for irrigation, often occur in the West" This suggests that there is some doubt

[24] "The Motions of Underground Waters", by C. S. Slichter, *Water Supply Paper 67*, U. S. Geological Survey, p. 32. 1902.

[25] "A Treatise on the Law of Irrigation and Water Rights and the Arid Region Doctrine of Appropriation of Water Rights", by C. S. Kinney, Bender-Moss Co., San Francisco, Calif., Second Edition, pp. 2111–2115, 1912.

in his mind as to what really constitutes a definite underground stream. Under the heading of "Percolation Through Basins", he describes the general hydrological features of the San Gabriel Basin. The writer does not know whether any Court decision has classified the movement of ground-water in the San Gabriel Basin as "percolation", but he believes that it is a proper classification according to the customary conception of that term as it is commonly used except perhaps for minor parts of the basin where certain geological conditions produce special conditions such as small artesian basins. This general classification is supported by maps of the water-table which show it to be continuous, with gradual slopes over a large area, and with no demarcation or indication of difference in water-table conditions beneath the wide alluvial wash channel of San Gabriel River and lands that extend for several miles on either side of the present channel[26].

San Gabriel Valley may be compared with San Fernando Valley. As far as the writer can determine from the statement of facts in the case of City of Los Angeles *v.* Hunter (156 Cal. 603), and from other information, the geologic and hydrologic conditions in the latter valley are essentially the same as in San Gabriel Valley in that the ground-water occurs in a vast body of alluvium surrounded by bed-rock hills, with a water-table continuous over practically the entire valley. Contours[27] of the water-table show that the ground-water for practically the entire valley is moving toward the locality where the Los Angeles River, which rises in the valley, passes through "narrows" with conditions essentially similar to the pass traversed by San Gabriel River between San Gabriel Valley and the Coastal Plain as described by Mr. Conkling; and yet, in the case of City of Los Angeles *v.* Hunter, the Court decided that water pumped from wells (some of which were 1 000 ft distant, but others 2 or 3 miles distant, from the Los Angeles River) was a part of the subterranean flow of that river and was not percolating water.

In another case relating to San Fernando Valley (City of Los Angeles *v.* Pomeroy (124 Cal. 597)) the difficulty in distinguishing between water in subterranean channels and percolating water is just as evident and the reasoning of the Court is confusing. In this case the decision of the Supreme Court quotes the instructions to the jury by the Superior Court. In Paragraph XVII of these instructions the Court stated certain physical conditions which, if they were considered to fit the case, should require the jury to decide the waters of certain tributary streams of the valley to be a part of Los Angeles River. In Paragraph XIX were other statements to show under what conditions the ground-water would not be in a definite watercourse, but would be percolating water. Both statements seem to fit the conditions in San Fernando Valley in so far as they go, and reading either of them alone one would conclude that the ground-water should properly be classified by that statement. In neither this case nor in Los Angeles *v.* Hunter (156 Cal. 603), does the writer find any discussion of the critical geological or hydrological

[26] "Ground Waters and Irrigation Enterprises in the Foothill Belt, Southern California", by W. C. Mendenhall, *Water Supply Paper 219*, U. S. Geological Survey, Pl. VII and IX, 1908; also, "South Coastal Basin Investigation—Geology and Ground-Water Storage Capacity of Valley Fill", by Rollin Eckis, *Bulletin 45*, California Div. of Water Resources, Plates D and E, 1934.

[27] *Loc cit.*, Rollin Eckis, Plate E.

factors that really would determine whether the subterranean channel or watercourse flowed in a definite, confined channel, with "beds, banks, or sides."[a] Such pertinent evidence should show either definite differences in the character of the water-bearing materials constituting the supposed subterranean channel of the river from the materials on either side that would be considered to constitute the banks; or it should show that the water-table or piezometric surface of the water in the materials constituting the banks and sides of the watercourse was discontinuous with the level of the surface water in the stream or in the water-table beneath it.

It would seem that, from the decision of Los Angeles *v.* Hunter and Los Angeles *v.* Pomeroy, by analogy, logically all the water in the vast underground reservoir of San Gabriel Valley, which eventually passes through the Whittier Narrows either as surface flow of San Gabriel River or underflow beneath it in a restricted channel, should be considered to be part of that stream. Mr. Conkling has pointed out ("Percolation Through Basins") how, with great increase in pumping from wells the quantity of "rising water" at the Narrows (that is presumably, the low-water flow of San Gabriel River) has greatly decreased; and this very fact suggests a relation between the body of "percolating water" and the river similar to that determined by the Courts for Los Angeles River in San Fernando Valley.

Since a large part of the firm flow of practically all streams of importance in the United States comes from the ground-water reservoir, from the foregoing reasoning it can also be argued that ground-water almost anywhere is a part of the nearest surface stream toward which the water-table slopes. The obvious consequence of this argument would be that riparian owners of surface waters might compel abandonment of many wells now diverting such percolating water. For most parts of the country this interpretation may seem absurd, but for certain regions, conceivably, it may have application, as, for example, along certain stretches of the Mohave River, in California, the Rio Grande in New Mexico and Texas, and the Platte River in Nebraska. On stretches along each of these rivers there is undoubtedly contribution of ground-water to the stream from lands some miles back from it.

In its length of more than 100 miles the Mohave River, in California, is alternately, here an effluent and there an influent stream, with stretches in which most of the time there is a surface stream and farther down stream no surface flow. Probably most of the flow comes from the San Bernardino Mountains, but undoubtedly some of the water moves ("percolates") toward the river beneath the bordering "mesas" or alluvial slopes that reach back to the mountains of the desert. In some, if not in all, of the stretches, both influent and effluent, the underflow might be considered to be part of the river. There is reliable evidence that, in a stretch between Hodge and Barstow, Calif., some of the underflow of the river—which is probably augmented by percolation from the surface flow when there is water in the river—leaves the valley of the Mohave River underground and moves northwestward beneath an area known as Hinkley Valley, past a surface divide and toward

[a] City of Los Angeles *v.* Pomeroy 124, Cal. 597, Paragraph XIX of charge to jury by Superior Court, quoted in the decision of the Supreme Court.

an undrained valley containing a "playa" known as Harper Dry Lake[29]. Apparently, at least in years of normal run-off, none of this ground-water that leaves the valley of the Mohave River, appears on the surface again, but is disposed of by evaporation from the soil and transpiration by plants. The question may now be asked: When it reaches Harper Valley, is this water still to be considered as part of the Mohave River although it is entirely outside the drainage basin of that river; although subsequently it does not reach any other stream; and, although it moves in a manner entirely similar to "percolating water" in numerous basins of the desert region? The answer might be different, depending upon whether a down-stream user along the Mohave River sought to enjoin a user in Harper Valley, or a Harper Valley user sought to enjoin an up-stream user along the Mohave River.

One more example may be cited to show the difficulties of attempting to set up definite distinctions between different types of occurrence. According to co-operative studies by the Nebraska State Geological Survey and the U. S. Geological Survey, between Chapman and Gothenburg, Nebr., about 30 000 acre-ft of water is pumped from wells on the flood-plain of the Platte River[30]. The writer does not know whether any Court decisions have defined this water in Nebraska, but under similar conditions in Colorado, it would certainly seem to be considered a component part of the Platte River The field studies have demonstrated beyond a doubt that a large quantity of water, estimated to be about 56 000 acre-ft per yr, percolates southward out of the Platte River Valley and beneath a high upland from a few to as many as 15 miles wide and re-appears in the tributaries of the Republican and Blue Rivers which flow at considerably lower altitudes[31]. The studies indicate that more water for irrigation can be taken from wells in the Platte River Valley as well as on the upland plains. If such development occurs to the extent that the flow of the Republican and Blue Rivers is seriously diminished, shall the ground-water beneath the upland (which normally would be considered to be "percolating water") and also the water used in the Platte River Valley, be considered to be part of the Republican and Blue Rivers? A case recently decided (Osterman *et al v.* Central Nebraska Public Power and Irrigation District, 268 N. W. 334), relates to the diversion of surface water from the Platte River into the drainage basins of the Blue and Republican Rivers. In this case the probability of underflow from the Platte River to the basins of the other rivers was recognized, but the ground-water conditions apparently were not specifically considered in the recent decision.

The foregoing examples have been cited primarily to point out inconsistencies in the reasoning by which certain principles of classification of ground-water have been set up in the course of a long period of litigation.

[31] For a cross-section showing this condition see "Water-Bearing Formations of Nebraska", by G. E. Condra and E. C. Reed, Nebraska Geological Survey *Paper No. 10*, p. 17, 1936.

Apparently, the complicated classification given by Kinney has been found necessary as case after case came up for decision in which the geological and hydrological conditions did not exactly fit the conditions of some previous case. He seems to have discovered the essential difficulty of the entire problem when he wrote, concerning the criteria for determining the classification of ground-waters[32]: "The difficulty has been not so much to determine the law as to rights which may be acquired in subterranean waters, where certain water has been determined to be of a certain character, as it has been to determine the character of the particular class to which the water belongs." This difficulty may be expected to become greater as still other cases, with peculiar but perfectly natural conditions, as in some of the areas suggested in the paper, come up for decision. The very existence of this difficulty raises a question as to whether it may be due to the fact that the classification that has developed in past cases, as outlined by Kinney, is not on a sound basis of geological and hydrological facts. All water beneath the surface of the ground, after all, is purely and simply ground-water, moving according to certain well recognized laws of physics. There seems to be no scientific reason why an elaborate and expanding classification of ground-waters should be necessary

One may wonder as to how the aforementioned confused state of affairs came about. It can be attributed to lack of knowledge of the geologic and hydrologic principles that govern the flow of water beneath the surface of the earth. It is not surprising, of course, that many facts now well known in regard to the occurrence of ground-water were not so widely understood when the early case relating to percolating water cited by Wiel[33] (Acton *v.* Blundell (12 Mees and W. 324)) was decided in 1843, although they were not wholly unknown even then. Some essential facts were known to a few scientific observers[34], but undoubtedly these ideas had not been very widely circulated. Unfortunately, even to-day not a few persons believe that subterranean water actually occurs in more or less distinct and open bodies with free surface similar to lakes and rivers that are seen above ground. The conception of "definite subterranean channels or watercourses" probably at least in part arose from this erroneous belief.

So far as percolating water is concerned the theory set up in early cases likewise rests on lack of knowledge of ground-water conditions. In Los Angeles *v.* Hunter (156 Cal. 603), the Court stated that percolating waters, in the common law sense of the term, were "vagrant, wandering drops moving by gravity in any and every direction along the line of least resistance." This judgment was in contrast to the Court's conception of water moving in a definite subterranean channel or watercourse of which it said,

"These waters percolate, it is true, but only in the sense that they form a vast mass of water confined in a basin filled with detritus, always slowly moving downward to the outlet, in the effort, in conformity with physical law, to attain a uniform level."

---

[32] "A Treatise on the Law of Irrigation and Water Rights and the Arid Region Doctrine of Appropriation of Water Rights", by C. S. Kinney, Second Edition, p. 2115, Bender-Moss Co., San Francisco, 1912.

[33] "Water Rights in the Western States", by S. C. Wiel, Second Edition, Vol. 2, p. 970, 1911.

[34] "History and Development of Ground-Water Hydrology", by O. E. Meinzer, *Journal*, Washington Acad. of Science, Vol. 24, pp. 14–16, 1934.

As a matter of fact, with the present knowledge of ground-water hydrology, it may be stated with considerable emphasis that practically all ground-water conforms with the requisite conditions set up in the last quotation because, until diverted by artificial means, the ground-water flow, in conformity with physical laws, at any given point is moving in a definite direction as a result of the interaction of geological and hydrological conditions, and, except for loss by transpiration and evaporation, nearly all ground-water is moving to maintain the flow of surface streams Furthermore, the direction and rate of movement can be determined within reasonable limitations of accuracy, although this may not everywhere be practical because of the cost involved.

If the foregoing arguments are tenable, namely, that from a logical continuation of the reasoning stated by the Court in such cases as Los Angeles *v.* Hunter and Los Angeles *v.* Pomeroy, it would seem to be a further logical conclusion that since nearly all ground-waters tend to maintain surface streams, they should be considered waters in subterranean channels, and thus practically all ground-waters should be subject to the laws that govern surface waters Under this reasoning, in States in which the doctrine of riparian rights now applies to surface water, this doctrine would logically be applied to ground-waters. In these States under a strict interpretation of the doctrine of riparian rights it would seem that the use of ground-water would be essentially prohibited unless all well owners were considered to have riparian rights equal to the riparian owners along the surface streams. At best, it would mean the application of the doctrine of correlative rights (see heading "Water Law in General"). On the other hand, in States in which the doctrine of appropriation is now applied to surface waters that doctrine would also be applied to all ground-waters, with consideration given to the question of the effect of their diversion on surface water rights already granted.

It may be stated that the application of the doctrine of appropriation to the control of ground-waters in certain areas in New Mexico is based on the scientific evidence of the movement of the water from its source to points of discharge in areas, which, although they may be of large extent, have boundaries that can be, and have been, definitely ascertained. To this extent there is recognized a similarity to "definite subterranean channels or water-courses." Thus, by recognizing definite boundaries and a definite direction of flow the doctrine of appropriation, which has been applied for many years to surface waters in New Mexico, has now been applied to ground-waters in areas in which, as pointed out by Mr. Conkling ("Underground Water Law in General"), the water occurs under conditions that formerly would have been considered to require a classification as "percolating water."

It is pertinent, perhaps, to state that the New Mexico law was first drawn up following an extensive study by the U. S. Geological Survey, of ground-water conditions in the Roswell Basin, to which the law was first applied[35]. This study showed that the safe yield of the artesian reservoir had been

[35] "Report on Investigations of the Roswell Artesian Basin, Chaves and Eddy Counties, New Mexico", by A. G. Fiedler, Seventh Biennial Rept. of the State Engr. of New Mexico, pp. 21-60, 1926; also, "Geology and Ground-Water Resources of the Roswell Artesian Basin, New Mexico", by A. G. Fiedler and S. S. Nye, U. S. Geological Survey *Water Supply Paper 639*, 1933.

exceeded and that any increase in the use of ground-water would jeopardize the investments of prior users; and it recommended legislation to prohibit new developments of artesian water except as it can be shown that such developments will not injure present users of water. The information collected in the investigation furnished the necessary basis for the determination and declaration by the State Engineer that the Roswell Basin comes within the purview of the new law in so far as the water is in an "artesian basin * * * having reasonably ascertainable boundaries." It is worthy of note that the law has indeed accomplished its objective in the Roswell Basin, and this is perhaps the outstanding instance of limitation of use of ground-water by law in the United States.

Doctrines of Correlative Rights and Appropriation.—The writer wishes to make himself clear that in what he has written thus far he is not suggesting what he believes should be a proper basis for the determination of water rights. He has merely endeavored to present what he believes must be logical conclusions if certain assumptions in legal decisions are accepted. At this point it is desirable to consider another phase of the problem, namely, the apportionment of water among land owners under the doctrine of correlative rights.

It is first necessary to consider just what is meant by the doctrine of correlative rights. Mr. Conkling states ("Underground Water Law in General") presumably referring to the doctrine of correlative rights, but not using the term specifically in the sentence quoted: "This rule holds that each land owner overlying a basin has a right to the underground water co-equal and correlative with that of all other land owners overlying the same basin." This interpretation is considered by some to require, in part, that if there is not sufficient water for unlimited use by all owners of land overlying water-bearing strata, there shall be a proportionate distribution among all. This view is stated, apparently as dictum of the Court—that is, mere discussion upon some collateral question of law not necessary to the decision of the case before the Court—and not as a part of the actual decision, in several cases, notably Katz *v.* Walkinshaw (141 Cal. 116 (especially p. 136)); and City Mill Co., Limited *v.* Honolulu Sewer and Water Commission *et al* (30 Haw. 912 (especially p. 922)).

The writer is aware that this view is not shared by others. Some appear to consider the doctrine of "correlative rights" as applied to ground-waters to be synonymous with the doctrine of "reasonable use." (See such expressions as the following in which the two phrases are used together, quoted from the annotation appended, Clinchfield Coal Corporation *v.* Compton (55 A. L. R. 1376): "a reasonable exercise of such right; or as said by the Court, the rights are correlative"; "* * * in Katz *v.* Walkinshaw, 1902 (141 Cal. 116, 64 L. R. A. 236, 99 Am. St. Rep. 35, 74 Poc. 766, 80 Poc. 633), the first case in which the rule of reasonable use applied to correlative rights is applied"; "the American rule, or rule of reasonable use, or as expressed by some Courts and writers, the rule of 'correlative rights'"; and, finally, in Horne *v.* Utah Oil Ref. Co. (59 Utah, 279, 31 A. L. R. 883, 202 Poc. 815), "the doctrine of correlative rights or reasonable use." On the other hand, in at least one case

the Court recognized a distinction between, and defined, these two doctrines, separately. (See heading "Underground Water Law in General"; also, City Mill Co., Limited *v.* Honolulu Sewer and Water Commission *et al* (30 Haw. 912 (especially p. 922)). In this case a definite part of the doctrine of reasonable use was stated to be that the water shall be used on "the owner's land" (in cases in other jurisdictions limited to lands of the owner overlying the water-bearing strata). As a matter of fact, in many, if not all, cases where the doctrines of reasonable use or correlative rights (whatever the application of this term may be) have been considered, water was taken for sale by public supply systems or for other use on lands distant from those beneath which the water was found; and this has generally been held to be an unreasonable use (Clinchfield Coal Corp. *v.* Compton (55 A. L. R.), annotation p. 1404). The writer has failed to find a single case in which there was actually decided by the Court the question of division of water among owners of land overlying the water-bearing strata when the supply was insufficient for all desired use, without the collateral question of use on distant land. Therefore, it is probable that the meaning of the term, "correlative rights", as applied to such a condition of insufficient supply, is still an open question except as Courts subsequently may be influenced by the dicta in the aforementioned cases.

Next, there is to be considered the doctrine of correlative rights from the viewpoint of ground-water hydrology. Of the total quantity of ground-water that flows beneath the average parcel of land, only part of it originates on that land and much, if not most of it, originates on lands farther up the ground-water gradient. In the case of an artesian aquifer covered by an impervious bed beneath the entire parcel no water would be contributed from rainfall on that parcel, and it would all move in from lands beyond its boundaries, perhaps from an outcrop many miles away. In fact, an artesian aquifer, perhaps, is one of the best examples of a condition that, by stretching considerably the geological concept, might fit the description of a subterranean watercourse with definitely bounded walls.

The supply of ground-water available in any area is dependent upon the rainfall either in the immediate area, or in some other area, perhaps fairly remote, from which it moves to the area in question either in a surface stream, which loses water to the underground reservoir, or through some underground aquifer. In many localities, particularly in the arid and semi-arid States, ground-water is available in large quantity only where geologic conditions are such as to concentrate part of the precipitation or surface run-off from large areas, or areas of heavy precipitation, into ground-water reservoirs of comparatively small size, or where large reservoirs nave been filled by infiltration from small areas continuing through long geologic periods. Under certain conditions the available supply is also limited by the permeability of the water aquifer; that is, the rate at which it can transmit water. As a consequence of these factors, there is a definite limit to the safe yield of water that can be taken perennially from wells in any locality. This limit has been reached and passed in several parts of the United States, although the supply may not yet be exhausted. In many other parts of the coun-

try this limit is far from being reached and, at present, gives no concern. In some areas it probably never will be reached. However, it seems necessary that the possibility of it being reached must be recognized in any effort to provide adequate control of ground-waters. This is particularly so where the possible use of ground-water might greatly exceed the safe yield of the water-bearing formations.

In Antelope Valley, California, for example, 200 000 acres or more is suitable for irrigation, but the annual contribution to the ground-water supply is of a magnitude of only about 50 000 acre-ft[36]. If this quantity were distributed over 200 00 acres it would be only 0.25 acre-ft per acre, which is not enough to do material good in irrigation. Obviously, if the water were divided among all lands proportionately under the doctrine of correlative rights, as suggested by the Court in Katz *v.* Walkinshaw, much of the land would be nearly worthless. Prior beneficial users would be insecure. Only by a reasonable application of the doctrine of appropriation can the maximum economic use of water be obtained in Antelope Valley.

In the Borough of Brooklyn, New York, a number of industrial concerns pump large quantities of water from wells on their property, and as a result there has been a serious drop in the water-table. However, if all industries of the Borough undertook to pump from wells, claiming a share of water under the doctrine of correlative rights as interpreted in Katz *v.* Walkinshaw, either salt water would quickly be drawn in, spoiling the water for many purposes, or, if the water was rationed in such a way as not to exceed the total safe yield, each owner's share would be so small that if no other supply were available many of the industrial concerns could not operate. Although the principle of correlative rights may be said to hold in the humid States, in many localities where much ground-water is used the actual situation is that there is no equitable distribution of water in proportion to ownership of land, but the water is available primarily only to those best able to pay for the deepest wells or the largest pumps.

Another important fact, which is not generally appreciated, is that, as stated by Mr. Conkling under "Administration: Underground Water", it is impossible to take water from any well either by natural flow from an artesian well in which the static head is above the surface, or by pumping from wells in which it is below the surface, without causing a drop in head, or static level, beneath the territory surrounding the well. Theoretically, this drop in head should extend ultimately to the outermost borders of the ground-water body under consideration[37]. The loss of head resulting from the withdrawal of water from several wells if within the cones of influence of each other, may be significant in amount over a large area, perhaps many square miles. Some loss of head can not be avoided even if the quantity of water withdrawn is only a small part of the total safe yield of the aquifer; and if a considerable part of the safe yield is to be obtained in some regions there

[36] "The Mohave Desert Region, California", by D. G. Thompson, U. S. Geological Survey *Water Supply Paper 578*, p. 322, 1929.

[37] In this connection see "The Relation Between the Lowering of the Piezometric Surface and the Rate and Duration of Discharge in a Well Using Ground Water Storage", by C. V. Theis, *Transactions*, Am. Geophys. Union, Pt. 2, pp. 519–524, 1935.

must be a considerable loss of head. It should be distinctly understood, however, that loss of head does not necessarily mean that the permanency of a well owner's supply is endangered. These facts are of interest in connection with the situation in Idaho, where, as pointed out by Mr. Conkling ("Summary, Discussion, and Conclusions (Item 15")) a strict interpretation of the Court's reasoning in Silkey *v.* Trego, (5 P. (2d), 1049), would prohibit every one from using ground-water except the first appropriator.

Examples of Lack of Appreciation of Fundamental Hydrologic Principles.—The failure to appreciate these facts has resulted in some unfortunate situations. Several years ago the writer had an opportunity to read the transcript of evidence in a case in a Western State. It was a striking fact that in this testimony wells were said to have gone "dry" when the water had merely ceased to flow over the top of the casings at or near ground level. Apparently, it was not evident to counsel or expert witnesses for the defendant that the wells were, in fact, not dry, and that it would only be necessary to install pumps in the wells to obtain as much water as, or more than, was originally obtained by natural flow. The failure to understand this simple hydrological principle is almost unbelievable, but it is borne out by other evidence that in the same region until a few years ago both well drillers and water users did not understand other essential principles to be considered in the construction of wells and developments of ground-water.

In 1935, the Colorado Legislature passed a law (Chapter 80) which provided that "it shall be unlawful for any person, persons, or corporations to pump water from an artesian well for any purpose or purposes whatever except for domestic or manufacturing purposes." An artesian well was defined as a well "the waters of which, if properly cased, will flow continuously over the natural surface of the ground adjacent to such well at any season of the year." The Act was worded so that apparently it was intended to apply principally to a particular area in which there are numerous flowing wells used for irrigation. As written, the law obviously prohibits pumping, but does not prohibit the drilling of a well that may perchance flow. The framers of the law appear to have been unaware of, or to have overlooked, the fact that the damage they sought to prevent by prohibiting pumping can be brought about by drilling flowing wells of large capacity in parts of the artesian basin where the head above the ground surface is high; for, as stated previously, a cone of depression, or an area of influence and interference, is created when a well with artesian head above the ground surface is permitted to flow just as much as when a well with head below the surface is pumped.

According to the definition of artesian well in this law, a well that may be near the border of the area of flow and which does not flow at any season of the year is not an artesian well and not affected by the law. Its owner can put in a pump and operate it to his heart's content, creating a considerable drop in head in wells in the near-by "artesian" part of the basin. On the other hand, a man whose well is situated just inside the "artesian" area, so that it flows in some seasons of the year and not at others, or one whose well is still farther inside the "artesian" area, so that the well flows continually but in some seasons the flow is very small (perhaps only a few

gallons per minute) can not install pumps to obtain water from his wells. Since the lowest head, and hence the period of low flow or non-flow, is generally in the height of the irrigation season, the owners of these wells are prohibited from pumping their wells to irrigate crops. It thus appears that if this law were applied strictly as worded it would in fact prohibit the use of ground-water by certain established users in a zone between the truly non-artesian area where water may be pumped from wells and the part of the artesian area where adequate supplies may be obtained by natural flow.

In connection with the situations just cited, it may be noted that in some cases it has been ruled that one riparian owner, in taking water from a surface stream, has so changed conditions at the intake or other control works of another riparian owner in such a way as to make such works useless, the latter owner does not have cause for redress, but must remodel his works at his own expense. By analogy it may be argued that when one well owner deepens his well or pumps it heavily in such a way as to lower the water level in another owner's well, or even dry it up, the latter must deepen his well at his own expense, provided the former is not taking more than his share of the water. This has, indeed, been the conclusion in cases of record relating to correlative rights. The result, as pointed out by Mr. Gourley[19], is a race to construct the deepest well, in which the weakest party financially, who may be the earliest user, "gets left."

Ground-water laws in some States have been written very poorly, in part, because of lack of understanding on the part of the writers as to principles of ground-water occurrence, construction of wells, etc. The poor wording of laws applies, for example, to sections defining artesian wells. In some laws, this covers only wells that flow. The quotation from the Colorado law, previously cited, is an example. A definition in another law includes not only wells "through which water is raised or carried to or above the surface of the ground by natural pressure or gravity", but also wells "through which water is or may be raised or carried to or above the surface of the ground by artificial means." This definition would include practically any well from which water is taken, whether by natural flow, by pump, or even by bucket; and the term, "artesian", which here is used very loosely, is superfluous. The really significant hydrologic principle involved in a scientific definition of artesian water and artesian wells is that the water is under artesian pressure beneath an impervious stratum so that it will rise above the level at which it is struck, regardless of whether the water flows at the surface or how many impervious layers may be between the aquifer and the level to which the water will rise[20]. A State legislature, in general, has the right to define terms as it wishes. Such action, however, does not help in developing scientific accuracy that is sought by technical workers and it can not change the natural laws and principles involved or, by mere edict, rectify the difficulties that the law is designed to meet. One is reminded of the law introduced in a State legislature a few years ago which, in order to simplify geometry for students and engineers,

[20] "Outline of Ground-Water Hydrology", by O. E. Meinzer, U. S. Geological Survey, *Water Supply Paper 494* (definitions of zone of saturation and water-table, pp. 21-22, and definition of artesian water, p. 39), 1923.

said that hereafter and forevermore the value of π, the factor used to designate the relation of the circumference of a circle to its diameter, shall be 3.00.

Conclusion.—The writer has discussed what he believes to be inconsistencies and misconceptions that have grown up both in written laws and in Court decisions relating to the control of underground waters. The need of control is being shown more and more, not only in the arid and semi-arid States but also in the humid States. A more definite control must come some time. The longer it is deferred the more complicated will the problem become. It is desirable therefore, that action be no longer delayed.

What shall the method of procedure be? It is the writer's opinion (and this is shared by his colleagues in the Division of Ground Water of the Geological Survey who have given serious thought to the problem), that all lines of argument lead to the conclusion that the only feasible and reasonable method of control of the use of ground-water for any purpose can be under the doctrine of appropriation, with the necessary control exercised by some State official. The recognition of the doctrine of appropriation as applied to ground-waters "whether flowing in definite channels, or standing in lakes or basins, or percolating through the soil, in areas of which the boundaries may be ascertained" is the first of several recommendations in regard to the control of ground-water, submitted by an advisory committee of the National Land Use Planning Committee[39]. As indicated by Mr. Conkling's statement ("Underground Water Law in General: Utah") in regard to the 1935 law of Utah, in a draft of a proposed "uniform underground water law for Western States", a committee of the Association of Western State Engineers has also applied the principle of appropriation for beneficial use[40]. (The draft of this law in many respects is patterned after the New Mexico law).

The Committee recognizes that the principle is not now applicable in States wherein the doctrines of riparian rights or correlative rights are recognized. The two organizations mentioned have concerned themselves primarily with conditions in the arid and semi-arid States, but it is the writer's belief that similar action can be recommended both for the humid States and those arid or semi-arid States in which the doctrines of riparian rights and correlative rights are now recognized; and definite steps should be taken to make possible the application of the doctrine of appropriation for beneficial use in these States.

In some States it may be necessary to apply the doctrine of appropriation with modification, for example to exempt, or to give special preference to the comparatively small use of ground-water for rural domestic use and watering stock. It may be desirable to provide control only in areas where there is large use of water, by permitting the formation of water districts; but control should be initiated at the earliest possible time in any area where it seems likely that at any time in the future the supply will be deficient. It

[39] Suggested principles of State legislation relating to the use of underground water, *Publication No. 3* (6 pp.) (mimeographed), prepared by Technical Advisory Committee on Reclamation, Drainage, and Irrigation Policies, W. W. McLaughlin, *Chairman.* The National Land Use Committee, organized in February, 1932, is not to be confused with the present National Resources Committee.

[40] *Proceedings*, Seventh Annual Conference, Assoc. of Western State Engrs. (1934), p. 45.

may be desirable to provide some means for water districts to acquire, for the common good, established rights in some parts of a ground-water basin, which, if they were utilized, would prevent a full and efficient use of the available supply. Thus, to satisfy early rights to a small quantity of water on high lands might mean the prevention of pumping which would lower the water level beneath such lands.

How may the principle of appropriation be introduced into States where it is not now recognized? This is a problem for the law-makers and the Courts to decide, of course, but it seems not inappropriate that the ground-water hydrologist give thought to the problem. Perhaps, in some States, it can be done by passing a law stating that all waters of the State, whether above or under the ground, are the property of the public, and, subject to all existing rights to the use thereof, hereafter shall be subject to appropriation for beneficial use under laws of the State existing or to be enacted. This method has been adopted in New Mexico, Utah, and Oregon. In some States it may be necessary to place such a declaration in the State Constitution by amendment. It may be difficult to arouse sufficient public interest to bring about the necessary legal enactment. However, it is not inconceivable that the Local Sections of the Society, the American Water Works Association, and similar organizations, could bring about the desired results, especially if campaigns of education were pushed during times of drought or other emergencies which emphasized the need of administrative control.

Even after the enabling declarations are obtained the problems of the control of ground-water will necessarily continue to be complicated. There will be the matter of determining rights established before the new principle became effective. All this will require much study of legal, hydrologic, and engineering problems, and funds for such study must be made available. Appropriation of funds raised by taxation perhaps will not be readily approved by the general public. However, inasmuch as the waters would be considered to be owned by the public, the developer using them by permission, it would not be unreasonable to require a fee in proportion to the quantity of water used. Since 1917 by law the New Jersey State Water Policy Commission and its predecessors have collected a fee of $1 per 1 000 000 gal for all water used by public supply systems in excess of certain initial allowances. This fee is very small, and it could be increased to several times as much without becoming an undue burden to the water user. The New Jersey Commission has used the money thus collected not only to carry on its work relating to current applications for approval of plans to divert water, but it has also undertaken studies as to the requirements of different parts of the State 10, 25, and 50 yr or more in the future, in order that it may be guided to a most efficient use of the water resources of the State. Some kind of fee has been collected for use of certain waters in other States, for example, in Ohio and Pennsylvania.

One other fact should be borne in mind, namely, that the movement of ground-waters is not limited by State boundaries, and sooner or later (in some States already) interstate problems must be considered. When these interstate problems are considered it further becomes evident that the general

problems should be considered not from the standpoint of any one section of the country, but on a country-wide basis By this statement the writer does not refer to the possibility of any Federal control of waters, which is doubtless both undesirable and unlikely of attainment, but merely the desirability of having the laws of adjacent States sufficiently similar to simplify the solution of interstate problems relating to ground-waters. This conclusion is readily reached when it is realized that certain of the water-bearing beds that underlie such of the Great Plains States as Nebraska and Kansas, extend into Iowa and Missouri; other formations of the latter States extend into Wisconsin and Illinois; and so on from one State to another with related problems.

Some progress has been made in the problem of legal control of ground-water, but the situation is still far from satisfactory. Conditions are ripe for another forward step. Probably no single organization has in its membership as many persons who are in close touch with the variety of problems of the control of ground-waters as the Society. Some of its members are involved primarily in the development of ground-water for public supply, industrial use, or irrigation; others in problems of the contamination of waters or of drainage; and others in positions of State administration. Accordingly, the Society is in a position to take the first step in initiating discussions on this important problem. However, the discussions should be on a very broad basis and should not be restricted to problems of one section of the country. They should include not merely the consideration of control of ground-water from the standpoint of the problem of water supply for irrigation or for public use, but also from the standpoint of contamination of ground-water supplies by oil-field developments or salt-water encroachment, the effect of ground-water developments on navigation of rivers, of drainage projects and the construction of dams on ground-water developments and *vice versa.* The discussions should be participated in by a variety of specialists, representatives of those who use the water—the public supply systems, industrial concerns, irrigators—to get their viewpoint; the well drillers and engineers to determine construction problems to be considered; the ground-water hydrologists to show the controlling natural principles; and, the State officials who generally are best aware of the difficulties of administration now encountered and who will have the duty of administering the laws subsequently to be enacted. Experienced men in these various lines can be obtained from a number of companion associations such as the American Water Works Association, the Section of Hydrology of the American Geophysical Union, the American Public Health Association, the Society of Economic Geologists, the Geological Society of America, the Association of State Geologists, the American Association of Petroleum Geologists, the American Petroleum Institute, the Association of Western State Engineers, and the American Association of Water Well Drillers. The Legal Profession, also, must be consulted; but is it not pertinent to suggest that in this problem—concerning whch all who have practical contact with it agree that conditions are most unsatisfactory—when once the majority of the technologists agree, the position of the lawyer is to show not what the desired result shall be, but how it can be

brought about? The writer has seen a statement (but can not now find definite reference to it), attributed to the late Chief Justice Marshall in which he indicated his belief that the Courts should be permitted to call more freely upon men of technical training entirely independent of the experts produced as witnesses in cases. In the case of Los Angeles *v.* Hunter (156 Cal. 603), Justice Henshaw stated: "For experts learned in geology to give their theories as to the manner in which Nature has created or developed a given physical condition is not an invasion of the domain of the law." From these statements it seems entirely fitting that the technologists take the initiative in endeavoring to solve the problem of the control of ground-water which is necessary to the most efficient use of this valuable resource.

Acknowledgments.—The writer wishes to acknowledge his indebtedness to his colleagues, Messrs. O. E. Meinzer, A. G. Fiedler, Walter N. White, and J. F. Deeds, of the U. S. Geological Survey, and to H. D. Padgett, of the U. S. Resettlement Administration, whose opinions have served to clarify the writer's viewpoint. Attention should also be called to a recent paper by Mr. S. C. Wiel[a], which deserves consideration in connection with the problems considered herein.

WELLS A. HUTCHINS,[a] ESQ. (by letter).—A scholarly discussion of ground-water law in the United States and of the physical situations to which it applies, is presented in this paper. Mr. Conkling's conclusions will merit study by those concerned with legislation pertaining to underground waters.

Status of Ground-Water Law in Several States.—Under the heading, "Underground Water Law in General", a statement is made as to the status of the law governing such waters in each of the seventeen Western States. Additional comments in the case of several States may be in point.

Arizona.—The water code provides that "the water of all sources, flowing * * * in definite underground channels" belongs to the public and is subject to appropriation. The Courts have held, as Mr. Conkling states, that waters percolating generally through the soil belong to the land-owner and that the rule of reasonable use applies, subterranean streams flowing in natural channels between well-defined banks being subject to appropriation under the same rule as surface streams.

The decision in Maricopa County Municipal Water Conservation District Number One *et al. v.* Southwest Cotton Company *et al.* (39 Ariz. 65, 4 Pac. (2d) 369), held that the presumption is that underground waters are percolating in their nature, and that one who asserts that they are not must prove his assertion by clear and convincing evidence; furthermore, that before an underground stream becomes subject to appropriation, there must be certainty of location as well as of existence of the stream. Whether surface or subterranean, a watercourse is held to be essentially a channel, consisting of a

[a] "Fifty Years of Water Law," by S. C. Wiel, *Harvard Law Review*, Vol. L, pp. 252–304, 1936.

[a] Irrig. Economist, Bureau of Agri. Eng., U. S. Dept. of Agriculture, Berkeley, Calif. Approved for publication by the Bureau of Agri. Eng., U. S. Dept. of Agriculture.

well-defined bed and banks, and a current of water which need not flow continuously. Hence, a prior appropriator from a surface stream, who asserts that his rights are being infringed by pumping plants in a valley traversed by the stream, must demonstrate this physical interference, according to the foregoing rule, "by clear and convincing evidence."

Nevada.—Important additions and amendments to the ground-water law were made in 1935. The State Engineer is to designate underground areas and sub-areas for administrative purposes. No administrative areas, however, have yet been designated.

Utah.—After a line of decisions supporting the correlative doctrine, the Supreme Court of Utah has now (1936) announced the application of the appropriation doctrine to at least some underground waters. The two cases in point are Wrathall *v.* Johnson *et al.* (86 Utah 50, 40 Pac. (2d) 755, January 2, 1935), and Justeson *v.* Olsen *et al.* (86 Utah, 158, 40 Pac. (2d) 802, January 10, 1935).

The Wrathall case went up on demurrer, and the Supreme Court held that the complaint stated a cause of action and that the demurrer should have been over-ruled; but the Justices were not in agreement as to why it should have been over-ruled. Two Justices stated that the doctrine of appropriation and beneficial use should be applied to underground percolating waters, and a third that a cause of action was stated under either doctrine, and that waters in an artesian basin should be distinguished from mere "percolating" or "diffused" waters in privately owned land, not connected with other waters. The other two Justices indicated that the complaint stated a cause of action under only the correlative doctrine.

A week later came the decision in the Justeson case, involving a conflict between owners of adjoining tracts, part of each being underlaid by a common artesian basin. Three Justices applied the appropriative doctrine to an "artesian basin", which is "nothing more than a body of water more or less compact, moving through the soils with more or less resistance." The concurring opinion distinguished such waters from "mere percolating or diffused waters." The two Justices who in the Wrathall case concurred in the results but in favor of the correlative doctrine, dissented in the Justeson case.

Shortly afterward the Legislature declared all waters in the State to be the property of the public, subject to existing rights, and provided complete machinery for appropriating underground waters. To the present time (November 2, 1936) the Supreme Court has not had occasion to construe these provisions. In the meantime, the State Engineer is actively administering the statute, twenty-six underground water areas having been defined to September 28, 1936.

In view of the facts: (*a*) That the recent decisions—all handed down prior to the comprehensive legislation—were rendered by a divided Court, with sharp and definite dissenting opinions; (*b*) that the prevailing opinions classified underground waters; and (*c*) that the legislation covering all underground waters has not yet been before the Supreme Court, it appears that further decisions should be awaited before stating, too conclusively, the law of Utah in regard to underground waters.

Wyoming.—So far as the writer is aware, the only decision of the Wyoming Supreme Court on underground waters is Hunt *v.* City of Laramie (26 Wyo. 160, 181 Pac. 137, June 2, 1919). This holds that, if developed artificially, percolating waters belong to the owner of the land on which they are developed.

Co-Ordination of Surface and Ground-Water Rights.—In discussing the administration of surface streams, the author states that only recently has the connection between surface water and underground water been recognized legally, and that the two are still, to a great extent, treated in separate and distinct doctrines of law. Doubtless, this situation has resulted from the fact that surface water is out in the open for all to see, its courses and boundaries readily ascertainable, and its quantity subject to reasonably accurate measurement; whereas, exactly the reverse is characteristic of underground water, although the technique of estimating ground-water supplies has been greatly developed and improved in recent years.

One of the cardinal principles of the doctrine of prior appropriation is that an appropriative right is entitled to protection on all sources of supply of the stream to which the right attaches. An attempted diversion of water from a tributary, at a time it is needed by prior appropriators on the main stream, will be enjoined; for it was recognized in early decisions that the unlimited acquisition of rights on tributaries would eventually deprive the main-stream prior appropriators of their water supply; and, yet, some of these States which follow the appropriation doctrine exclusively as to surface streams have applied the common-law doctrine to underground waters generally, regardless of the fact that such waters may be an important source of supply of surface streams to which prior rights have attached. Doubtless, these inconsistencies have resulted, in part, from the location of tracts over which the first controversies arose; from the failure of river appropriators to recognize the implications of a suit between owners of land overlying a basin constituting one of their sources of supply, and to intervene to protect their rights; and from the difficulties of proving the physical inter-connections of subterranean and surface waters.

Obviously, underground and surface waters cannot be entirely dissociated. The connection between surface streams and tributary or supporting underground waters is too marked. An aggregate flow of 100 cu ft per sec entering a river is no less tributary, physically, when it rises in numerous places through the bottom or seeps through the sides of the channel than when it spills over the bank. To intercept this flow of 100 cu ft per sec by pumping plants, if underground, or by dams, if a surface flow, reduces the river to the same extent; yet in a correlative-doctrine State, such as California, these methods of interception are subject to different rules of law. In States in which the doctrine of appropriation of all waters is carried to its logical conclusion, such as in Colorado, neither pumping nor surface diversions would be permitted to interfere with the passage of this 100 cu ft per sec while it is needed to satisfy earlier river priorities. The pumping diversion, however, would have its own priority to the same extent as would a surface intercep-

tion if it antedated the river appropriation or became vested with a prescriptive right. All priorities, in other words, relate to the stream system—the river and all contributing sources. To divide the surface waters in an area embracing any part of that system according to one set of priorities, and the underground waters according to a different set, without regard to possible inter-relationships, would (if the development proceeded far enough), inevitably infringe sooner or later upon prior river rights and result in a hopeless confusion of water titles.

Co-ordination of rights to surface and underground waters, therefore, appears to be a condition precedent to the most complete utilization of water in areas in which physical interconnections exist. Under the doctrine of appropriation this will involve in a given region the separation of percolating waters tributary to surface streams from those not so tributary; adjudications of existing rights; allocation of the remainder of the water supply to further appropriations at diversion points consistent with those of established priorities; and extinguishment of some existing priorities, either through voluntary agreement or condemnation by public authority, in order that ground-water development may proceed, where the proposed development is sufficiently valuable to justify the expense.

Desirability of Administrative Control.—In summing up the results of his examination of State laws affecting the use of underground waters, the author lists four doctrines of law, three of which recognize ownership of water by the land owner and one by the State. Administrative control will be concerned with this fourth doctrine, under which the title to the ground-water is in the public or the State, subject to beneficial use by individual appropriators. There is a possible field for State control under the correlative doctrine likewise, in basins subject to overdrafts; but if experience with riparian rights on surface streams may be taken as a guide, adjustments of controversies over water in individual ownership will be left to the Courts

When a State is once committed to a doctrine of private ownership of water, change to a public ownership system is difficult. The change is much more feasible before great development has been made, than afterward; before vested rights and their protection offer serious resistance. The Nevada Courts for a period of thirteen years recognized the riparian doctrine as to surface streams, to a certain extent at least, and then abrogated it. Riparian rights embodied in Court decrees became vested, but the abrogation was sufficiently early in the State's development to avoid widespread complications. After a long line of decisions supporting the correlative doctrine of ground-waters, the Utah Court now favors the appropriation doctrine; but only a very small percentage of the irrigated area receives its supply from wells. The situation in California is very different; in that State nearly one-third of the total irrigated area secures water exclusively from wells. A movement now under way to effect a modification of the correlative doctrine in California is faced with difficult constitutional questions.

Undoubtedly, in various areas, development of ground-water exists that would not have existed had control been in effect. Nevertheless, a certain amount of this has taken place at the expense and to the injury of early

appropriators. This may or may not be in the public interest in a given locality, depending upon local conditions. In parts of California—a correlative-doctrine State—early users of underground water have been forced to go deeper and deeper into the ground for their water supplies as a result of increasing later use by other owners of land overlying the same basin. Development has been great; but against this must be cited the great increase in cost of operation forced upon the early users, the failures on the part of those who could not stand the mounting costs, and the uncertainty as to available water supply if and when all those who are entitled to pump the water choose to exercise their rights. Under the correlative doctrine, as compared with the appropriation doctrine, those who install pumping plants have little protection in the maintenance of their water right; no matter how long they may use the water, its adequacy and availability may be impaired at any time by the installation of pumping plants by other correlative owners. In other words, a correlative right to pump in an area in which the tillable land exceeds the water supply simply means that when all exercise their rights no one will have enough; if some develop a supply adequate for their needs in the meantime, they will be deprived of at least part of it later.

Extreme application of the appropriation doctrine, on the other hand, is open sometimes to serious objections. For example, the first appropriator is entitled to have the water flow in the stream to his point of diversion when it will do so in quantities sufficient to be useful; and he is not to be deprived of this right in favor of a later appropriator higher up the stream on the ground that the water would be greater in quantity and, consequently, more useful up stream. Regardless of heavy losses in the stream bed, the earlier appropriator is entitled to the flow to the extent of his appropriation. To require 100 cu ft per sec to be released up stream to supply 5 cu ft per sec to the early priority down stream may appear unreasonable, but it is the latter's right. Analogous to this situation would be the prevention of any later development of underground water that would lower the water level at the earliest user's well below the point from which he can afford to pump. The earliest user in each case would have protection under the strict application of the appropriation doctrine. This is a property right, important to the individual. The application in such case is objectionable from the standpoint of the public interest, for it requires an allotment of natural resources to one individual that is capable of serving many to greater advantage.

The appropriation doctrine has proved better suited to the Western States than the riparian doctrine. Nevertheless, the last word in its development has not necessarily been spoken. The author indicates that there is a tendency toward modification; undoubtedly, there is room for modification to include economic use, and for laying more stress upon the element of public benefit.

Granted that the appropriation doctrine as to surface waters, in substantially its present form, will be retained, and that interest in bringing ground-waters under State control on an appropriative basis has grown in recent years, the key to the future development of ground-waters tributary to a stream system in a strict appropriation State may lie in some form of public

or co-operative acquisition and extinguishment of prior rights which interfere with development, compensation to be made to the holders of the rights thus extinguished. The same reasoning applies to extinguishing prior ground-water rights along the rim of a basin, which if not extinguished may prevent the use of a much greater water supply drawn from storage in the interior of the basin. The prospective ground-water use must justify itself however; and if the user can not afford to pay just compensation, the necessity for any such exchange of water right is questionable unless some other public benefit is involved. In the case of surface-water appropriations, the working out of an equitable basis for an adjustment should not present great difficulties. In the case of ground-water it is more complicated, of course, both physically and economically.

Difficulties of Administration.—The author indicates some of the difficulties that face the administrator charged with control of ground-water. It is a complicated proceeding, of course, and it is appreciated that precise determinations may be difficult or impossible in a given case, or so costly as to be prohibitive. Nevertheless, in view of the increasing knowledge and mastery of ground-water hydrology, there seems little reason to doubt that a careful, scientific investigation will yield substantial justice to the claimants.

Administration of underground waters will be more expensive than that of surface streams, due to the cost of necessary investigations. That, however, is an element to be considered in any proposed development of ground-waters, just as is the high cost of pumping from underground, as compared with the cost of gravity diversions from surface, streams.

The fact that the administrator must enter the field of economics, from which he has been free in the administration of surface streams, may be an unwelcome departure to the individual, but is not an insuperable obstacle. Methods have been developed for determining costs and returns in farming operations, costs of water, and capacity of lands to pay for irrigation development. The administrator will adapt existing methods in reaching his decisions as to issuance of permits and regulation of pumping drafts, rather than develop an entirely new technique.

JOHN E. FIELD,[43] M. AM. SOC. C. E. (by letter).—Dealing as it does, with a very complicated subject, this paper is unusually comprehensive and clear. For simplicity, it would be well to separate the discussion into two major parts: First, where riparian rights obtain—geographically east of the 98th Meridian; and, second, where the appropriative doctrine rules (that is, west of that line). The westerly area should be subdivided into the several States, and the one which offers the least departure from the strictly appropriative doctrine and in which, through judicial decision, the rules are becoming fixed, should be discussed first. With a code for such a State as a basis, modifications in conformity with laws and customs can be made and applied to other States.

Colorado seems to be the State where riparian rights intrude the least, and where the laws and practice have reached a fair degree of stability. The

[43] Cons. Engr., Denver, Colo.

practice in Colorado is based largely on judicial decisions and many of the statutory laws have followed rather than preceded the decisions of the Court. Until 1879, the practice was "go as you please" with only the Constitution as a guide, which provided that "the right to divert water for beneficial purposes shall never be denied" and "the first in time is the first in right." In 1879, a law was passed providing for "proving up" on claims of the irrigator, of recording and defining the rights, and for "adjudication." State-wide adjudications were had in the period from 1883 to 1886. The right to transfer water from one canal to another was recognized and although it sometimes led to injustice to the individual, nevertheless, it encouraged economy of use and caused the transfer of water from the poorer land to the more productive. These transfers were decidedly in the public interest, and, in part, they account for the rapid development in Colorado. On the other hand, State governments that tried to tie the water to the land and to avoid individual injustices, lagged in their development. A statute prescribing the method of effecting the transfer was passed in 1899, which the State Supreme Court declared was the expression of the existing law and merely made definite the procedure to be followed.

In the matter of laws, regulations, and administration of underground waters, as the author indicates (see "Underground Water Law in General: Colorado"), the Colorado Courts have applied the same regulations as for surface water, but the time has now arrived when the method of administering and recording underground water rights should be embodied in statutory law, based on practice, custom, and the decisions of the Courts. This orderly procedure which has characterized the evolution in water laws in Colorado, will result in an equitable and practical expression of pre-existing fact. It is for these reasons that the writer uses Colorado as the example to clarify his theories and arguments.

As it passes from the mountains to the plains, the South Platte River derives less than one-half its supply from the South Park area (see "Underflow Which May Support a Surface Stream.") It passes through Denver about ten miles east of the foot-hills and at the bend near Greeley, is 30 miles from the mountains and enters Nebraska close to the northeast corner of Colorado. The minimum precipitation on the eastern slope (about 12 in.) is found about 50 miles east of the mountains; it increases to the west to 15 in. at the foot-hills, and increases easterly to about 16 in. at the Kansas-Colorado line. Due to the rapid fall in the river (about 2 000 ft in 200 miles), existing canals could be extended to cover the greater portion of the area east of the mountains and between the Wyoming line on the north to the South Platte-Arkansas divide on the south, and water could be carried on to land in the Arkansas water-shed or, following the divide, enter Kansas at the point of highest elevation in that State. In other words, practical gravity canals can reach lands far in excess of the water supply and if the present supply could be increased (through trans-mountain diversions) by 50%, only moderate extensions of existing canals would be required to use the increase. This possibility explains the absence of pumping. Pumping to provide storage space has not been proposed heretofore, for the South

Platte Valley, as it is water and not reservoir space that is needed; and, furthermore, diversion dams now raise the underflow into many canals quite as effectively as pumps could. Below these dams, during the period of ordinary flow, the river bed is dry and would remain dry for the remainder of its course, except for the invisible inflow of natural and return seepage water, which amounts to about 1 000 cu ft per sec, or 5 cu ft per sec per mile of river.

Consequently, the writer must differ with Mr. Conkling in his facts and conclusions as stated under the headings, "Underflow Which May Support a Surface Stream" and "Administration: Underground Water", as far as they refer to conditions on the South Platte.

Numerous pumping plants on the mesa lands are used to supplement the canal supply. These wells are below the canals and their supply is from seepage water on its way, underground, to the watercourses. The right to pump has not been seriously questioned due in part to the difficulty of proving that the pumped water would reach the stream at a time when needed by a plaintiff. The damage in reality is inconsequential to any one canal. One-half the seepage water reaches the river in the non-irrigation season and the other half is diverted and demanded by one canal to-day and another to-morrow. All are probably affected at one time or another, each in its turn, depending on the stage of the river flow and the dates of priority. If all factors were determinable, canals that are remote and in other districts, may be the ones damaged at some particular time. A small quantity of the return seepage is intercepted by the pumps, but which canal is damaged, and to what extent, is impossible of even approximate determination. The only benefit that pumping would accomplish would be to furnish, from the underflow, some water to meet the emergency needs of canals. Numerous pumps have been installed in the five years (1932 to 1937), for such emergency purposes and the "live and let live" attitude of canal administrators who have been adversely affected has permitted their use, because each canal administrator suspects that he too will sometime wish to do the same thing. Contrary to the author's contention, the South Platte does not offer an example of the wisdom or possibilities of pumping; nor will pumping create reservoir capacity that may be filled by water now escaping.

Under "Artesian Areas or Basins", the author does not mention the great artesian wells of the San Luis Valley, near the head-waters of the Rio Grande. Slichter gave their number as about 6 000, and the aggregate supply as about 300 000 acre-ft. After more than forty years, they are still active and such as show a decreased discharge have probably become choked, the casing has failed, or the water is escaping before reaching the surface.

Table 1 seems to be in serious error in the columns, "Areas Supplied from Streams with Supplemental Well Supply", for in the San Luis Valley there is an area of more than 200 000 acres receiving water from wells, in addition to their canal supply. The area is sub-irrigated, and so this item of double source of supply escaped the eye of the field agent taking the census. In Table 2, remarks as to Colorado should read: "Pumping for emergency

purposes only, is advisable." An increase in water supply will be necessary before much further development is possible. Otherwise, only through economy of use, can any further development of consequences be expected east of the mountains in Colorado. The error mentioned lays the accuracy of Table 1 open to suspicion. In any case the data pertaining to agriculture in 1919, are eccentric (that is, out of balance), especially when considering trends. They should be used with great caution as the stimulus to agriculture due to the World War makes them unreliable.

The question, "Is the diverter from a stream protected in his means of diversion?" (see "Water Law in General") is answered by a decided "No". It is quite enough that the early appropriator enjoys at all times an exclusive 100% right (when it is in the river) and, although he is entitled to the maintenance of conditions as of the date of his appropriations, to have it apply to the means of diversion would lead to intolerable conditions, contrary to the public interest. For example, when, by reason of diversion of the water above, the first appropriator finds his head-gate too high and the water too low for him to divert his full right, it would be wasteful to send sufficient water down to him to raise its surface to the old gage height; and, therefore, the law provides that he may move his head-gate up stream, build a diversion dam, or put in a pump. Assuming that it is Canal No. 2 which causes the low flow, to compel Canal No. 2 to pay for the change might well impose such a burden on that canal as to prevent its construction. Canal No. 1 could, by reason of its preference right, better afford to assume the burden. The author states that (see "Water Law in General") "the hurdle, faced by the individual who proposes to divert at an up-stream point would indeed be high, if he had to compensate all down-stream appropriators." Although there are no statutes in Colorado which protect the appropriator in his means of diversion there are statutes which permit him to take such measures as will enable him to secure his full appropriations and which by implication denies him the right to insist on a *status quo* as to his means or instrumentality of diversion.

In the case of overflow on meadows, when the river falls so low by reason of diversions above, that the meadows are no longer overflowed, the law permits the construction of canals, with a date of priority as of the date of its first use as a meadow.

In a recent decision of the Supreme Court of Colorado, the Court reversed itself and ruled that reservoirs and canals were on the same basis—and that the first in time, was the first in right. Here, it is quite definitely indicated that the instrumentality employed to accomplish beneficial use, in no way affects the right of use. Therefore, pumps have no different standing from gravity canals, reservoirs, pipe lines, or carrying the water in a bucket. Such being the case, it seems that in Colorado a practical plan of administration alone remains to be evolved and that at this time, the Administrator, the State Engineer, and Water Commissioner, should be given definite rules and clear instructions under which they will perform their administrative duties in handling underground water. The statute should require that filings be made as in the case of canals, that all wells to be used, for other

than household and stock purposes, must be drilled under the direction of the State Geologist who would preserve a careful log of the well and make a study and report on the geology, the replenishment, and the source of supply. This report would be filed with the State Engineer, who, in turn, would make a tentative determination of the duty of water, and at the beginning and end of each irrigation season would check the height of the water-table. The statute should require the installation of a meter, a reading of which would be taken by the Water Commissioner as often as the State Engineer deemed advisable, or the latter could require the installation of a self-recording meter. The quantity of water pumped would be limited by the tentative duty of water as fixed by the State Engineer and the acreage irrigated, and the quantity pumped each year would be recorded and would form the basis for later adjudication.

Adjudication should be initiated by the State Engineer when, in his judgment, it was advisable, or upon the petition of the water users. In this adjudication, the Court would fix the depth below which the water could not be drawn, based on the records gathered and compiled by the State Engineer or by any competent investigator. The appropriator should be limited in the quantity of water he could pump in any one year; but the time or the rate of flow should be at the discretion of the user. The State Administrators would be concerned principally in the gross acre-feet pumped per year. The tentative duty of water would be changed from time to time until a fixed duty could be determined on the basis of the records. At first, the tentative duty might well be placed at 1.25 acre-ft per yr, which approximates the consumptive use for Colorado, a use over and above the rainfall. After the adjudications were had, the water officials would act thereunder, shut down such pumps as had reached the quantity allowed by the decree, or when the water-table approached its minimum allowable elevation. In periods of extra large supply, or of drought, the pumps with the later decrees would be allowed to run or would be closed down. After a period of years, the replenishment possibilities would be determined quite closely and the junior decrees would, in practice, become void. The writer does not anticipate that there would be an under-development; if this should occur, there would be almost no call for administrative control.

If pumps should be installed in the bottom-lands (land a few feet above the stream), they would be allowed to operate in the order of their priority; that is, after the demands of prior rights had been satisfied. Pumps more remote from the river should be allowed to operate until holders of earlier priorities make complaint, in which case, the State Engineer would investigate and render his decision, which would be binding until altered by the Courts.

In time, the necessity of classifying the land would probably arise, the entire underground supply in some areas would be reserved for domestic and stock uses, and, in others (as in river bottoms) all water pumped would be considered as a diversion from the river supply. In the matter of preference uses, the laws now provide that domestic use is superior to agricultural use,

but by the Court's decision this means that the water used for irrigation may be condemned and converted to domestic use.

Summary, Discussion, and Conclusions.—In addition to what the author states in Item 2 of his "Conclusions", it should be added, that the damage occasioned by the decrease of supply on the South Platte is inconsequential, as it is shared by all priorities, each in its turn. Referring to Item 4, the fundamentals of Colorado laws were adopted before Statehood (in fact, coincident with the creation of the Territory in 1861). The same is true of most of the other arid States.

The practical operation of Colorado laws and decisions relative to underground water (see Item 5), may have prevented the development of pumping to some extent, but they have prevented infringement on existing rights, have protected developed areas, and have prevented unwise and "wild-cat" enterprises. The writer, with an intimate knowledge of the State for more than fifty years, is unable to visualize a materially greater development by the use of pumps than has occurred without them; and, on the other hand, he can readily visualize interminable legal controversies and a less development had the California law prevailed. In fact, the physical conditions in Colorado and in California in the matter of underground waters are so different that no comparison can be made; nor can conclusions be drawn with profit.

Much research and investigation are necessary for accurate and intelligent control (see Item 19), but unless the development is sudden and complete, the data can be gathered over a period of years, and as a part of the ordinary administration duties. The cost will be borne largely by the appropriator, just as it is now borne by canals in the construction of weirs, registers, and co-operative measurements. The administrative control and the gathering of data should not wait until overdraft threatens, but to be of greatest value, must be gathered during the years of development, and must be available when overdraft threatens and adjudications are asked.

In conclusion, the paramount consideration in such matters as the paper touches, is the public interest; the greatest economical development possible, even at the sacrifice or infringement of individual or property rights, should be the objective. Old laws must be abrogated and new ones enacted to meet physical and economic conditions. In the arid States, the riparian doctrine was ruthlessly set aside, or so modified as to meet the necessities of the people. Most of the early Court decisions were based on the necessities, and on common sense rather than on precedent, or the common law; and it is to be hoped that the Courts will continue to recognize paramount necessities as controlling, rather than adhere to the outworn laws and outworn decisions.

The State of Colorado has been very fortunate in having a Court willing to reverse itself and willing to consider facts and the public interest in making its decisions; and, in Wyoming, the Court, recognizing the benefits of the transfer of water, "hedged" on the "water-attached-to-land" constitutional provision and held that this provision did not apply to ditches built before the Territory became a State. It is axiomatic that water should be used where the user can pay the most for it.

In a mining camp, in Colorado, a "district" was formed, about 1859, and rules and regulations were adopted. In conclusion this document reads: "In matters not covered by the above rules, the laws of the United States shall apply." The writer's theory also is, that "when existing laws and decisions do not conflict with the public interest, they shall prevail."

George S. Knapp,[44] M. Am. Soc. C. E. (by letter).—Studies such as those made by Mr. Conkling in the preparation of this paper should aid materially in an understanding of ground-water administrative problems, and in a region as young, relatively, as that of the Western States, where ground-water laws are still in a formative state, the paper should be a valuable guide in the shaping of legislation for administrative control.

The paper shows the great diversity among the various States in laws governing rights to the use of ground-water. In their scope they vary from those vesting absolute and unrestricted ownership to ground-water in the ownership of the land under which it is found, to those which apply the appropriative doctrine so strictly that, in some States, a land owner may be barred from using any of the water under his land for irrigation because owners of other land have been permitted to appropriate the entire supply.

The object of such laws and administrative regulations is to permit the orderly development of ground-water supplies and, at the same time, to prevent over-development of the supply and injury to water users. Some effort has been made in recent years to secure the enactment of uniform ground-water laws for irrigation in the Western States. Uniformity of State laws is desirable in so far as it can be attained. With respect to ground-water under land no longer in public ownership, the process of changing the law is difficult, particularly if it is attempted to change from some form of the riparian or ownership doctrine to the appropriative doctrine. The process of separating the ownership of the water from that of the land by legislative enactment would undoubtedly be held by the Courts as the taking of property without due process of law; that is, without condemnation and compensation.

In some States both surface water and ground-water are under the same rule of law. In others, it is not. A number of States attempt to apply the rule of priority of right to ground-water in the same manner as it is applied to surface water. In this connection, it should be noted, perhaps, that the appropriative doctrine does not apply to ground-water, as among various appropriators, with the same effect, and in the same manner, as it does to surface streams. The available quantity of ground-water does not fluctuate rapidly from day to day as surface water does. Even if it moves in well-defined channels, ground-water constitutes essentially a reservoir and not a stream. Its surface is drawn down slowly with use, and the supply is replenished slowly. It is only the earliest appropriators from surface streams who enjoy their full measure of water in all years. The remainder receive their appropriation on a fewer number of days, depending on the relative priority of their appropriations. The last appropriators may be entitled to water only

[44] Chf. Engr., Div. of Water Resources of Kansas, Topeka, Kans.

during the few days from time to time when the stream may be at flood-stage. In applying the appropriative doctrine to ground-water it is necessary to determine the quantity which may be withdrawn each year, and from year to year, without depletion of the reservoir. That group of users, whose aggregate appropriations come within this quantity, becomes, together, a preferred group which receives a full supply each year, whereas the latter, would-be appropriators, are denied any part of the water supply.

There has been a great increase in the acreage irrigated from wells in the Arkansas and Platte River Valleys in Colorado, Kansas, and Nebraska, since the 1929 census data were secured. Much of it has occurred during the five years of drought experienced in this region in 1932–37. Some of these recently constructed pumping plants are used for the irrigation of new land. Others are used as a supplemental supply for land hitherto "dry-farmed", or for land under canal systems, either pumping into the canals, or directly on to the land to supplement deficient surface supplies. All these pumping plants are situated in the river valleys. As Mr. Conkling states, no extensive use of this ground-water can be made without diminishing the flow of the streams to users below. If the rule of priority of right had been enforced in Colorado, these pumping plants, being junior to canals down stream, as to dates of construction, would not have been permitted to operate when the lower canals were short of water. The immediate effect of the operation of these pumping plants would be the lowering of the water-table in the valley rather than a reduction of stream flow, since the water-table would necessarily have to be lowered before stream flow could be affected. At the time, therefore, they virtually drew on a reserve water supply during a period of drought. To permit them to continue to operate regularly from year to year, however, will result in an increased irrigated acreage, or an increased use of water at such points to the injury of surface-water users down stream.

Ground-water supplies constitute a reservoir that can be held in reserve for long periods without the evaporation losses sustained in the storage of surface supplies. The value of these underground supplies in supplementing deficient stream flow during the recent drought suggests the possible wisdom, as a matter of public policy, of holding them in reserve in certain localities to be used only in times of drought, but that could not be done legally under either the appropriative or the absolute ownership doctrines. It would require an entirely new rule of law.

Ground-water laws are still in the making throughout the West. As they develop it scarcely seems probable that they will grow in uniformity among the States as much as they will grow to meet the different needs and the different conditions of use in the various States.

CHANDLER DAVIS,[45] M. AM. SOC. C. E. (by letter).—The engineer's mission is to establish the mean number of gallons of water that may safely be pumped from the underground reservoir; the exploitation of the source should be controlled by the Federal Government or by the State Government, and the

[45] Cons. Engr., New York, N. Y.

pumping should be limited to the quantity determined by the engineer; thus, there need be no fear of overdrawing on the sources of supply and causing alarm as Mr. Conkling states happened in California, in areas exploited prior to the organization of the State Division of Water Resources.

Mr. Conkling is correct in advocating that the exploitation of an underground water source be preceded by a thorough investigation, that pumping stations be erected only under license and supervision of some branch of Government, and that the pumping be limited to the findings of the engineer. To emphasize these views, the writer wishes to comment briefly on the status of underground storage in Long Island.

After the recession of the ice of the last glacial period, what is known to-day under the name of Long Island, New York, covered a much larger area than it does now, the south shore extending more than 100 miles farther out to sea. When the subsidence occurred the clay deposited by the melting ice settled below the surface of the Atlantic and is found at various depths, and in various positions (horizontal layers, vertical, and others at all angles). Soon afterward, the sea began to pile sand on the shore front eventually forming the present Island, with its highest dune or backbone nearer the north shore, so that the slope to the north is quite steep, whereas the land slopes gently to the south. Similarly, the ground-water slopes toward the Atlantic very gradually, the highest point of the water-table being south of the highest point of the land. Streams and ponds are found where land contours cut the water-table, their size varying with the rainfall; that is, they shrink after a period of drought and grow larger after a very heavy rainfall period. A perceptible lag is observed due to time required for the rain (which is absorbed by the ground) to reach the water-table. There is one interesting exception, the high lying Lake Ronkonkoma, which does not seem to have any connection with the remainder of the underground water of the Island and seems to follow rules of its own.

The Borough of Brooklyn received its water supply from a line of wells driven along the south shore of the Island. Between 1900 and 1905, a group of farmers sued the City for diverting the water from beneath the farms situated along the line of, and in the vicinity of, the aqueduct. At first the City was not very successful in defending these suits; but, later, its engineers completed their studies of the situation and were able to prove that the farmers had suffered no damage, with the exception of such litigants whose farms lay directly alongside the aqueduct and within the cone influence of the pumps when operating.

A study of the tree growth within the area of the farms under litigation, as well as elsewhere in the United States, where rainfall and underground-water data were obtainable, made by the writer, established the fact that such growth was not affected by the pumping, and that as the water-table lay so far below the surface throughout the area under litigation, vegetation depended on rainfall for its growth.

There is an important question to be solved: How much of the rainfall, which is absorbed by the ground and finally reaches the ground-water, may be

pumped safely without damage to the underground reservoir? This is especially important in cases such as Long Island, as the fresh water holds back the salt water, and if the latter is permitted to encroach on the former the volume of fresh water available will be reduced by that quantity irretrievably, and this is the real problem which confronts the engineer.

Mr. Conkling is to be congratulated on his very valuable and timely paper.

L. Standish Hall,[46] Assoc. M. Am. Soc. C. E. (by letter).—A thorough treatment of the physical and legal aspects of the control of underground water is presented in this paper. The many and varied possibilities with reference to the physical conditions are adequately expressed in the sentence (see heading, "Underground Water in General"), "each situation is a separate study which must be exhaustive and widespread to reach reliable conclusions". The only generality that can be expressed is that all surface, vadose, and ground-waters were derived primarily from rainfall. (Vadose waters[47] are the suspended sub-surface waters found in the zone of aeration between the land surface and the water-table.)

The author states that ground-water cannot be developed without reducing the flow of the adjacent streams. This statement is true, in general, because it was implied that the streams in question were perennial, and that the development of surface-water diversions was possible. Such streams in semi-arid regions usually rest on the water-table and, to some extent, are effluent, or they may be both influent and effluent along various stretches of the channel. A ground-water development in these areas will naturally result in a lowering of the water-table, but if the pumping is not excessive a balance will be reached ultimately subject to the normal fluctuation of ground-water levels resulting from the natural variation in rainfall. This balance is reached from the increased seepage or percolation from the stream induced by the steeper gradient from the water level in the channel to that in the adjacent ground-water body. If the streams were originally influent, a change to effluent will result.

A natural limit to the process of increasing percolation from ground-water development is reached if the ground-water is lowered below the stream bed at points adjacent to the channel. When this condition occurs, no further lowering of the water-table will increase percolation under a given flow. The stream then would have reached the natural condition existing in ground-water adjacent to intermittent and ephemeral streams, where stream channels are above the water-table at all times. Under such conditions, percolation depends on the volume and duration of flow, and ground-water withdrawals exert no influence on the recharge.

If surface-water irrigation has developed in a basin prior to the use of the underground water, it does not appear possible, on a perennial stream, to permit a subsequent pumping development under administrative

[46] Hydr. Engr., East Bay Municipal Utility Dist., Oakland, Calif.

[47] "Outline of Ground Water Hydrology", by Oscar E. Meinzer, *Water Supply Paper No. 494*, U. S. Geological Survey, p. 22.

control. If the surface-water use occurs on an intermittent or an ephemeral stream, the ground-water development would not conflict with the surface-water use. However, if surface-water use on the latter type of streams succeeded ground-water development, there would be a conflict of rights, since diversion of surface flow would reduce the quantity that would percolate.

Even a subsequent ground-water development on a perennial stream subject to appropriation, must occur up stream from the point of diversion to be of damage since (as is noted by the author) excess water is always carried from the stream with surface irrigation and frequently results in a rising water-table in the lower part of the irrigated area. Ground-water development down stream from the surface irrigation would frequently be a benefit and, in fact, is sometimes resorted to under a canal system to prevent water-logging of the lower areas.

The economics of the situation may also enter into the extent that development of ground-waters may progress unhindered. Sufficient lowering of the water-table eventually would result in excessive costs so that some users would be forced to abandon their development. Here, again, priority might establish the justice of such a method of survival depending on whether or not the lands forced out of cultivation were first in the ground-water field but, because of their location, were the first to feel the effects of mounting water costs.

The variety of conflicts that may arise in connection with ground-water uses and surface-water diversions would lead to the careful consideration of the author's conclusion (Item 19) that where fullest development of water resources are desired, "administrative control of underground water should not be adopted until over-draft threatens, and then only in particular areas." Furthermore, "a step at a time may be the safest course."

HAROLD CONKLING,[48] M. AM. SOC. C. E. (by letter).—The able and instructive discussions of the subject-matter of this paper "bring home" the considerable thought which is being devoted to the subject by hydrological engineers. The paper and the discussions do not deal with a matter that has been finished, nor with a mathematical certainty, nor with the results of an experiment; rather they deal with what may be the difficulties in, and what may be the desirability of, administrative control of a natural resource, the limitation on the use of which is obscure and is enwrapped with questions of economics. In such discussions informed opinion naturally plays a large part.

The discussions have indicated at least a part of the errors of commission and omission in the original paper. The writer is grateful for this, and it is hoped that all readers will note them. Any errors in acreage irrigated by pumping are not at all material to the purpose of the paper. These data are from the Federal Census which is the only source available, as was found by the writer after attempting to obtain

[48] Deputy State Engr., Sacramento, Calif.

the same information from the various State offices. In the discussions the scope of the paper has been amplified to the benefit of all. It was hoped that both correction and amplification would be the outcome. "Consider," said Prah-hotep 5 000 yr ago, "How thou mayest be opposed by an expert in council. It is foolish to speak on every kind of work;" and said Tai Tung, "Were I to await perfection my book would never be finished."

Many lines of thought have been suggested in the discussion which, however tempting, would lead to an inordinately long closure, and because of this, specific mention is made of only a few of the factual discussions of conditions in specific areas.

That of Mr. Gourley gives light on conditions in England where the development of modern industry is bringing to the fore the desirability of the control of underground water use. Mr. Baldwin has also called attention to industrial developments in the Mid-Western United States which show that even there a problem now exists. The discussion of Professor Smith describes in detail conditions in Arizona and neighboring States. In this connection a *Bulletin* by Professor Smith[49] on ground-water law, published in 1937, is well worth reading. Mr. Thompson has supplemented and amplified the original paper by a broad and masterly outline of conditions in the eastern part of the United States and by an analysis of legal decisions in both the West and the East. A discussion of conditions in Colorado, by Mr. Field, is illuminating because of the intensive development of water supplies in the eastern part of Colorado. This latter discussion appears to support the writer's thesis that in a State having the appropriative doctrine, use of underground water would be legally inhibited by surface rights below the point of use as long as the concept prevails that surface flow is necessary to fill a right which, heretofore, has depended on surface flow. The successful pumping which has been instituted along the South Platte River in the recent years of drought, has been successful because "the live and let live attitude of canal administrators who have been adversely affected, has permitted their use."[50] In other words, development of ground-water succeeded, and the crops of the area were preserved in the recent stressful years because the law was not invoked. This is cogent commentary on the difficulties that arise in the complete application of the law of prior appropriation when ground-water is involved. The foregoing statement, however, seems somewhat contradictory to a subsequent statement in the same discussion to the effect that the prior appropriator is not protected in his means of diversion and may be forced to pump. Perhaps Mr. Field did not have in mind pumping from under-flow as an alternative means of diversion.

All who have discussed the paper unite as to the need of administrative control. To the writer this seems clear also, but he is not so definite

[49] "Ground Water Law in Arizona and Neighboring States", by G. E. P. Smith, M. Am. Soc. C. E., *Bulletin No. 65*, Coll. of Agriculture, Tucson, Ariz.

[50] See p. 826.

in his belief that actual control is needed at an early stage of development. A ground-water basin in its original state contains large deposits of water which, in most cases, can be withdrawn without great harm except that the water-table is lowered and the permanent supply is thus rendered more expensive to secure. In this respect, it is not different from an ore body or an oil field. If these deposits of water are not exploited, the potential wealth of the country is not developed; and yet, if they are exploited, it means that some of those using the water during the period of exploitation must cease using it at some future period. In other words, these users have only a temporary right; but it seems to violate a traditional concept to speak of a temporary right in water. How valuable this exploitation may be in some cases is witnessed by development in Southern California and in the San Joaquin Valley of California where, with mining of water as a foundation and mining of oil as a supplement—in the fields side by side with the water basin—wealth has been produced which has enabled or is enabling the communities to construct huge aqueducts to import water from sources hundreds of miles distant to replace the mined water and to bring in supplies much greater than the permanent local supplies.

An uncontrolled development may bring about the best development or it may not; but whatever the result the means of its achievement are costly. Administrative control at its best would bring about the best result in the least costly manner, but it cannot depart too widely from the natural trend of events. If a temporary over-development which mined the impounded water supplies of the past ages seemed best for the public it would be permitted and, therefore, permanent and temporary rights would exist. The same results would thus be achieved finally as are achieved in many cases by uncontrolled development; that is, temporary over-draft and final adjustment of draft to recharge, with resulting abandonment of part of the development. The difference in such case would be that the temporary rights would be designated in the case of control, whereas, with lack of control, such rights would be those of the economically marginal users instead of the last users.

The point is that the need for flexibility in administration is paramount. The principle of prior appropriation, if actually administered according to the doctrine, can be very inflexible. The doctrine of correlative rights can be very flexible. Either doctrine may lead to beneficial results or either may lead to harmful results. In contemplating possibilities, the writer confesses to a distinct distaste for "freezing" any situation within the narrow confines of administrative action and control unless the administrator can be given the right to accept or to reject the areas to be placed within his control, either by his own initiative or by action on a petition of those using water. As an alternative the administrator can be given a power he is not now given in any jurisdiction; namely, the exercise of judicial functions.

Mr. Thompson's discussion brings out the apparent necessity felt by the Courts to define classes of underground water so that each situation falls

into a certain category as to which a precedent exists or as to which a new precedent can be set. Even by a hydrologist, the artificiality of such definitions can be appreciated only when he must examine them in detail. Recently, the writer was faced with the necessity of deciding, for purposes of determining jurisdiction, whether a certain body of water was a "definite underground stream," or otherwise. Any reasoning a hydrologist could bring to bear on the matter which led to the conclusion that this body of water is an underground stream, would also lead to the conclusion that almost any moving underground water is an underground stream, and *vice versa*; but the first-mentioned reasoning process seemed the soundest. The writer is heartily in accord with Mr. Thompson's axiom that "all water beneath the ground is * * * simply ground-water." The difficulty is that the definitions and the need for definitions have been due to lack of knowledge, with little appreciation of the broader phases of the matter.

To summarize: The numerous and able discussions have done much to clarify the subject. It is felt that control is desirable, but that it can be accomplished best through a step-by-step process whereby the results of each step can be considered before going further. The attempts at control in the various jurisdictions and in England have been outlined. Of course, they are first steps, but it can scarcely be concluded after reading these discussions that a uniform law is desirable. Contrast conditions in Colorado as described by Mr. Field, with conditions in California as typified by San Gabriel Valley; or contrast with these, conditions in Long Island as described by Mr. Davis. Nevertheless, the basic ideal would necessarily be the same no matter how diverse the form of the law; and by it questions of draft which would cause final retrogression would be encompassed whether the retrogression were caused by marine or other saline intrusion, by too great concentration of chemicals, or simply by drawing more water from the basin than the recharge permits.

If engineers feel that control is desirable they must formulate the kind of control. This matter has become, in some areas (and will become in others), a matter which ranks with other phases of life which have been given into the control of commissioners with judicial or quasi-judicial power. If the development of underground water brings such a situation about as to its control, it will naturally extend to surface water since the two are physically interdependent. It is suggested that such a body, combining in its personnel, both scientific knowledge and ability for investigational research, can most intelligently cope with the present problem, subject of course, to review by the Court.

DYNAMIC DISTORTIONS IN STRUCTURES SUBJECTED TO SUDDEN EARTH SHOCK

By Harry A. Williams,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Arthur C. Ruge, H. M. Engle, Merit P. White, L. S. Jacobsen, and Harry A. Williams.

Synopsis

An inspection of earthquake records indicates that the ground may have practically harmonic motion for several successive swings after the initial shock. The amplitude and perhaps the period of the motion is then changed, sometimes quite radically. Some engineers feel that it is scarcely possible, under these conditions, for a structure with a period of vibration very close to that of the ground to attain critical distortions because of insufficient time for the amplitude to build up. This paper contains the results of model experiments on a single-mass system and a theoretical analysis of the behavior of an elevated water tank, all subjected to a sudden shock followed by harmonic vibrations. The results indicate that for single-mass structures in the near-resonance condition, critical displacements can be built up before the type of ground motion changes. There is as yet insufficient experimental evidence from which to draw similar conclusions for multi-mass structures.

Experimental Procedure[2]

The experimental investigation, which was made in the Vibration Laboratory at Stanford University, in California, dealt with the dynamic equivalent of a single-mass structure. A diagrammatic sketch of the model as installed on the shaking-table is shown in Fig. 1. The operation of the vibrating system was as follows: The table was given a sudden acceleration by dropping the pendulum against the bumper spring. When the stiff bumper spring recoiled,

Note.—Published in May, 1936, *Proceedings*.

[1] Asst. Prof. of Civ. Eng., Stanford Univ., Stanford University, Calif.

contact with the pendulum ceased, and the latter was withdrawn from action. The resulting motion of the table—the ground motion—was harmonic, the amplitude gradually decreasing because of friction.

The model consisted of a 4-in **I**-beam approximately 2 ft long, supported and guided on three balls and having a tension spring attached to each end. The model was constructed so that the amount of viscous damping (resis-

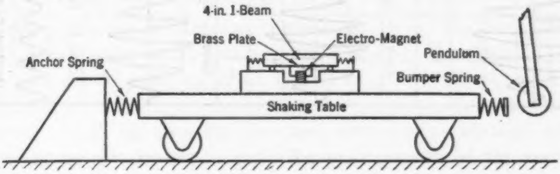

FIG. 1.

tance to vibration which is directly proportional to velocity, such as that offered by air or fluid friction) could be varied and the effect on the model motion studied, by fastening a brass plate on the under side of the **I**-beam in such a way that the plate moved through a magnetic field set up by two electro-magnets. The damping that resulted from this arrangement was directly proportional to the relative velocity of the model with respect to the shaking-table. It was found that constant or sliding friction could be neglected in the experiment.

Wires were attached to the model and to pens in such a way that records could be obtained simultaneously for the motion of the shaking-table, the absolute motion of the model with respect to the floor of the laboratory, and the relative motion of the model with respect to the table. Since the engineer is concerned only with the relative motion of a structure with respect to the ground, the records of absolute motion have not been included in this paper.

The motion of the shaking-table, which was the same for all tests, is shown by Curve 4 in Fig. 2. The pendulum was in contact with the bumper spring for 0.077 sec. During the impact the table received a maximum absolute acceleration of 14% of gravity, this maximum occurring at the end of 0.035 sec. After contact between the pendulum and bumper spring ceased, the table vibrated with a damped harmonic motion, the period of which was 0.508 sec. It reached a maximum amplitude of 0.23 in. on the first swing, at which point the acceleration was 8.5% of gravity.

All the curves of relative motion in the paper are upside down with respect to ground motion. It was necessary to take the experimental records in this form and the theoretical curves were made in the same way to be consistent.

Tests were made with three different sets of springs for the model. The spring factors were such that in the first series of tests (Fig. 2(*a*)), the free period of vibration for the model, 0.390 sec, was less than the period of the table; in the second series (Fig. 2(*b*)), it was 0.534 sec, or very nearly the same as that of the table; and in the third series (Fig. 2(*c*)), it was 0.611 sec. With each set of springs, tests were made for three different degrees of viscous damping by varying the current through the electro-magnets. Curve 1 of

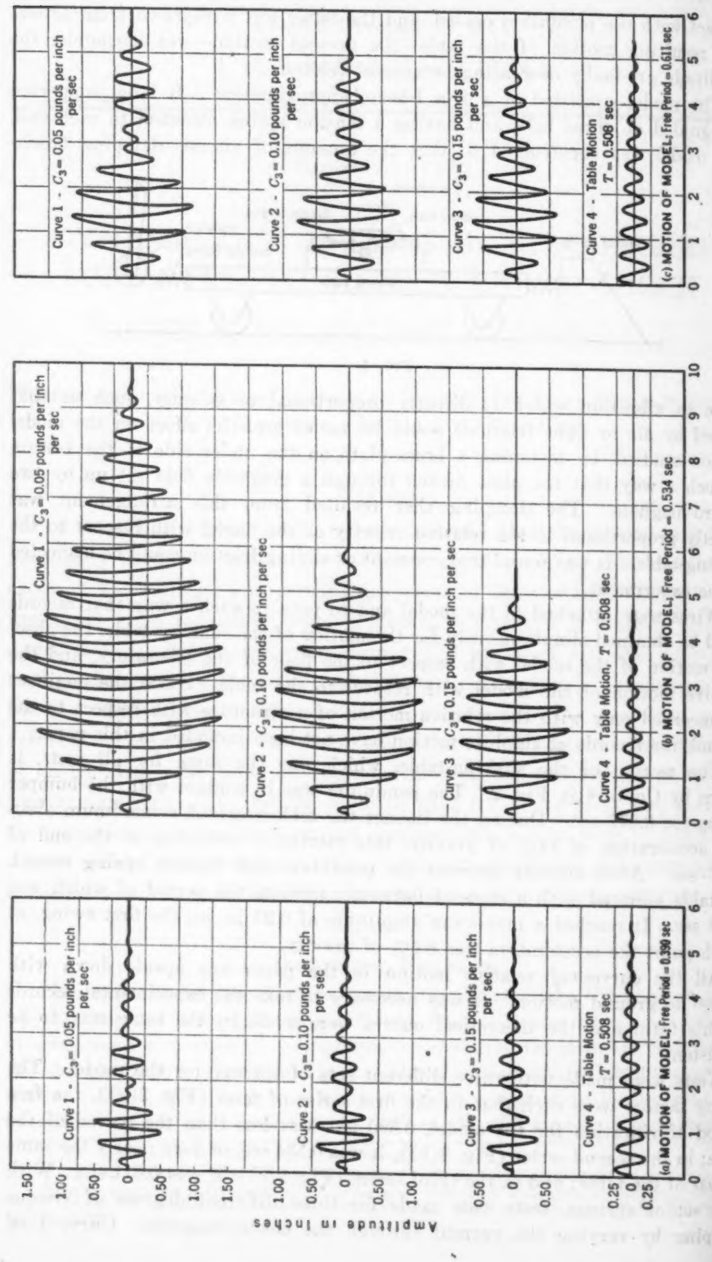

FIG. 2.—EXPERIMENTAL RECORDS OF MODEL MOTION.

Fig. 2(*b*), for instance, records the test in which the viscous damping constant, c_3, was quite small. It is increased from 0.05 to 0.10 and thence to 0.15 lb per in. per sec in the tests recorded in Curves 2 and 3, respectively, of Fig. 2(*b*).

Very good agreement was obtained between the experimental records and corresponding theoretical curves.

Discussion and Analysis of Test Results

When the pendulum strikes the bumper spring on the table, the latter is accelerated for a very short period—0.077 sec in the present case—after which the pendulum ceases to affect the natural free vibration of the table. The amplitudes of these free vibrations are reduced by friction until motion finally ceases. Only the first two or three complete oscillations of the table are of interest in this investigation. An examination of the records shown in Fig. 2 reveals that:

(1) When the free period of the model is somewhat less (Fig. 2 (*a*)), or somewhat greater (Fig. 2(*c*)), than that of the table, the amplitude is not large, and the maximum is attained in a very few cycles;

(2) When a near-resonance condition prevails (Fig. 2(*b*)), the amplitude is large, and the time required to reach the maximum is somewhat longer; and

(3) The effect of increasing the viscous damping factor, c_3, is to decrease the amplitude.

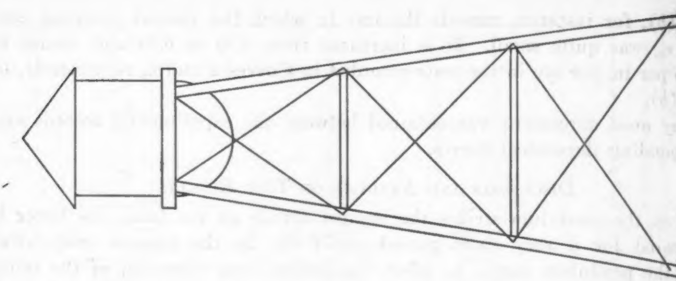
With reference to Item (2), it is important to notice that the amplitude built up in the first few cycles is large when compared to the maximum. The enveloping curves for these tests, plotted in Fig. 3, show that a large percentage of the maximum amplitude reached in any given test is attained very quickly.

In connection with Item (3), the effect of damping on the period of vibration is negligible. If the friction is small, the amplitude will build up somewhat more rapidly and will be greater eventually than if considerable friction is present. The curves of Fig. 3 show that friction has no appreciable effect during the first few cycles. Theoretically, this would be expected since the major part of the damping results from the presence of the exponential factor, $e^{-\frac{c}{2m}t}$, in the mathematical expression for displacement. When t is small, this factor differs but little from unity, and, therefore, the amplitude decreases slowly. Hence, the presence of a moderate amount of viscous friction in an actual structure may not prevent the attainment of dangerous amplitudes. A critical amplitude may be reached before friction has much effect.

Behavior of Model for Different Periods of Table Motion

Theoretical curves in Fig. 4 show the behavior of the model for three different table motions. In Fig. 4(*a*), the period of the table is greater than that of the model; in Fig. 4(*b*), it is the same as in Curve 3 of Fig. 2(*b*), which is the near-resonance condition; in Fig. 4(*c*), the table period is smaller than that of the model.[3]

[3] The mathematical expressions used in plotting the curves in Fig. 4 are similar to those developed by Professor L. S. Jacobsen, in his paper, "Vibration Research at Stanford University", *Bulletin*, Seismological Soc. of America, Vol. 19, No. 1, March, 1929.



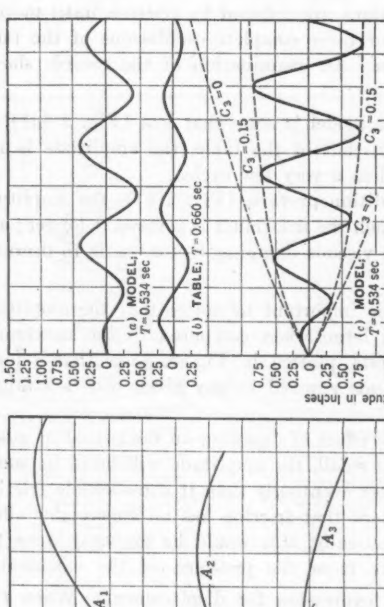


FIG. 4.—THEORETICAL BEHAVIOR OF MODEL FOR DIFFERENT PERIODS OF TABLE MOTION.

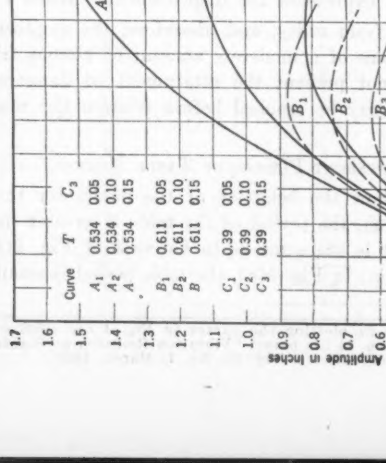

FIG. 3.—ENVELOPES OF MODEL MOTION FROM EXPERIMENTAL RECORDS.

The result, in general, is the same as for the actual tests. As the system is removed from the near-resonance condition, the maximum amplitude is less than it is for that condition, and it is built up in a very few cycles.

It should be emphasized at this point that the distortion attained by the vibrating mass is directly proportional to the ground amplitude. Hence, it is entirely possible for an actual structure to be out of resonance with the ground and still be over-stressed because of the large amplitude of the ground motion.

Amplitude Versus Acceleration

The preceding discussion has purposely been concerned with the amplitude of the motion rather than with the acceleration. In the final analysis, the important item is the stress created in a structure by the ground movement. If the structure does not distort with respect to the ground, obviously there is no stress. A large ground acceleration may cause large distortions and, hence, high stresses; but these stresses may not actually exist until the ground acceleration has decreased almost to zero. Moreover, the force causing the high stresses may bear no relation whatever to that fictitious force so frequently used, which equals mass times acceleration.

Notation

The following symbols of this paper conform essentially with "Symbols for Mechanics, Structural Engineering, and Testing Materials", compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932 (the numbered subscripts are consistent with those used in the reference previously cited[2]):

c_3 = viscous damping factor for the model, in pounds per inch per second.

F = frequency, in radians per second, of the elevated water tank $= \sqrt{\frac{\kappa}{m}}$; F_2 = frequency of the table or ground motion $= \sqrt{\frac{\kappa_2}{m_2}}$; F_3 = frequency of the model $= \sqrt{\frac{\kappa_3}{m_3}}$.

G = maximum amplitude of table or ground motion, in inches.

g = acceleration due to gravity, in inches per second^2.

m = the effective mass of the elevated water tank $= \frac{w}{g}$, in pounds-second^2 per inch; m_3 = mass of the model.

r = a subscript denoting "resonance condition."

T = period, in seconds.

t = time, in seconds.

V_0 = initial absolute velocity, in inches per second, when $t = 0$.

W = total weight.

Y = displacement with respect to the ground, in inches.

y = absolute deflection, deformation of spring, or amplitude of the center of gravity of a structure, in inches; y_0 = absolute displacement of the ground, in inches.

elastic constant, or spring factor for the elevated water tank; $_2$ = spring factor for the shaking-table; κ_3 = spring factor for the model, in pounds per inch.

Theoretical Behavior of an Elevated Water Tank

The model experiments show that the amplitude of motion builds up rapidly but, since the model is not intended to show stress similitude, the experiments do not indicate at what point the distortion might become critical. The behavior of a 125-ft, 50 000-gal elevated water tank is investigated mathematically with this in mind. A sketch of the structure is shown in Fig. 5. For purposes of the investigation, certain assumptions are made:

(1) It is assumed that the tank is filled with water, but only 50% of this water acts as a rigid mass in affecting the motion of the structure. This admittedly is a rough approximation. The value was selected because, at the time the investigation was begun, it seemed consistent with available data. More recent studies, together with records[4] obtained by the United States Coast and Geodetic Survey, indicate that it is probably low and that the original discrepancies between computed and actual periods were due largely to other factors. If the expressions relating to the instantaneous shock properties of water in a tank, as given by Professors Hoskins and Jacobsen[5] are applied to a rectangular tank having the same cross-sectional area and containing the same volume of water as the tank in question, a value of 78% is obtained. Professor Hoskins also computed that for shock approximately 75% of the water would act as a rigid mass in a cylindrical flat-bottom tank, 19 ft in diameter and 17.5 ft high, the same dimensions as the cylindrical portion of the water tank. The effect of a considerable error in the assumed value of 50% is discussed subsequently.

(2) In order to simplify the problem, it is assumed that the gravitational surge of water from side to side in the tank does not materially affect the behavior of the structure during the first few cycles. Tests made by the U. S. Coast and Geodetic Survey indicate that the vibrating tank tower water system may be thought of as a coupled system and that, for certain characteristic depths of water in a tank, the resulting oscillations of the system are affected considerably by the water surges even during the first few seconds.[4] Experiments made at the Massachusetts Institute of Technology with an elevated tank tower model show a "cushioning effect" which has been attributed to water surge.[6] The latter tests indicate that to neglect water surge is probably on the side of safety for the particular tank tower used for illustration. However, experimental evidence does not yet warrant the same assumption being made for elevated tanks of all sizes, or with water at any depth.

(3) The total effective mass, which includes 50% of the water, the tank, and its appurtenances, and one-half the supporting tower structure, is assumed as being concentrated at the walk line. (It is higher than this for the static condition, but if only one-half the water is considered effective during motion, it would seem reasonable to lower the center of gravity somewhat, and such an assumption does not materially affect the result in any event.)

[4] "Observed Vibrations of Steel Water Towers", by D. S. Carder, *Bulletin*, Seismological Soc. of America, Vol. 26, No. 1, January, 1936, p. 69.

[5] "Water Pressure in a Tank Caused by a Simulated Earthquake", *Bulletin*, Seismological Soc. of America, Vol. 24, No. 1, January, 1934.

[6] "Changed Elevated Tank Design Required for Safety Against Earthquakes", by A. L. Brown, *Engineering News-Record*, October 4, 1934, p. 424.

(4) The structure is assumed to rest on a rigid foundation. (Actually, the elasticity of the ground under the footings will lengthen the period of the structure.)

(5) Viscous damping and constant friction are neglected. (Records obtained by the U. S. Coast and Geodetic Survey from the motion of elevated water tanks indicate the presence of only a small amount of friction. Damping ratios given by Mr. Carder[4] show that friction decreases the amplitude of each succeeding cycle about 1%.)

(6) Initial tension in the diagonal rods is neglected. (The effect of this assumption is discussed subsequently.)

Under the foregoing assumptions, the mass, m, of the system is 663 lb-sec^2 per in., and the elastic constant or spring factor, κ = 12 300 lb per in.[7] Hence, the free period of the structure is $T = 2\pi \sqrt{\frac{m}{\kappa}} = 1.45$ sec. Let it be assumed that for a number of cycles the ground has a harmonic motion in accordance with the expression:

$$y_0 = G \sin F_2 t \qquad (1)$$

Let it also be assumed that this motion starts when the time $t = 0$; that is, the motion is assumed to start with a fictitious finite velocity from the zero displacement position. The differential equation for the absolute motion of the system then becomes:[8]

$$m \frac{d^2y}{dt^2} + \kappa (y - y_0) = 0 \qquad (2)$$

or, substituting for y_0:

$$m \frac{d^2y}{dt^2} + \kappa y = \kappa G \sin F_2 t \qquad (3)$$

The solution of Equation (3) is:

$$y = \frac{\kappa G}{\kappa - F^2_2 m} \left(\sin F_2 t - F_2 \sqrt{\frac{m}{\kappa}} \sin \sqrt{\frac{\kappa}{m}}\, t\right) \qquad (4)$$

For the resonance condition, this expression can be differentiated with respect to F_2. In the limit, $\sqrt{\frac{\kappa}{m}} = F_2$, and the result is:

$$y_r = 0.5\, G\, (\sin F_2 t - F_2 t \cos F_2 t) \qquad (5)$$

However, this is the absolute motion of the assumed center of gravity. The displacement with respect to the ground is:

$$Y_r = y_r - y_0 = -0.5\, G\, (\sin F_2 t + F_2 t \cos F_2 t) \qquad (6)$$

[7] For method of computing the elastic constant see "Computation of the Vibration Period of Steel Tank Towers", by R. S. McLean and W. W. Moore, Juniors, Am. Soc. C. E., *Bulletin*, Seismological Soc. of America, Vol. 26, No. 1, January, 1936, p. 63.

[8] See "Vibration Problems in Engineering", by S. Timoshenko, p. 13.

In Equation (6) the term, $\sin F_2 t$, will be much smaller that $F_2 t \cos F_2 t$. Hence, for all practical purposes, the motion can be expressed as:

$$Y_r = -0.5\ G\ F_2\ t \cos F_2\ t \ldots\ldots\ldots\ldots\ldots\ldots\ldots(7)$$

The resulting motion is shown by Curve *A* in Fig. 6 for the case in which the maximum amplitude of the ground displacement is 1 in. (Displacements of this order, with periods of 1 sec to 1.5 sec occurred in the Long Beach

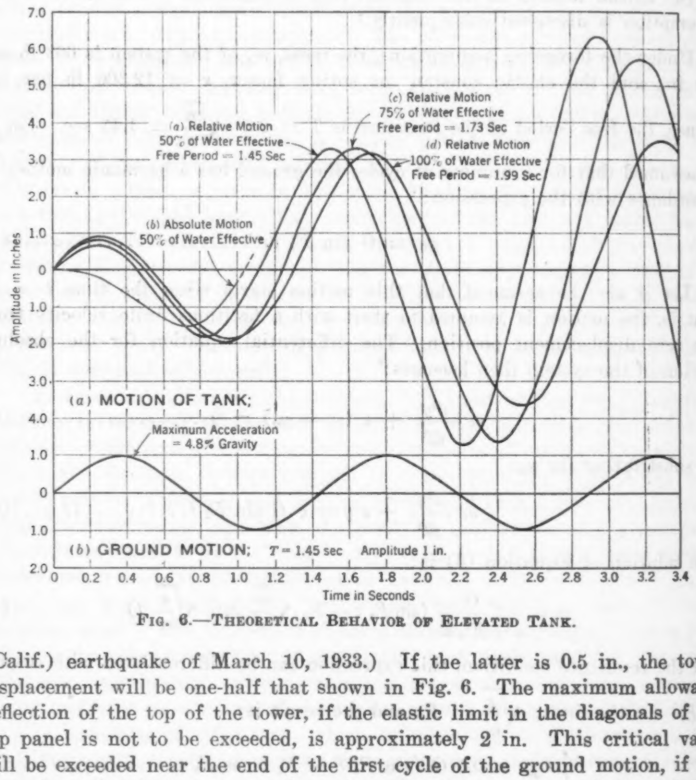

FIG. 6.—THEORETICAL BEHAVIOR OF ELEVATED TANK.

(Calif.) earthquake of March 10, 1933.) If the latter is 0.5 in., the tower displacement will be one-half that shown in Fig. 6. The maximum allowable deflection of the top of the tower, if the elastic limit in the diagonals of the top panel is not to be exceeded, is approximately 2 in. This critical value will be exceeded near the end of the first cycle of the ground motion, if the ground amplitude is 1 in., and, at the end of one and one-half cycles, if the latter is 0.5 in. The time element is too short for a moderate amount of friction to be of much help.

Admittedly, the foregoing quantitative results should be accepted with some reservations, since their accuracy is limited by the original assumptions. A study of the effect of possible errors in the assumptions, however, showed that the results are indicative of the probable behavior of the structure during the first few major swings of the ground. If 75% instead of 50% of

the water acts as a rigid mass, the free period of the structure becomes 1.73 sec. When subjected to the ground motion shown in Fig. 6, the relative motion is as shown by Curve *C*. If 100% of the water is effective, the motion is shown by Curve *D*. The expression used in plotting the latter curves was obtained by subtracting Equation (1) from Equation (4).

The behavior of the structure was studied also for the condition in which considerable initial tension was present in all diagonal rods during the first few cycles of the ground motion. The elastic constant is increased about 70% in this case and the free period is reduced to 1.12 sec. If the ground has the same period as before (1.45 sec.), the tank motion curve is of the same type as Curve *A* in Fig. 6, but the cycles are shorter and the peak amplitudes are roughly 30% less during the first two cycles.

It should be apparent that a considerable change can be made in the free period of the vibrating system and yet not eliminate the possibility of critical distortions occurring during the first few cycles, especially if large ground amplitudes prevail. As pointed out in connection with Fig. 4, the period of the ground motion can be considerably larger or smaller than the free period of a given single-mass structure with relatively little effect on the amplitude during the first cycle, or so. This statement is further substantiated by experiments made at the Massachusetts Institute of Technology with an elevated tank tower model.[6]

If the initial tension in the diagonal rods is not large, the behavior of the structure is as follows:[4, 7] As the top of the tower deflects relative to the ground, a pair of rods in the top panel drop out of action first and the elastic constant is decreased; a further deflection, and a pair of rods in the second panel drop out of action, with a consequent additional decrease in the elastic constant. On the back-swing these changes are reversed. If a rod on one side drops out of action before the corresponding rod on the opposite side, the motion is further complicated by a twisting action, which might be serious.

The behavior of the structure after the yield point has been reached in the top panel rods is even more complicated. (During the following description, the reader will do well to bear in mind a typical stress-strain diagram for structural steel.) Thus, if initial tension is negligible, the elastic constant does not vary until a critical distortion is reached and the stress in the top panel rods exceeds the elastic limit. Then this constant is decreased to a rough average value which is about 8% of its former value and the structure becomes very flexible. If the ground motion continues with the same period and amplitude, the time required for the structure to reach the end of its outward swing under these conditions depends largely on its absolute velocity at the instant the critical distortion is reached.

As the structure starts on its back-swing, the rods again increase the elastic constant for a short time until they drop out of action because of permanent elongation. That is, during the unloading, stress is again approximately proportional to strain for a steel rod which has been permanently stretched. When the center of gravity of the structure crosses the position of static equilibrium, the unimpaired rods which resist motion in the other

direction come into action. Under certain conditions, the same cycle could be repeated on that side. Once all top panel rods have been broken, the free period of the structure will be in excess of 5 sec.

There is no doubt but that the behavior of an elevated water tank beyond the critical distortion stage is an important phase of the problem. In the Long Beach earthquake of March, 1933, the top panel rods in many such tanks were badly stretched or entirely broken and yet the structures did not collapse. It is quite possible that many of the failures took place very soon after the start of the major shock and the fact that the elastic constant for such a structure no longer had a constant value but changed several times during a full swing enabled it to "weather" the remainder of the shock. Another view is that expressed by Mr. Carder.[4] He points out that, since the torsional period of most tank towers was about the same as the dominant period (0.3 sec) of the Long Beach earthquake, "it seems probable that much of the observed damage to these structures in the Long Beach region resulted from the circumstance that a large torsional motion was set up in resonance with the earth motion."

No attempt is made in this paper to plot theoretical curves for the behavior of the structure after the critical distortion has been exceeded, or to show the early behavior when there is initial tension in the diagonal rods, Any such theoretical computation should be verified by experiment.

Remarks on Behavior of Buildings

A single-story building can be expected to act as a single-mass system only if the walls are very light in comparison with the roof structure. In this case, its response to the initial shocks of an earthquake should parallel that of the model on the shaking-table. If the structure has heavy masonry walls, it usually cannot be considered a single-mass system and it is difficult to design a model that will adequately simulate its behavior.

Impact tests on a model of a multi-story building have been made by Professor Jacobsen. These tests, as yet unpublished, indicate that the distortions occurring during the first two cycles of the table motion are as large as any which occur later. Further experiment is needed, however.

Effect of Small Waves Before Major Shock

A number of waves of small amplitude usually precede the major shock. If the period of these waves is very short as compared to that of the structure the latter has very little motion, and the effect of the major shock will be practically the same as if the system had been at rest. If the preliminary waves are in resonance wih the structure for a short time, the structure will be "tuned in" and the first large swing might be disastrous.

Several theoretical curves have been plotted (see Fig. 7) which show the behavior of the elevated water tank for various starting conditions. The relative amplitude for the resonance condition can be expressed as:

$$X_r = \left(\frac{V_0}{F_2} - \frac{G}{2}\right) \sin F_2\, t + \left(Y_0 - \frac{G}{2}\right) F_2\, t \cos F_2\, t \ldots\ldots\ldots (8)$$

in which Y_0 is the initial absolute displacement, in inches; and V_0 is the initial absolute velocity, in inches per second, at the instant when $t = 0$; that is, at the assumed starting point of the major ground displacements.

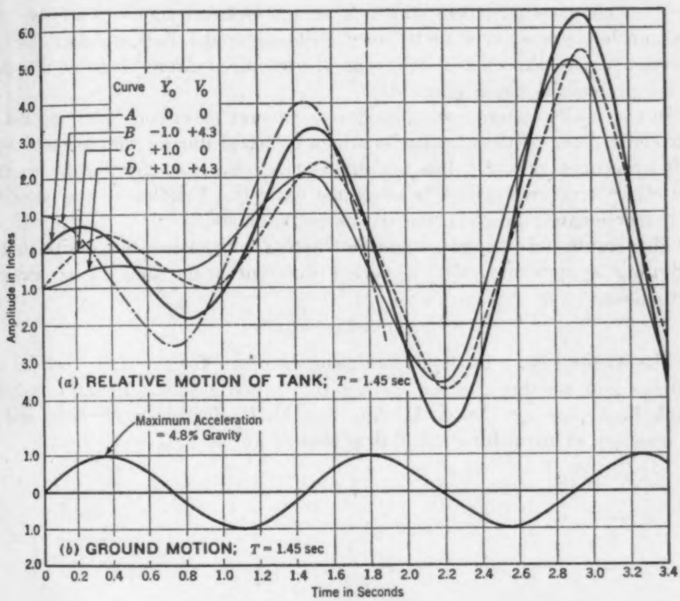

FIG. 7.—THEORETICAL BEHAVIOR OF ELEVATED TANK AT RESONANCE FOR VARIOUS STARTING CONDITIONS.

Referring to Fig. 7, Curve A is the same as Curve A in Fig. 6. The slope of this curve is not zero when $t = 0$, because of the assumption regarding ground motion. Note the slope of the curve of absolute motion in Fig. 6. It is assumed for the beginning of Curve B that the previous ground motion has been such that when t is assumed equal to zero, the tower has a displacement of 1 in. to the left and is moving at a velocity of 4.3 in. per sec to the right (the same direction as the ground motion on the first swing). The effect of the other starting conditions is indicated by Curves C and D.

Curves could be drawn for many other starting conditions. Some would be more and some less favorable than those shown. There is no consolation to be gained from the former because the latter are just as likely to occur. In any event, it is important to note that the rather severe starting conditions used in the example materially affected only the first one and one-half cycles. This further illustrates the fact that large ground motions and resonance are a dangerous combination at any time even if the condition prevails for only a few cycles.

Conclusions

The investigation indicates that if the ground is suddenly accelerated from rest or near rest, and then continues for a few cycles with a harmonic motion of constant period and amplitude, large displacements will be built up for a single-mass structure which is in the near-resonance condition. The tests made to date on a multi-story building model indicate that the same behavior can be expected of this type of structure. More study of this phase of the problem is being planned.

In the model experiments a moderate amount of viscous damping did not materially decrease the amplitudes which occurred during the first few cycles. This experimental result does not necessarily mean that friction in buildings and other structures should be neglected entirely. Friction in the latter may be proportionately greater than it was in the model.

The results of the investigation further emphasize the desirability of designing a structure with a period different from that of an expected earthquake.

Acknowledgments

The writer wishes to thank Professor Jacobsen for the many helpful suggestions and assistance given during this investigation. He also wishes to thank L. A. Elsener, Assoc. M. Am. Soc. C. E., for his suggestions and for his courtesy in furnishing detail drawings of an elevated water tank.

DISCUSSION

ARTHUR C. RUGE,[9] ASSOC. M. AM. SOC. C. E. (by letter).—Engineers who have been complacently designing "quake-proof" structures by the statical method will find much to disturb their peace of mind in Professor Williams' excellent paper. The importance of considering the dynamics of structures is made clear, and the author has experimentally demonstrated the validity of theoretical analyses in a manner that should satisfy the most skeptical.

The author's attitude toward interpreting the results obtained from experiments in simple harmonic motion is well taken. To carry the interpretation beyond the first one or two cycles of the assumed simple ground motion is meaningless from the engineering standpoint and, as the results show, is unnecessary in the case of elevated water tanks. The writer was led to substantially the same conclusions that Professor Williams has stated by means of experiments of quite a different character, in which the water motion in the tank was not neglected.

There is only one statement in the paper (see "Conclusions") which seems to the writer to be open to question: "The results of the investigation further emphasize the desirability of designing a structure with a period different from that of an expected earthquake."

Unintentionally, this statement is misleading because there is no known single period or narrow range of periods to be expected in an earthquake, and because the practical problems of avoiding even the known earthquake periods are quite difficult in the case of tall tank structures.

If, for the sake of argument, one assumes that there exists in an earthquake a motion having the simple form expressed by Equation (1), in which the amplitude, G, is 1 in., and the period, $\frac{2\pi}{F_2}$, is 1.45 sec (exactly in resonance with the tank), then Professor Williams has shown that critical stresses will be reached during the first cycle of the ground motion. Now, suppose it is decided to strengthen this structure in order to destroy the condition of resonance. Let the new stiffness be twice the original stiffness (which means the addition of 8 or 10 tons of steel to the framework); the new natural period of vibration will be $\frac{1.45}{\sqrt{2}}$, or 1.02 sec.

Fig. 8 shows the deflections of the stiffened structure as compared with the curve for the original structure in Fig. 7 (shown dotted in Fig. 8). It is seen that critical stresses are still reached during the first cycle of the ground motion. Hence, although the stiffening has limited the deflections, it has not prevented overstressing of the structure. Once the elastic limit has been exceeded, the subsequent behavior of the structure is largely a matter of chance and the calculated deflections become fictitious (that is, after $t = 1.25$ sec).

[9] Research Assoc. in Seismology, Dept. of Civ. and San. Eng., Mass. Inst. Tech., Cambridge, Mass.

Now, suppose the earthquake motion contains, somewhere in it, one wave of 1-sec period with a 1-in. amplitude, as well as one wave of 1.5-sec period with a 1-in. amplitude (both of which are entirely possible). Doubling the

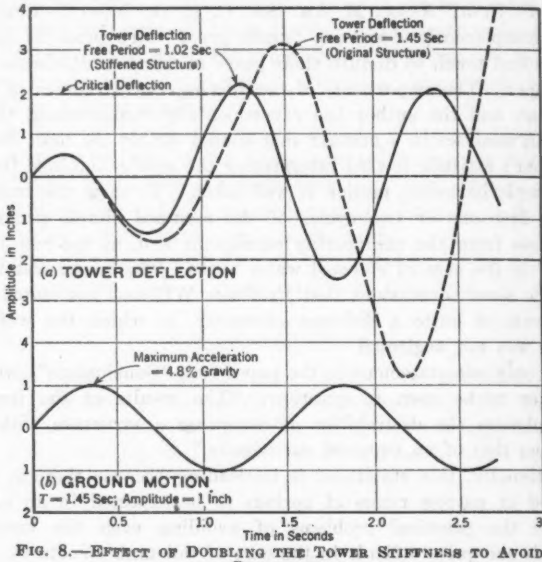

FIG. 8.—EFFECT OF DOUBLING THE TOWER STIFFNESS TO AVOID RESONANCE.

tower stiffness would then have absolutely no beneficial effect and, even if the stiffness of the original structure were to be quadrupled, critical stresses would still be reached, and the stiffening would not have achieved its purpose. Furthermore, since the wave periods and amplitudes cannot possibly be predicted in advance for an actual earthquake, it clearly depends purely upon chance whether a moderate amount of stiffening will increase or decrease the safety of a given tank structure.

Measurements of actual tank-tower periods made[10] by the U. S. Coast and Geodetic Survey clearly illustrate how little is accomplished in avoiding known earthquake periods by moderate strengthening of structures in the 60 000 to 100 000-gal class. These excellent data should be of inestimable value in analyzing failures in future earthquakes.

The author rightly points out that consideration of the behavior of elevated water tanks beyond the critical distortion stage is of importance in attempting to explain many of the near-failures in the Long Beach, Calif., earthquake. In this phase of the problem chance again enters to a great extent. Even given some simple analytical method of attack, there is little justification for applying mathematical analysis very far beyond the yield point because of the strong probability of one side of the tower failing before the other side, which means almost certain collapse of the structure if the strong earthquake motions have not ceased by that time.

[10] *Bulletin*, Seismological Soc. of America, January, 1936.

The Long Beach earthquake was indeed violent, but the most violent part was over in a few seconds. What might have happened to the many near-failures had there been a few more seconds of strong shaking can only be conjectured. There is reason to believe that the strong-motion phase of the San Francisco earthquake of 1906 was of longer duration than that of the Long Beach shock.

H. M. ENGLE,[11] ESQ. (by letter).—The Long Beach, Calif., earthquake of March 10, 1933, stimulated interest in the behavior of structures of various kinds. Elevated tank towers were adversely affected in many cases (although only three collapsed), and considerable attention has been focused on this particular type of structure. Due to the symmetry and structural simplicity of design, these towers lend themselves to model experiments and to theoretical attempts to explain what happened as well as to the determination of what the proper means of safeguard may be.

There has been a tendency on the part of those interested in shaking-table experiments and so-called "dynamic design" to consider the behavior of these structures as somewhat of a mystery, requiring complicated model study and theoretical experimentation. The writer has had intimate contact with the investigation, re-bracing, and repair of perhaps one hundred of such structures and also of a number of new towers. It is his belief: (1) That there is no particular mystery involved; (2) that a reasonable explanation of the damage can be made; and (3) that design to give assured safety against earthquakes is neither difficult nor economically impossible. Furthermore, no radical change in the proportions of towers, method of bracing, erection procedure, or past methods of design are necessary even if design in the past has been based on a static method of analysis. At present, there is no definite proof that the static method of analysis involves any more assumptions or uncertainties than the so-called dynamic method. A static analysis of damaged towers shows that they should have failed where failure occurred. There should be no particular mystery about a structure being damaged under action of forces of a magnitude it was never designed to resist. The writer does not mean to infer that all tall towers of standardized design were wrecked or fatally damaged. Considering that they were braced for wind loads only, their behavior was surprisingly good, and not such as to warrant the idea that the entire conception of their design is faulty for earthquake resistance. They are the result of long years of development and, contrary to some expressed opinions, are skillfully detailed and proportioned not only for economy, but also to utilize the metal involved to its fullest extent.

Following the Long Beach shock of March 10, 1933, the writer inspected in detail a large number of tank towers, some in the Long Beach area and many in other parts of California, which had never been subjected to a severe shock. It was found that the towers had usually been erected with the bracing rods rather loose. Conversation with the erection foremen brought out the fact that in some cases this was done purposely as it was considered desirable

[11] Engr., Board of Fire Underwriters of the Pacific, San Francisco, Calif.

that the tower be somewhat limber. How this idea originated the writer was unable to discover. In some cases the towers were considerably out of line. It is probable that correction of this defect alone would have reduced, somewhat, the damage to such structures in the Long Beach area. It is easy to see that, where loose, the rods would pick up their loads with a jerk. The tank would surge around on the tower, with possible heavy impact. Furthermore, twisting of the tank on the tower would be possible. Proper rigging with rods having good initial tension would reduce these secondary effects and would give a better chance for the structure to develop its strength effectively.

In the past most tanks have been built with hemi-spherical bottoms and a body about as high as, or somewhat higher than, the diameter. The tower legs are attached at the junction of the bottom and the cylindrical shell. The center of the mass of the tank and water is, therefore, a considerable distance above the column-to-tank connection. Under lateral movement the tank would tend to rotate in a vertical plane about the top of the tower. With wave action developed in the tank appreciable stresses could be developed in the tower and bracing. With loose rods this tendency to rotate on top of the tower might add additional impact. Tanks with ellipsoidal bottoms have this defect in a less degree, and the writer believes their more general use in earthquake zones would be desirable.

In regard to tank design and behavior a number of problems may be discussed. Consider three tanks, each with a capacity of 100 000 gal. Let one tank be 75 ft in diameter and 3 ft high, with a flat bottom (see Fig. 9(*a*)). It could probably be shaken indefinitely without any appreciable lateral forces due to weight of water being developed. Friction between tank and water would be small. No appreciable wave action could develop. It would be much like a popcorn shaker. Consider another tank 12 ft in diameter and 132 ft high (see Fig. 9(*c*)). Under shock probably the entire mass of water, or most of it, would have to be moved. Consider as a third tank the common standard design approximately 22 ft in diameter and 24 ft high (see Fig. 9(*b*)). The action of this tank would probably be intermediate. A certain proportion of the water would probably move with the tank, and appreciable wave action could develop. A strictly theoretical analysis of one of these towers to resist earthquake is probably impossible, being a complicated problem in wave action combined with various inertia effects, all produced by a chaotic earth motion impossible, as yet, to forecast. Perhaps Nature's shaking-table experiments on full-sized structures are the best guide. Actual disaster experience where properly interpreted is a fairly good foundation for basing future practice. One tower near Long Beach known to have been designed for a lateral force of 10% of the weight was undamaged in the shock of March 10, 1933. A static method of analysis was used with the lateral force applied at the center of gravity of the tank.

Proponents of dynamic design have laid considerable emphasis on the natural period of structures, generally assuming that there are certain dangerous and predominate natural ground periods which should be avoided. A period of from 1 sec to 1.5 sec has often been considered to be particularly dangerous and one to be avoided. As far as the writer can discover there is

no certain basis for this belief. It is not concurred in by all outstanding seismologists. Periods from a fraction of a second to several minutes have been recorded. For instance, both the Long Beach and Helena (Mont.) shocks

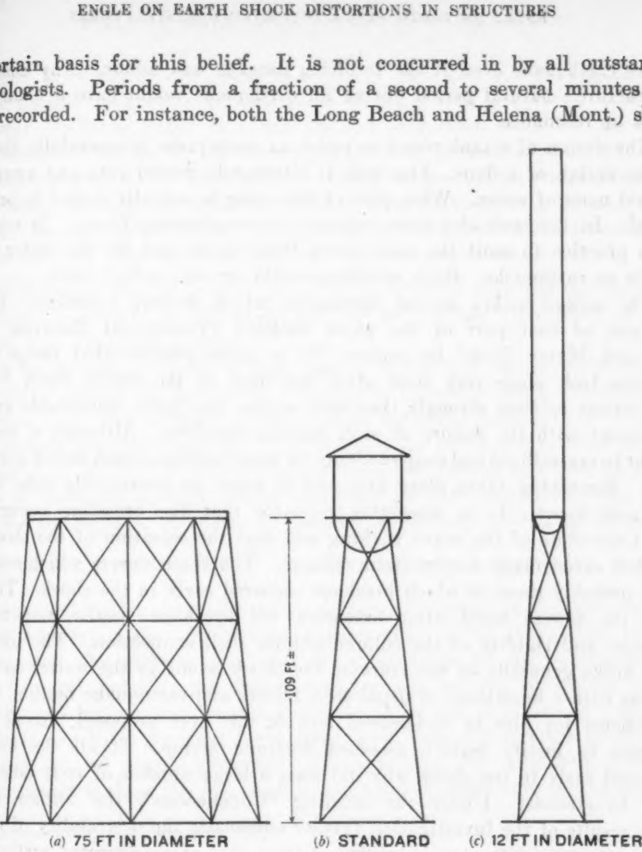

Fig. 9.

had natural periods of only a fraction of a second. It would appear that the range of natural periods of structures is such that it is nearly impossible to dodge the possibility of a comparable natural ground period.

Resonance is often dwelt on in connection with behavior of structures. The danger from resonance has probably been exaggerated. The chaotic and changing nature of the earth motion alone takes away some of the danger. It is probable that the combination of tank and water has no set natural period of vibration. The movement of the water in the tank probably has a tendency to break up the natural period of the tank and water as measured under the slight movement produced by moderate wind pressure. It is also a proved fact, and one consistent with structural design, that as a structure is damaged or loosened in an earthquake its natural period changes. Few structures are put together so that some loosening might not occur in a

severe earthquake even if the resulting damage was minor. Any change in a structure's natural period during an earthquake would have a tendency to break up resonance.

The design of a tank tower to resist an earthquake is essentially the same as the design of a dam. The tank is alternately moved into and away from a fluid mass of water. What part of the water is actually moved is problematical. In the tank also wave action is a complicating factor. It might be good practice to omit the roofs from these tanks and let the water splash out in an earthquake. Such splashing might act as a safety valve.

The author makes several statements which deserve comment. Toward the end of that part of the paper entitled "Theoretical Behavior of an Elevated Water Tank" he states: "It is quite possible that many of the failures took place very soon after the start of the major shock * * *". The writer believes strongly that such action was quite improbable and not consistent with the failure of steel tension members. Although a steel rod might be crystallized and snap suddenly, in most instances such would not be the case. Stretching takes place first and it takes an appreciable time to jerk the rods apart. It is altogether probable that the breakage occurred at about the close of the heavy shaking and that the cessation of the shock was all that saved many towers from collapse. The three towers which collapsed were probably those in which breakage occurred early in the shock. The fact that the towers stood after extensive rod breakage speaks well for the strength and rigidity of the column-to-tank shell connection. The idea that rods broke generally at the start of the shock seems to the writer so inconsistent with a knowledge of usual steel failure and earthquake motion, that it is difficult for him to understand how it was ever proposed, except as an attempt to justify certain assumed dynamic action. If all the breakage occurred early in the shock why did such a large number of rods take "time out" to stretch? Under the heading "Conclusions", the author states: "The results of the investigation further emphasize the desirability of designing a structure with a period different from that of an expected earthquake." Who is going to forecast what type the expected earthquake will be, or how much energy will be released, or exactly how the varying types of soil in a district will respond? Who will guarantee that the period of the grand motion will be 0.2 sec, or 1.5 sec? Who will guarantee what time of year the shock may occur and whether the soil in a district is saturated and lubricated from long rains, or well drained after a long dry period? It seems to the writer that when some one can foretell what type the expected earthquake will be, that assured earthquake prediction will be achieved. Some competent seismologists doubt whether such exact prediction will ever be possible. It certainly is not possible now.

Many of the measurements of natural periods of vibration of structures are of no practical value whatever unless closely correlated with the known features of structural design. There has been ample disaster experience to show that, as yet, no practical substitute has been evolved for ample and assured strength and unity of structure.

MERIT P. WHITE,[12] JUN. AM. SOC. C. E. (by letter).—To engineers of certain regions the question of earthquake effects is most important. Although Professor Williams' paper does not pretend to furnish rules for the earthquake-resistant design of structures, nevertheless it does offer, to a certain extent, something which all engineers should possess before undertaking any such design, namely, an understanding of what happens to a structure subjected to an earthquake shock. The following facts (which are either stated in this paper or may be easily verified) seem especially important:

(1) Moderate viscous friction has no great effect in reducing the maximum deflections occurring in the early part of the motion (the effect of solid friction was not investigated);

(2) Amplitudes are built up very rapidly in the first stages of the motion;

(3) The region of dangerous frequencies (causing large deflections) is somewhat wider for suddenly applied simple harmonic motion than for established simple harmonic motion. (Fig. 10 shows the calculated relation between the maximum deflections of any one-story structure during one cycle or several cycles of suddenly applied simple harmonic ground motion ($Y_0 \sin F\, t$); also, for comparison, it shows the maximum deflections due to established simple harmonic motion, and $\frac{F}{F_1}$ (in distorted scale, horizontally), the ratio of the ground-motion frequency to the natural frequency of the structure);

(4) An earthquake acts not as a force, but as an irresistible motion; furthermore, the stresses produced in a structure by an earthquake are dependent not only on the ground motion (or on the maximum ground acceleration) but on the dynamical properties of the structure as well; and,

(5) It can be shown that for a given amplitude and number of cycles of suddenly applied simple harmonic ground motion the maximum deflection of a structure such as the one considered herein depends only on the so-called resonance ratio, $\frac{F}{F_1}$ (see Fig. 10).

From Item (5) it follows that an attempt to strengthen such a structure will affect its maximum deflections (and, therefore, its maximum stresses) only indirectly, through changing the stiffness and thus the ratio, $\frac{F}{F_1}$. This change is quite likely to increase deflections instead of decreasing them. An increase will result if $\frac{F}{F_1}$ approaches unity.

In view of the care which was probably taken in constructing the shaking-table and elevated tank model used in the author's experiments, it is not surprising that the model results should agree so well with those obtained from theory. It would be very surprising to the writer if this were not the case.

In discussing the effect of small waves preceding a major shock the author makes a relatively simple matter unnecessarily complicated. Whatever the

[12] Asst. Engr., SCS, Iowa Inst. for Hydr. Research, Iowa Univ., Iowa City, Iowa.

preliminary waves and whatever the major shock, the effect of each alone as a function of time may be computed. Then, these deflections can be simply superimposed to give the actual deflection due to the combination. In any

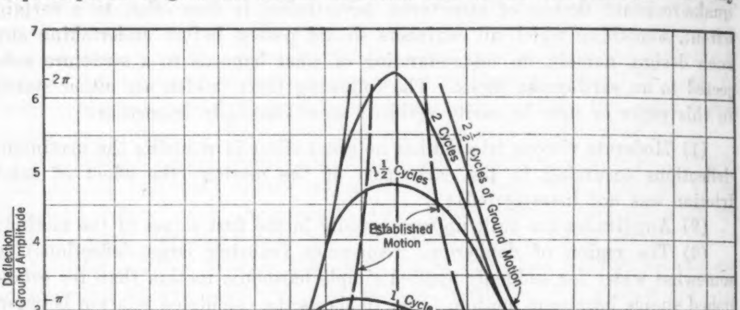

FIG. 10.—MAXIMUM DEFLECTIONS OF A SYSTEM OF ONE DEGREE OF FREEDOM, SUBJECTED TO SUDDENLY APPLIED SIMPLE HARMONIC DISPLACEMENTS AND DEFLECTIONS OCCURRING IN THE CASE OF ESTABLISHED SIMPLE HARMONIC MOTION.

case the preliminary waves (ceasing at the beginning of the major shock) will cause an oscillation of frequency, F_2, and of amplitude, D_0, the latter (in the notation of the paper) being expressed as:

$$D_0 = \sqrt{Y^2{}_0 + \left(\frac{V_0}{F_2}\right)^2} \ldots\ldots\ldots\ldots\ldots\ldots(9)$$

This oscillation can increase or decrease the maximum amplitudes which would result from the major shock alone by amounts not greater than D_0. What the effect will be, will depend on the phase difference between maxima of the motion due to the preliminary shock and those due to the major shock.

L. S. JACOBSEN,[13] ESQ. (by letter).—If a vibrating system with one degree of freedom experiences a transitory ground motion of constant period, but of variable amplitude, the dynamic distortions depend mainly on the ratio of the period of the ground to the one of the system. This fact has been demonstrated conclusively by Professor Williams. The paper shows by model experiments that for the case of near resonance large dynamic distortions of the system are produced even by a few oscillations of the ground.

[13] Prof. of Mech. Eng., Stanford Univ., Stanford University, Calif.

The primary object of this discussion is to emphasize the absolute necessity of considering the dynamic properties of structures if a rational understanding of the problem of earthquake resistant design is to be evolved in the future. The secondary object of the discussion is to supply information concerning the dynamic distortions of a multiple-mass system as exemplified by a model of a 17-story building.

It is true that, at present, very few engineers can afford to make searching studies of the dynamic properties of the structures they design. Time limitations demand that so-called "rules of thumb" must be used for assuming the magnitudes of the dynamic loads. Because of this insufficient and imperfect knowledge of ground motions that occur during earthquakes, it is obvious that designers are not justified in making any specific assumptions in regard to the periods, durations, and intensities of the composite motions. Perhaps definite probable periods exist in particular localities, or perhaps the entire question of probable ground motions is so vague that no one can afford to risk making assumptions concerning the specific motions. Whatever their attitudes are toward the ground-motion question, they are forced to admit that forward and backward, as well as up and down, motions occur. This fact alone means that dynamic loadings varying with time must be sustained by the structures.

Professor Williams attempts to show the effects of a few specific ground motions in a horizontal direction on a single mass structure. It is of importance to note that the ground motion must be specific; otherwise, an elementary analysis is impossible. Moreover, if the ground motion were not specific and simple, it would not be feasible to extend and interpret the analysis by principles of superposition to more complicated types of ground motions. It is true, however, that when the results of the simple system and simple ground motion are applied to actual problems, the quantitative aspect of the analysis is lost and only the qualitative remains. It is precisely here that engineering judgment is necessary.

How is sound engineering judgment concerning seismic loadings to be formed? Naturally, one must admit that actual field evidence has given, and still gives, the first and indisputable clue as to what "stands up" and what "falls down", or what is seriously damaged. Under no circumstances can one afford to minimize the value of the expensive lessons given by "Nature's own laboratory." It is well known, however, that a group of engineers visiting the stricken region after an earthquake can, and does, find abundant evidence for supporting many different individual points of view. This is especially so if the damage is considerable so that the wreckage is largely in the form of heaps of bricks, concrete, tiles, and steel. Too many observers of earthquake damage lack something which is of extreme importance for the formation of sound engineering judgment, namely, a "pattern of characteristic behavior" of simple systems subjected to simple, although perhaps improbable, types of ground motion. Before it is possible to estimate how a complicated phenomenon has occurred one must have not only a pic-

ture, but also a quantitative picture of the simple phenomenon. Professor Williams has attempted to give such a "pattern of behavior", for which he deserves credit.

Since the customary practice of engineers is to design structures to resist fictitious, horizontal, static loadings expressed in percentages of the static, vertical loads, or in terms of horizontal, constant accelerations of the ground, it has occurred to the writer that a slight re-arrangement of the author's results may show more clearly the relation of the truly dynamic loadings to the fictitious, static loadings. It must be remembered that, in Professor Williams' experiments, the dynamic loadings have been inferred from the actually observed dynamic distortions; they are real loads, and, therefore, can not be explained away by the all too frequently heard remarks that such dynamic loads will not have time to become real loads and have the same effect as static loads.

Results obtained from Fig. 3 of the paper have been re-arranged as shown in Table 1, with the following supporting data:

(1) The properties of the model are: Weight, 25.5 lb; spring factors, 17.3, 9.2, and 7.1 lb per in.; friction factors, 0.05, 0.10, and 0.15 lb per in. per sec; and free vibration periods, 0.390, 0.534, and 0.611 sec.

(2) For ground motion, or shaking-table motion: The period is 0.505 sec; the duration of motion is about 5.5 sec; the maximum impact acceleration is about 14% of gravity; the maximum harmonic acceleration is about 8.5% of gravity; the maximum displacement is about 0.25 in.; and, the constant friction reduces the amplitude of the table by approximately 0.022 in. per cycle.

TABLE 1.—RE-ARRANGEMENT OF RESULTS OBTAINED FROM FIG. 3 OF THE PAPER

	BELOW RESONANCE			NEAR RESONANCE			ABOVE RESONANCE		
Ratio of model period to ground period	0.77			1.06			1.21		
Ratio of consecutive, free, damped amplitudes of model corresponding to the three values of damping used by Professor Williams	1.16	1.34	1.55	1.22	1.49	1.83	1.26	1.58	1.99
Ratio of maximum dynamic force on model to weight of model	0.38	0.30	0.27	0.58	0.41	0.29	0.24	0.20	0.17
Number of cycles of ground motion when the maximum dynamic force occurs	1.8	1.7	1.6	5.1	4.3	3.9	2.8	2.6	2.4
Ratio of maximum dynamic force to a constant fictitious force of same value as the maximum harmonic acceleration of the ground, 0.085 g times mass of the model	4.5	3.5	3.2	6.8	4.8	3.4	2.8	2.4	2.0

For the three cases investigated Table 1 shows that the ratios of the maximum dynamic forces, acting on the model as a result of the motion of the ground, are greatly in excess of the fictitious static forces which are equal to the mass of the model times the maximum, harmonic acceleration of 8.5% of gravity. In other words, the inherent vibrational properties of the model for the three cases are such that, with the minimum friction used, a

force of 4.5 times the fictitious, static force results for the first case, or the "below resonance" case, whereas a force of 6.8 times the fictitious, static force is experienced by the model in the second or "near resonance" case; and, finally, a force of 2.8 times the fictitious, static force is in action for the third or "above resonance" case. If one notes that the number of cycles of ground motion necessary to establish the distortions corresponding to the foregoing dynamic forces are 1.8, 5.1, and 2.8, respectively, one is forced to conclude that the first case (or the "below resonance" case) assumes a sinister aspect since in an actual earthquake the probability of encountering a constant periodic motion lasting for 1.8 cycles is quite high. For the three cases, with the maximum friction used, the force ratios are 3.2, 3.4, and 2.0, whereas the numbers of cycles necessary for producing the distortions corresponding to the forces are 1.6, 3.9, and 2.4.

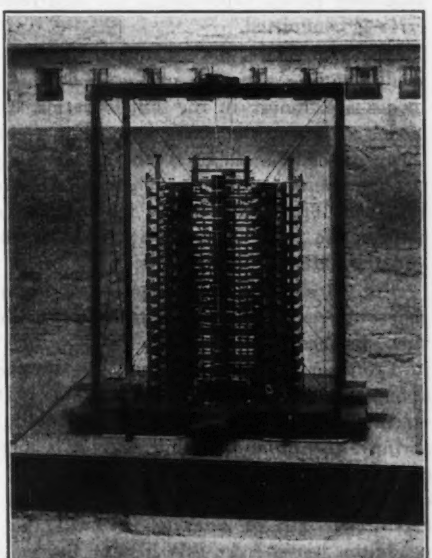

FIG. 11.—MODEL OF 17-STORY BUILDING.

Furthermore, in this case, the "below resonance" condition seems to be rather dangerous.

The first three columns of Table 2 give information concerning the mass and elastic shear properties of the 17-story model shown in Fig. 11. The model, built in 1931, was tested in 1932–33. Since the construction of this model allows only distortions due to shear and neglects those due to

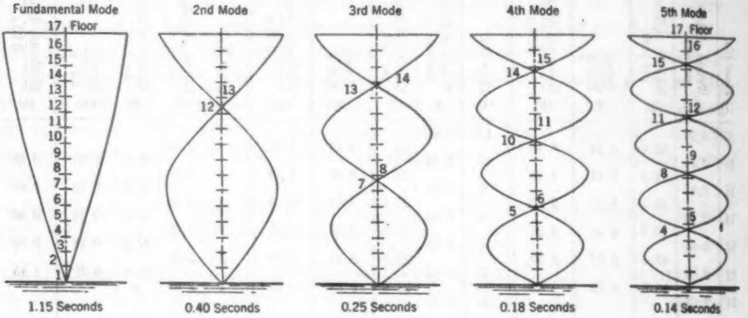

FIG. 12.

flexure of the building as a whole, the experiments have never been published before. It can be shown, however, that in the case of a rather stubby building, flexure of the building as a whole may be neglected, so that if the following model experiments are restricted to stubby buildings no serious error is committed.

Fig. 12 shows the calculated displacement diagrams of the first five modes of free vibration of the model. The free vibration periods of these modes are almost in the simple ratios, 3, 5, 7, and 9, corresponding to a model with constant mass and shear rigidity distribution. The maximum shear distortions occur at the nodal points. Thus, for the second mode, the maximum shears occur between the 1st and 2d floor and between the 12th and 13th floor, whereas for the fifth mode, the maximum shears occur between the 1st and 2d, the 4th and 5th, the 7th and 8th, the 11th and 12th, and the 14th and 15th floors.

Fig. 13 shows sixteen time records of the dynamic forces acting between the seventeen floors of the model when the ground motion is given by the time displacement records below it. The ground motion is generated, as in Professor Williams' experiments, by the impact of a pendulum against a bumper spring on the shaking-table. During the impact interval (that is, the time during which the pendulum is in contact with the bumper spring), the ground motion may be thought of as being composed of two component motions, the primary motion of 0.15-sec period, lasting for about one-half cycle and the secondary motion of 0.46-sec period, lasting for about one-sixth of a cycle, or until the instant when contact with the pendulum ceases. At this instant the motion of the shaking-table becomes a free, damped vibration with a period of 0.47 sec, and this motion lasts

for several cycles until friction in the shaking-table makes it cease. Nearly all the sixteen records in Fig. 13 give evidence of the existence of the two ground periods, 0.15, and 0.47 sec, in the dynamic force fluctuations.

The reasons for the pronounced effects are that the natural period of 0.14 sec of the model's fifth mode of vibration is in "near resonance" with the period of 0.15 sec of the primary impact motion of the shaking-table. In spite of the fact that this ground motion exists for only one-half cycle, its effect is observable throughout the records. Moreover, the secondary ground motion of 0.46-sec period, or the free vibration ground motion of 0.47-sec period, is also in "near resonance" with the model's second mode period of 0.40 sec. The effect of this "near resonance" is a building up of the dynamic forces with time, especially at the nodal points; that is, between the 1st and 2d, and between the 12th and 13th floors. Almost no dynamic forces of this period occur at the anti-nodal point between the 7th and 9th floors.

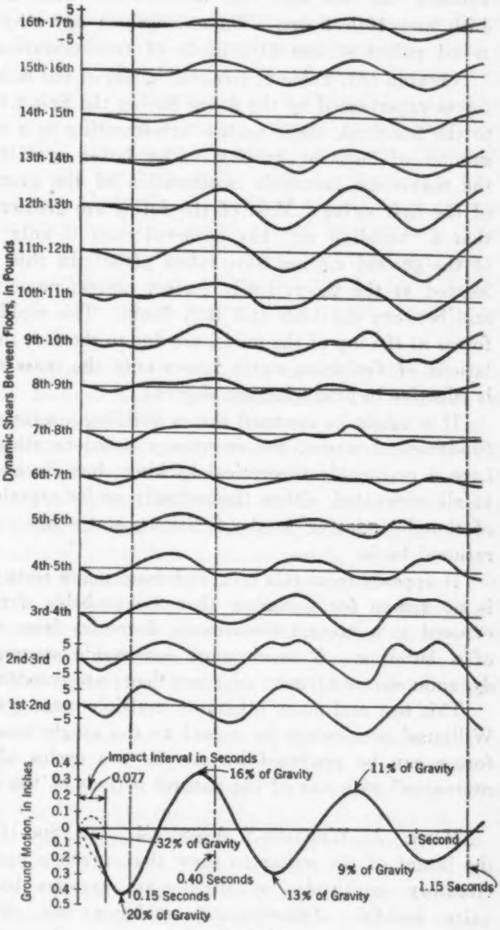

FIG. 13.

Columns (4) and (5), Table 2, give the measured, dynamic, maximum forces between adjacent floors divided by the fictitious, static forces corresponding to an assumed constant acceleration of the model. Column (4) relates to the maximum loads experienced by the floors during the first 0.15 sec of the ground motion. They are compared to the fictitious, static loads corresponding to a constant ground acceleration, equal to the maximum impact acceleration of 32% of gravity.

These ratios are all less than unity, signifying that the full effects of such a rapid ground motion are not established in the model. It should be noted, however, that the effects are maxima between the 3d and 4th, between the 7th and 8th, between the 11th and 12th, and between the 15th and 16th floors. These locations agree very well with those of the nodal points of the fifth mode of free vibration of the model.

Column (5), Table 2, gives the ratios of the maximum, "built-up", dynamic forces experienced by the floors during the first 1.15 sec of the ground motion to the fictitious, static forces corresponding to a constant acceleration of the ground of 20% of gravity. The latter gravity acceleration is equal to the maximum harmonic acceleration of the ground occurring at the peak of the first swing. Most of the ratios are greater than unity for the reason that a "building up" has occurred even if only about two complete cycles of the ground motion have taken place. In this case, also, the maxima are located at the theoretically correct places, namely, between the 1st and 2d and between the 12th and 13th floors. The rapidly increasing ratios of the forces at the top of the model are due to the fact that for the customary calculations of fictitious, static forces only the mass of the model above a floor is effective in producing the shears.

If it might be assumed that a building always were to vibrate solely in its fundamental modes, the customary fictitious static force calculations would have a reasonably theoretical backing; but since such an assumption is not at all warranted, either theoretically or by experience, the customary "rules of thumb" relating to the fictitious, static force assumptions are without a rational basis.

It appears from this test, and from many tests yet unpublished, that there is no reason for assuming that the probable dynamic shear in a building exposed to a ground disturbance decreases from the top toward the bottom of a building. A much more reasonable assumption is that the probable dynamic shears between adjacent floors are constant throughout the building.

This test and many others on multiple-mass systems corroborate Professor Williams' conclusions in regard to the single mass system. Large dynamic forces can be produced by one or two cycles of ground motion in "near resonance" with one of the natural periods of the multiple-mass system.

Harry A. Williams,[14] Assoc. M. Am. Soc. C. E. (by letter).—It was the intent of the writer to show that, given a near resonance condition, the vibratory amplitudes of single-mass systems build up to critical values quite rapidly. Experimental evidence was offered in support of the mathematical theory. The theory was then simplified and applied to an elevated water tank. This was not done with the idea that all future elevated tanks or other single-mass structures should be designed only in accordance with the simplified equation presented by the writer. It was offered rather as another approach by which an engineer might check his designs and guide his judgment.

[14] Asst. Prof. of Civ. Eng., Stanford Univ., Stanford University, Calif.

Discussions were presented by Messrs. Ruge, Engle, White, and Jacobsen. Professor Ruge further substantiated the writer's contentions. His comments on the writer's conclusion regarding the desirability of designing a structure with a period different from that of an expected earthquake are well taken. The writer's original statement was made with the hope that in the distant future the type of local ground motions might be reasonably predictable. Only a study of the records of many future earthquakes will answer this question. Meanwhile, it is doubtful whether an elevated water-tank structure can be designed along conventional lines and not be in resonance with any dangerous ground motions. Designing the structure so that the elastic constant varies with the amplitude might be a solution to the problem. Certainly the method of adding more steel to stiffen the structure is open to the criticism offered by Professor Ruge.

Mr. Engle presents the so-called "static" point of view and in so doing raises a number of questions with which the writer finds himself in disagreement. A few of these are as follows (the quotations are from Mr. Engle's discussion):

(1) "There has been a tendency on the part of those interested in shaking-table experiments and so-called 'dynamic design' to consider the behavior of these structures [elevated water tanks] as somewhat of a mystery, requiring complicated model study and theoretical experimentation." Knowing that the behavior of a vibrating structure cannot be explained by the static method, those interested in the dynamic viewpoint are inclined to approach such a problem with some humility and study the reactions of a structure to simplified motions rather than attempt to explain its actual behavior during an earthquake by reasoning *a priori* from theories having very little, if anything, to do with the problem. Mr. Engle states, furthermore, that "there is no particular mystery involved" in the behavior of these structures, and that "a reasonable explanation of the damage can be made." Yet he asserts in a later paragraph that the problem is extremely complicated.

(2) To quote further: "At present there is no definite proof that the static method of analysis involves any more assumptions or uncertainties than the so-called dynamic method." Obviously, it is necessary to make assumptions in applying the dynamic method to practical problems. The writer made a number of these assumptions in his paper when he investigated the behavior of the elevated water tank. He also showed how there could be considerable variation in many of the assumed conditions and yet the results would remain fairly indicative of the probable behavior of the structure during a short interval of an earthquake; and he warned the reader against drawing quantitative conclusions from such an investigation. In the static method, a fictitious force is applied to the center of gravity of the structure, this force being made equal to the mass of the structure times an arbitrarily assumed acceleration. Only by sheer coincidence, as emphasized in Professor Jacobsen's discussion, will it give stresses which are indicative of the actual stresses which might be

expected. It would be just as logical a procedure to design the tank structure for a 200-mile wind. In doing this, one would be candidly admitting that he is merely applying an empirical formula to his problem. The writer, of course, is not advocating that the wind-force method be substituted for the static method. The latter is at least a step in the right direction, and it is making designers "mass conscious."

(3) "A static analysis of damaged towers shows that they should have failed where failure occurred." No doubt this was true, yet it does not justify the static method, because this method only divulges the weak points in the structure. If a collapsed tower is replaced with a structure which is identical except that the weaker points are strengthened, another earthquake of no greater intensity than the first may easily wreck the new tower.

The structural engineer has always been trained to design for strength. If a structure failed because of the weakness of a particular member, that member was strengthened in the new structure. The mechanical engineer designed in the same way until he was confronted with the development of high-speed machinery. He then discovered that it was sometimes better—as in De Laval's steam turbines and cream separators—to make a shaft more flexible rather than stronger and stiffer in order to avoid resonance and large vibrations at operating speeds. It is true that in some cases an equally acceptable result could have been attained by using a heavier shaft, but this would have required very accurate workmanship and, consequently, would have materially increased the cost of the machine. In the same manner, certain structures can be made quite safe if they are stiffened sufficiently, but this is economical and practicable only in certain cases.

(4) During the Long Beach earthquake, the top panel rods in many tank structures were badly stretched or entirely broken. The writer suggested that possibly many of these failures occurred soon after the beginning of the major shock, because of a near-resonance condition. Mr. Engle strongly disagreed with this contention, mainly because such action was "not consistent with the failure of steel tension members" since "stretching takes place first and it takes an appreciable time to jerk the rods apart." The elementary theory of dynamics and strength of materials should make it apparent that the dynamic forces take time to stretch the rods of such a structure. The length of time taken depends on the velocity of the mass center of the structure at the instant the elastic limit is reached in the top panel rods. As soon as this critical deflection is reached the tower becomes a structure with radically different dynamic and elastic properties. It may not return to its original position for several seconds. It seems to verge on the miraculous that "the cessation of the shock was all that saved many towers [with badly stretched or broken rods] from collapse"—not to mention the chimney of the Seal Beach Power Plant with broken diagonals in its supporting steel structure. It appears improbable to the writer that each tower was sub-

jected to a motion which stretched or broke its top panel rods and then stopped just in time to prevent collapse. In evaluating the effect of slack rods picking up their loads with a "jerk," it should be remembered that a flexible tower may not necessarily have very high velocities engendered by the ground motion. Moreover, the nature of the "jerk" is in reality a gradually applied elastic force.

There are a number of other points presented by Mr. Engle that could be discussed. It is agreed that the behavior of elevated tanks in recent earthquakes has been surprisingly good. Only further study and earthquake experience, combined with a rational dynamic point of view, will divulge how much present design can be improved.

The writer does not believe that the dangers from resonance or near resonance have been exaggerated. Chaotic motion does alleviate some of the danger, but evidence is reasonably conclusive that large distortions do build up rapidly, at least for single-mass systems, and records show that the ground does follow a more or less regular motion for a few cycles at a time. Shaking-table experiments made at Leland Stanford University and at the Massachusetts Institute of Technology leave little doubt but that a vessel and a part of the liquid it contains act as a single-mass system for a few cycles. Wave action, although having some "cushioning effect" at once, is most noticeable later. Mr. Engle's remarks concerning resonance apply if one is thinking of the general behavior of the elevated-tank structure throughout the major part of a shock. They do not detract from the writer's contentions.

Mr. White's emphasis and elaboration of certain points of the paper are interesting. It is important to note, as he indicates, that the region of dangerous frequencies is somewhat wider in the case of suddenly applied motion. This point further emphasizes the difficulty of avoiding near resonance by making only nominal changes in a single-mass system subject to earth shock.

The writer is very much indebted to Professor Jacobsen, not only for his comments on the paper, but also for the addition of a very desirable discussion pertaining to buildings. The last line of Table 1 shows how much in error one might be if he were guided entirely by the static method. As Professor Jacobsen points out, the dynamic forces involved for the "below resonance" condition are of a large order, and they occur very shortly after the beginning of the ground motion. In comparing the "below resonance" and "near resonance" results, the reader may be interested in the data as it is arranged in Table 3 for the tests involving the least friction only. These results show that relatively large dynamic forces are set up also for the "near resonance" condition during the first few cycles even if the maximum does not occur for some time. It will be noted that the dynamic force equals 38% of the weight of the model at the end of 1.8 ground-motion cycles in the case of "below resonance" whereas it reaches 27% in approximately the same time for the "near resonance" model. If the models represented two conventionally

designed structures, there would be a question, depending on the design, as to which structure was being subjected to the more critical unit stresses. The rigidity of one structure may be double that of another whereas its critical strength is only slightly greater. In other cases, the more rigid structure may be very much stronger.

TABLE 3.—DATA OBTAINED FROM FIGS. 2 AND 3

	Below Resonance		Near Resonance		Above Resonance	
(a) Ratio of model period to ground period	0.77		1.06		1.21	
(b) Relative values of elastic constants	2.4		1.3		1.0	
(c) Number of cycles of ground motion when the dynamic force occurs	1.1	1.8	1.9	2.4	1.5	2.0
(d) Ratio of dynamic force on model to weight of model	0.31	0.38	0.27	0.40	0.19	0.23
(e) Ratio of dynamic force to a constant fictitious force based on maximum harmonic acceleration of the ground, 0.085 g times mass of the model	3.7	4.5	3.2	4.7	2.3	2.7

The results of experiments with a 17-story building model, which Professor Jacobsen presented as a part of his discussion, further emphasize the effects of resonance, these effects becoming quite important in one or two cycles of ground motion.

It is agreed, as Mr. Engle stated, that "actual disaster experience where properly interpreted is a fairly good foundation for basing future practice." The proper interpretation of the results of "Nature's shaking-table experiments" is of the utmost importance. Although it is entirely possible that at some future time those interested in the dynamic approach will conclude that there are too many variables in most practical problems to justify the use of mathematical expressions based on the more exact dynamic theory and that an empirical approach similar to the existing static method must be resorted to, that time has not yet arrived. When and if it does arrive, those applying the empirical method will find that a familiarity with the behavior of structures when subjected to very simple motions will be an invaluable aid.

ANALYSIS OF VIERENDEEL TRUSSES

By Dana Young,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. L. J. Mensch, A. A. Eremin, Leon Blog, A. W. Fischer, L. C. Maugh, John E. Goldberg, Louis Baes, E. C. Ingalls and Ralph B. Peck, Harold E. Wessman, A. Floris, Kimball R. Garland, J. D. Gedo, and Dana Young.

Synopsis

A Vierendeel or quadrangular truss is a hyperstatic frame composed of a series of rectangular or trapezoidal panels without diagonal members. The end connections of all members are rigid and designed to take moment.

Although it is possible to analyze such trusses by any of the so-called "exact" methods, the labor involved is prohibitive in all except the simplest cases. The purpose of this paper is to present a practical and accurate method of determining the stresses in the Vierendeel type of trusses. This method is based upon the theory of virtual work and involves a re-arrangement of the standard equations to produce a workable solution.

The interesting questions of design, economics, and field of usefulness of such trusses are not considered, the scope of this paper being limited to stress analysis.

Historical

Vierendeel trusses have been used for bridges in Europe, chiefly in Belgium, since 1896. The first bridge of this type was built at Tervueren, Belgium, by Professor Arthur Vierendeel, of the University of Louvain. Professor Virendeel is the originator of this form of truss and has been its main sponsor. To date (1936), approximately one hundred bridges of this type have been built. The longest has a span of 274 ft and carries a double-track railway. Both steel and reinforced concrete have been used and, since 1932,

Note.—Published in August, 1936, *Proceedings*.

[1] Asst. Prof. of Eng., Connecticut State Coll., Storrs, Conn.

several arc-welded steel trusses of this type have been built, including the trusses for a swing bridge.[2]

In addition, various other structures using this system have been constructed. Eight wireless towers, each 960 ft high and only 13 ft square in plan, with bracing of the Vierendeel type, have been built in Belgium. Towers for elevated water tanks have been similarly braced.

In the United States, Vierendeel trusses have not been used for bridges, but a number of other structures have been built with this system of bracing. The towers of the old Kinzua Viaduct of the Erie Railroad Company were of that form.[3] Various reinforced concrete viaduct bents have been built utilizing this construction. The towers of the Waldo-Hancock Suspension Bridge in Maine are braced transversely as Vierendeel trusses.[4] A modified form of Vierendeel truss was used for the foundation of the Telephone Building[5], at Albany, N. Y.

Introduction to Stress Analysis

In the general type of Vierendeel truss, with n panels and $(n + 1)$ web members, there are $3\,(n + 1)$ unknowns. It is necessary to obtain an equal number of equations to solve the problem. The equations of statics furnish three relations and the remainder are found from the elastic properties of the truss.

Any of the standard methods of elastic analysis may be used. In books on structural theory methods of solution will be found for a few limited cases, using the principles of least work[6], virtual work[7], slope deflection[7], and moment distribution.[8] However, in all except the simplest cases, the application of these methods is laborious.

The aim of the writer is to describe a method of analysis which is less laborious to apply. It is based upon the principles of virtual work and consists in re-arranging the fundamental equations, and the order of their solution. For trusses with chords that are symmetrical about a longitudinal axis (such as parallel chord trusses and viaduct bents), the solution is exact; that is, it involves no assumptions except those that are inherent in the elastic theory. For other trusses it is necessary to make use of certain simplifying assumptions. In most cases the relative error thus introduced is negligible.

E., John Wiley & Sons, New York, pp. 236–238; also, see, "A Rapid and Concise Method of Analyzing Rigid Viaduct Bents", by L. C. Maugh, Assoc. M. Am. Soc. C. E., *Engineering News-Record*, March 14, 1935, p. 379.

The first part of the analysis follows, in general outline, the method developed by Professor Vierendeel.[9] However, in order to obtain greater accuracy, this analysis does not involve all the simplifying assumptions that Professor Vierendeel uses. As a result, the detailed treatment and final formulas are different.

Notation.—The letter symbols in this paper are introduced in the text as they occur and are summarized for reference in Appendix I. An effort has been made to conform essentially with "Symbols for Mechanics, Structural Engineering and Testing Materials"[10], compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932.

Analysis of Trusses with Symmetrical Chords

By a truss with symmetrical chords is meant one in which the chords are symmetrical about a longitudinal axis, with the corresponding chord members having equal moments of inertia. This class includes parallel-chord trusses and viaduct bents with inclined posts.

For the present, deformations due to axial stress will be neglected. Subsequently, the analysis will be extended to include this effect. Fig. 1 represents

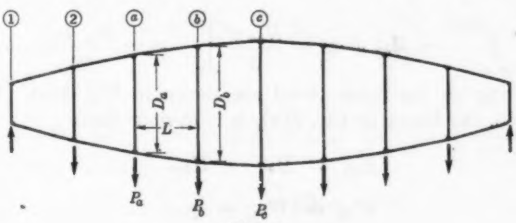

FIG. 1.

a general form of such a truss. From the symmetry of the truss, it is seen that the bending moments and shears in the upper and lower chords will be equal. It also follows that the point of contraflexure of each vertical member will be at its mid-height.

FIG. 2.

[9] "Cours de Stabilité des Construction", Tome IV, by Arthur Vierendeel, Louvain, 1920, and succeeding editions. This text contains Professor Vierendeel's approximate method of solution and a bibliography on the subject. The references in the bibliography are mainly to European publications, few of which are available to engineers in the United States.

[10] A. S. A.—Z10a—1932.

Consider a typical panel, ab, removed from the truss and cut into two parts by a horizontal plane through the centers of the vertical members. Let Δ_x = horizontal deflection; L_t = the length of an inclined chord member; H_w = transverse shear in a web member; H_{ab} = horizontal component of axial stress in Chord Member a-b; D_a = depth of truss at Panel Point a, etc.; V'_{ab} = vertical shear in the upper chord between Panel Points a and b, etc.; M''_{bc} = bending moment at Point b in the lower chord member, b-c (that is, the member extending between Panel Points b and c), etc. The forces acting on the upper part are shown in Fig. 2(a). For this section the horizontal displacement of Point B with respect to Point A is:

$$E\,\Delta_x = \int \frac{M\,y}{I}\,ds = \frac{1}{I_b}\int_0^{0.5D_b} H_{bw}\,y^2\,dy + \frac{1}{I_C}\int_0^{L_t}\left[H_{bw}\left(\frac{D_b}{2} - y\right) - M'_{bc}\right.$$
$$\left. - (V'_{bc} + q_{bw})\,x + H_{bc}\,y\right]\left(\frac{D_b}{2} - y\right)dL_t + \frac{1}{I_a}\int_0^{0.5D_a} - H_{aw}\,y^2\,dy \;\ldots(1)$$

The values of the first and third integrals of Equation (1) are:

$$\int_0^{0.5D_b} H_{bw}\,y^2\,dy = \frac{H_{bw}\,y^3}{3}\Big]_0^{0.5D_b} = \frac{H_{bw}\,D_b^3}{24} \;\ldots\ldots\ldots\ldots(2a)$$

and,

$$\int_0^{0.5D_a} - H_{aw}\,y^2\,dy = \frac{H_{aw}\,y^3}{3}\Big]_0^{0.5D_a} = -\frac{H_{aw}\,D_a^3}{24} \;\ldots\ldots\ldots(2b)$$

The forces acting on the upper chord are shown in Fig. 2(b). Comparing these forces with the forces in Fig. 2(a), it is obvious that:

$$H_{ab} = H_{bc} - H_{bw} \ldots\ldots\ldots\ldots\ldots\ldots\ldots(3a)$$

$$V'_{ab} = V'_{bc} + q_{bw} \ldots\ldots\ldots\ldots\ldots\ldots\ldots(3b)$$

and,

$$M'_{ba} = \frac{H_{bw}\,D_b}{2} - M'_{bc} \ldots\ldots\ldots\ldots\ldots\ldots\ldots(3c)$$

Substitute Equations (3) in the second integral of Equation (1) and perform the integration. In the resulting expression substitute $d = \frac{1}{2}(D_b - D_a)$ and $H_{ab} = \sum_1^a H_w$, and this integral finally becomes:

$$\int_0^{L_t} (M'_{ba} - V'_{ab}\,x + H_{ab}\,y)\left(\frac{D_b}{2} - y\right)dL_t = \frac{M'_{ba}\,L_t}{4}\,(D_b + D_a)$$
$$- V'_{ab}\,\frac{L_t L}{12}\,(D_b + 2\,D_a) + \frac{L_t}{24}\,(D_b^2 + D_b\,D_a - 2\,D_a^2)\sum_1^a H_w \ldots(4)$$

The integral values in Equations (2a), (2b), and (4) substituted in Equation (1), give Equation (5) directly, as follows:

$$E\,\Delta_x = \frac{D_b^3\,H_{bw}}{24\,I_b} - \frac{D_a^3\,H_{aw}}{24\,I_a} + \frac{L_t\,M'_{ba}}{4\,I_C}\,(D_a + D_b) - \frac{L_t\,L\,V'_{ab}}{12\,I_C}\,(D_b + 2\,D_a)$$
$$+ \frac{L_t}{24\,I_C}\,(D_b^2 + D_b\,D_a - 2\,D_a^2)\sum_1^a H_w \;\ldots\ldots\ldots\ldots(5)$$

From symmetry, it is seen that $\Delta_x = 0$. Now, consider that part of the entire truss which is to the left of Panel Point b, as shown in Fig. 2(c). Taking moments about Panel Point b:

$$M_b - M'_{ba} - M''_{ba} - H_{ab} D_b = 0 \qquad (6)$$

and, since $M'_{ba} = M''_{ba}$ and $H_{ab} = \sum_1^a H_w$, Equation (6) becomes:

$$M'_{ba} = \frac{1}{2} M_b - \frac{1}{2} D_b \sum_1^a H_w \qquad (7)$$

It is obvious that:

$$V'_{ab} + V''_{ab} = 2\, V'_{ab} = V_{ab} \qquad (8)$$

Substituting these values for M'_{ba} and V'_{ab} in Equation (5) and collecting terms:

$$E\,\Delta_x = 0 = \frac{D^3_b\, H_{bw}}{24\, I_b} - \frac{D^3_a\, H_{aw}}{24\, I_a} + \frac{L_1 M_b}{8\, I_C} (D_a + D_b) - \frac{L_1 L\, V_{ab}}{24\, I_C} (D_b + 2\, D_a)$$

$$- \frac{L_1}{12\, I_C} (D^2_b + D_b D_a + D^2_a) \sum_1^a H_w \qquad (9)$$

Solving for H_{bw}:

$$H_{bw} = \frac{D^3_a I_b H_{aw}}{D^3_b I_a} + \frac{2 L_1 I_b}{D^3_b I_C} (D^2_b + D_b D_a + D^2_a) \sum_1^a H_w - \frac{3 L_1 I_b M_b}{D^3_b I_C} (D_a + D_b)$$

$$+ \frac{L_1 L\, I_b V_{ab}}{D^3_b I_C} (D_b + 2\, D_a) \qquad (10)$$

For parallel chords and constant, I, Equation (10) reduces to:

$$H_{bw} = H_{aw} + 6\, \frac{L}{D} \sum_1^a H_w - \frac{6\, L}{D^2} M_b + \frac{3\, L^2}{D^2} V_{ab} \qquad (11)$$

Equation (10) is the general equation for trusses with symmetrical chords. All the coefficients involved are constants which depend only on the dimensions of the truss. Hence, Equation (10) is really of the simple form:

$$H_{bw} = C_1 H_{aw} + C_2 \sum_1^a H_w + C_3 M_b + C_4 V_{ab} \qquad (12)$$

and since M_b and V_{ab} are constants which depend on the external loads, Equation (12) may be expressed in the simpler form:

$$H_{bw} = C_1 H_{aw} + C_2 \sum_1^a H_w + C_5 \qquad (13)$$

An expression of the form of Equation (13) may be written for each panel in the truss. Then, by successive substitutions, each value of H_w may be expressed in terms of the shear, H_{1w}, for the first vertical. Since the sum

of all the H_w-values is equal to zero, it is a simple matter to solve for the value of H_{1w} and thence for the other values of H_w. The following two examples illustrate this method of solution.

Example 1.—Parallel Chord Truss.—Consider a four-panel, parallel chord truss with a height of 10 ft and a span of 40 ft, carrying 1 000 lb at each panel point, as shown in Fig. 3. The moment of inertia of all members is assumed

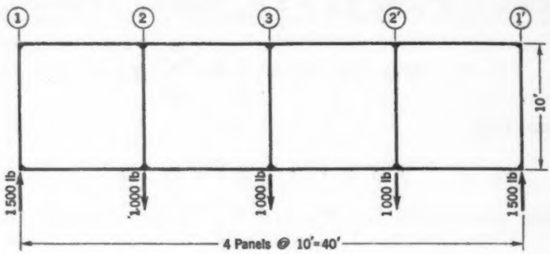

Fig. 3.

to be the same. Substituting numerical values for this particular case in Equation (11):

$$H_{bw} = H_{aw} + 6 \sum_{1}^{a} H_w - 0.6\, M_b + 3\, V_{ab} \qquad (14)$$

It should be noted that Equation (14) remains the same for any loading, since the coefficients depend only on the truss dimensions. The values for M_b and V_{ab} for this particular loading are, respectively: $M_2 = 15\,000$ ft-lb; $M_3 = 20\,000$ ft-lb; $V_{12} = 1\,500$ lb; and $V_{23} = 500$ lb. Substituting these values in Equation (14):

$$H_{1w} = H_{1w} \qquad (15a)$$

$$H_{2w} = H_{1w} + 6\, H_{1w} - 9\,000 + 4\,500 = 7\, H_{1w} - 4\,500 \qquad (15b)$$

and,

$$H_{3w} = H_{2w} + 6\,(H_{1w} + H_{2w}) - 12\,000 + 1\,500 \qquad (15c)$$

Substituting Equation (15b) in Equation (15c):

$$H_{3w} = 55\, H_{1w} - 42\,000 \qquad (16)$$

From the symmetry of the loading in this particular case, it is obvious that $H_{3w} = 0$; hence:

$$H_{3w} = 55\, H_{1w} - 42\,000 = 0 \qquad (17)$$

Solving for H_{1w}: $H_{1w} = \dfrac{42\,000}{55} = 763.6$ lb, and, thence, $H_{2w} = 7\,(763.6) - 4\,500 = 845$ lb.

Example 2.—Viaduct Bent.—As a second example, a bent of the Kinzua Viaduct will be studied. This particular structure has been analyzed by Mr. C. R. Grimm[9], using the method of least work, and by Messrs Johnson, Bryan, and Turneaure[11], using the general method of virtual work. Their solutions afford a check on the method presented herein.

FIG. 4.

Fig. 4 shows the dimensions of the bent and the lateral loads to be considered. The bases of the posts are assumed to be fixed. This is equivalent to assuming that the shear, H_{6w}, in the bottom strut is zero. Equation (10) applies in this problem. Evaluating the coefficients in this equation by substituting the numerical values of the truss dimensions, the following series of equations is obtained from Equation (10):

$$H_{1w} = H_{1w} \qquad (18a)$$

$$H_{2w} = 0.00557\, H_{1w} + 2.77\, H_{1w} - 0.1810\, M_2 + 2.50\, V_{12} \qquad (18b)$$

$$H_{3w} = 0.358\, H_{2w} + 8.30\, (H_{1w} + H_{2w}) - 0.264\, M_3 + 7.26\, V_{23} \qquad (18c)$$

$$H_{4w} = 0.565\, H_{3w} + 13.02\, (H_{1w} + H_{2w} + H_{3w}) - 0.252\, M_4 + 7.29\, V_{34} \qquad (18d)$$

$$H_{5w} = 0.565\, H_{4w} + 12.52\, (H_{1w} + H_{2w} + H_{3w} + H_{4w}) - 0.1745\, M_5 + 5.14\, V_{45} \qquad (18e)$$

and,

$$H_{6w} = 0 = 1.043\, H_{5w} + 21.0\, (H_{1w} + H_{2w} + H_{3w} + H_{4w} + H_{5w}) - 0.227\, M_6 + 6.60\, V_{56} \qquad (18f)$$

Equations (18) are true for any loading. For the loading in Example 2, M_b and V_{ab} have the following values: M_2 = 835 000 ft-lb; M_3 = 2 798 000; M_4 = 5 128 000; M_5 = 7 830 000; M_6 = 10 825 000; V_{12} = 26 800 lb; V_{23} = 31 600; V_{34} = 37 600; V_{45} = 43 600; and V_{56} = 49 600. Substituting these numerical values in Equations (18):

$$H_{1w} = H_{1w} \qquad (19a)$$

$$H_{2w} = 0.00557\, H_{1w} + 2.77\, H_{1w} - 84\,100 \qquad (19b)$$

$$H_{3w} = 0.358\, H_{2w} + 8.30\, (H_{1w} + H_{2w}) - 509\,000 \qquad (19c)$$

[11] "Modern Framed Structures", Pt. II, by J. B. Johnson, C. W. Bryan, and F. E. Turneaure, John Wiley & Sons, New York, 1926, pp. 353–354.

$$H_{4w} = 0.565\ H_{3w} + 13.02\,(H_{1w} + H_{2w} + H_{3w}) - 1\,018\,000 \qquad (19d)$$

$$H_{5w} = 0.565\ H_{4w} + 12.52\ (H_{1w} + H_{2w} + H_{3w} + H_{4w}) - 1\,142\,000 \qquad (19e)$$

and,

$$0 = 0.0497\ H_{5w} + 1.00\ (H_{1w} + H_{2w} + H_{3w} + H_{4w} + H_{5w}) - 101\,300 \qquad (19f)$$

To this point, slide-rule calculations have been used; but now the computations must be carried to more places. This is not false accuracy. It is an arithmetical procedure which is necessary because of the subtractions that occur in solving the equations.

By successive substitutions, each H_w may be expressed in terms of H_{1w}; thus:

$$H_{1w} = H_{1w} \qquad (20a)$$

$$H_{2w} = 2.776\ H_{1w} - 84\,100 \qquad (20b)$$

$$H_{3w} = 32.33461\ H_{1w} - 1\,237\,138 \qquad (20c)$$

$$H_{4w} = 488.4292\ H_{1w} - 18\,919\,500 \qquad (20d)$$

$$H_{5w} = 6\,843.200\ H_{1w} - 265\,245\,500 \qquad (20e)$$

and,

$$0 = 7\,707.8473\ H_{1w} - 298\,770\,300 \qquad (20f)$$

Solving Equation (20*f*) to determine H_{1w}: $H_{1w} = \dfrac{298\,770\,300}{7707.847}$ $= 38\,761.83$. Substituting this value of H_{1w} in Equations (20*a*) to (20*e*) supplies the remaining values of H_w, thus: $H_{2w} = 23\,500$ lb; $H_{3w} = 16\,200$; $H_{4w} = 12\,900$; and, $H^5{}_w = 9\,400$.

The corresponding values, as found by Johnson, Bryan, and Turneaure, are: $H_{1w} = 38\,900$; $H_{2w} = 23\,400$; $H_{3w} = 16\,300$; $H_{4w} = 12\,400$; and $H_{5w} = 9\,900$. It is seen that these values are in close agreement with those computed by the writer. The differences are due to the slide-rule calculations of the coefficients in this Example.

Analysis of Trusses with Inclined Upper Chords

Trusses with inclined upper chords and horizontal lower chords are generally the most desirable type for bridges. The exact analysis of this form is more complicated than the case of the symmetrical chords. However, by making a few reasonable assumptions a satisfactory solution may be obtained. Fig. 5(*a*) represents a Vierendeel truss with an inclined upper chord. Consider a typical panel, *a–b*, removed from the truss and cut into two parts by sections through the top of each vertical. The forces acting on each part are shown in Fig. 5(*b*) and Fig. 5(*c*).

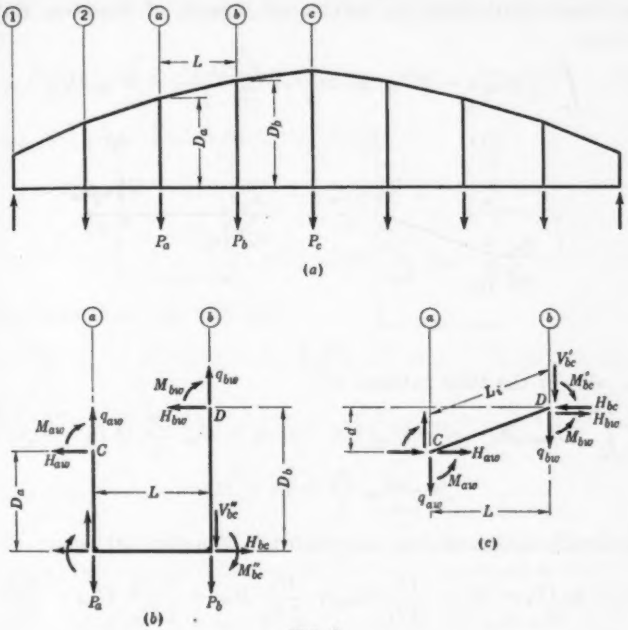

FIG. 5.

Considering the lower part, as shown in Fig. 5(*b*), the horizontal displacement of Point D with respect to Point C is:

$$E\,\Delta''_x = E\,\theta_C\,(D_b - D_a) + \int \frac{M\,y}{I}\,ds = E\,\theta_C\,(D_b - D_a)$$

$$+ \frac{1}{I_b}\int_0^{D_b} (M_{bw} - H_{bw}\,y)\,y\,dy + \frac{1}{I''_C}\int_0^{L} \Big[M_{bw} + M''_{bc} + (V''_{bc} + P_b$$

$$- q_{bw})\,x - H_{bw}\,D_b \Big]\,D_b\,dx + \frac{1}{I_a}\int_0^{D_a} \Big[H_{aw}\,(D_a - y) - M_{aw} \Big]\,(D_b - y)\,dy \;..(21)$$

The value of the first integral in Equation (21) is:

$$\int_0^{D_b} (M_{bw} - H_{bw}\,y)\,y\,dy = M_{bw}\,\frac{D_b^2}{2} - H_{bw}\,\frac{D_b^3}{3} \;.........(22)$$

From statics, it is evident that (see Fig. 5(*b*) and Fig. 6(*b*)):

$$M''_{ba} = H_{bw}\,D_b - M_{bw} - M''_{bc} \;...............(23a)$$

and,

$$V''_{ab} = V''_{bc} + P_b - q_{bw} \;.................(23b)$$

Making these substitutions in the second integral of Equation (21) and integrating:

$$\int_0^L (V''_{ab}\, x - M''_{ba})\, D_b\, dx = V''_{ab} \frac{D_b L^2}{2} - M''_{ba}\, D_b\, L \quad \text{......(24)}$$

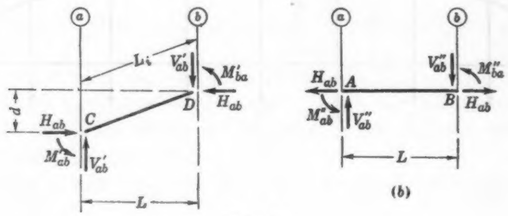

FIG. 6.

The value of the third integral is:

$$\int_0^{D_a} [H_{aw}(D_a - y) - M_{aw}]\,(D_b - y)\, dy = H_{aw} \frac{D^2_a}{6} (3\, D_b - D_a)$$

$$- M_{aw} \frac{D_a}{2} (2\, D_b - D_a) \quad \text{....................(25)}$$

Equations (22), (24), and (25), substituted in Equation (21) give:

$$E\, \Delta''_x = E\, \theta_C\, (D_b - D_a) - \frac{D^3_b}{3\, I_b} H_{bw} + \frac{D^2_b}{2\, I_b} M_{bw} + \frac{L^2\, D_b}{2\, I''_C} V''_{ab} - \frac{D_b\, L}{I''_C} M''_{ba}$$

$$+ \frac{D^3_a}{6\, I_a} (3\, D_b - D_a)\, H_{aw} - \frac{D_a}{2\, I_a} (2\, D_b - D_a)\, M_{aw} \quad \text{........(26)}$$

The forces acting on the upper chord, as shown in Fig. 5(*c*), may be replaced by the equivalent system shown in Fig. 6(*a*). Then, for the upper chord, the horizontal displacement of Point D with respect to Point C is:

$$E\, \Delta'_x = E\, \theta_C\, (D_b - D_a) + \int \frac{M\, y}{I}\, ds = E\, \theta_C\, (D_b - D_a)$$

$$+ \frac{1}{I'_C} \int_0^{L_i} (V'_{ab}\, x - H_{ab}\, y - M'_{ba})\, y\, dL_i \quad \text{.............(27)}$$

From the geometry of the truss:

$$x = \frac{L}{d}\, y \quad \text{.........................(28a)}$$

and,

$$d\, L_i = \frac{L_i}{d}\, dy \quad \text{.......................(28b)}$$

Substituting Equations (28) in the integral of Equation (27), changing the limits of integration, and integrating:

$$\int_0^{L_i} (V'_{ab}\, x - H_{ab}\, y - M'_{ba})\, y\, dL_i = V'_{ab} \frac{L\, L_i\, d}{3} - H_{ab} \frac{L_i\, d^2}{3} - M'_{ba} \frac{L_i\, d}{2} \quad \text{..(29)}$$

Substituting $d = D_b - D_a$ and $H_{ab} = \sum_1^a H_w$, Equation (29) becomes:

$$V'_{ab}\,\frac{L\,L_1}{3}\,(D_b - D_a) - \sum_1^a H_w\,\frac{L_1}{3}\,(D_b - D_a)^2 - M'_{ba}\,\frac{L_1}{2}\,(D_b - D_a)\,.\,(30)$$

Equation (30) substituted in Equation (27) gives:

$$E\,\Delta'_x = E\,\theta_C\,(D_b - D_a) + \frac{L_1 L}{3\,I'_C}\,(D_b - D_a)\,V'_{ab} - \frac{L_1}{2\,I'_C}\,(D_b - D_a)\,M'_{ba}$$

$$- \frac{L_1}{3\,I'_C}\,(D_b - D_a)^2 \sum_1^a H_w \ldots\ldots\ldots\ldots\ldots\ldots\,(31)$$

Equating Equations (26) and (31):

$$0 = -\frac{D^3_b}{3\,I_b}\,H_{bw} + \frac{D^2_a}{6I_a}\,(3\,D_b - D_a)\,H_{aw} + \frac{D^2_b}{2\,I_b}\,M_{bw} - \frac{D_a}{2\,I_a}\,(2\,D_b - D_a)\,M_{aw}$$

$$+ \frac{L^2 D_b}{2\,I''_C}\,V''_{ab} - \frac{L\,L_1}{3\,I'_C}\,(D_b - D_a)\,V'_{ab} - \frac{D_b L}{I''_C}\,M''_{ba} + \frac{L_1}{2\,I'_C}\,(D_b - D_c)\,M'_{ba}$$

$$+ \frac{L_1}{3\,I'_C}\,(D_b - D_a)^2 \sum_1^a H_w \ldots\ldots\ldots\ldots\ldots\ldots\,(32)$$

Referring to Fig. 5(*b*), and Fig. 6(*b*) (which show the forces acting on the lower chord), the vertical deflection of Point D with respect to Point C is:

$$E\,\Delta''_y = -E\,\theta_C L + \frac{1}{I''_C}\int_0^L (M''_{ba} - V''_{ab}\,x)\,x\,dx$$

$$+ \frac{1}{I_a}\int_0^{D_a} (M_{aw} - H_{aw}\,y)\,L\,dy \ldots\ldots\ldots\ldots\ldots\ldots\,(33)$$

Integrating Equation (33):

$$E\,\Delta''_y = -E\,\theta_C L + \frac{L^2}{2\,I''_C}\,M''_{ba} - \frac{L^3}{3\,I''_C}\,V''_{ab} + \frac{L\,D_a}{I_a}\,M_{aw} - \frac{L\,D^2_a}{2\,I_a}\,H_{aw}\,..\,(34)$$

Referring to Fig. 6(*a*), the vertical deflection of Point D with respect to Point C is:

$$E\,\Delta'_y = -E\,\theta_C\,L + \frac{1}{I'_C}\int_0^{L_1} (M'_{ba} - V'_{ab}\,x + H_{ab}\,y)\,x\,dL_1 \ldots.(35)$$

Integrating Equation (35):

$$E\,\Delta'_y = -E\,\theta_C\,L + \frac{L\,L_1}{2\,I'_C}\,M'_{ba} - \frac{L^2 L_1}{3\,I'_C}\,V'_{ab} + \frac{L\,L_1}{3\,I'_C}\,(D_b - D_a)\,H_{ab}\,..\,(36)$$

Equating Equations (34) and (36):

$$0 = -\frac{L\,D^2_a}{2\,I_a}\,H_{aw} + \frac{L\,D_a}{I_a}\,M_{aw} - \frac{L^3}{3\,I''_C}\,V''_{ab} + \frac{L^2 L_1}{3\,I'_C}\,V'_{ab} + \frac{L^2}{2\,I''_C}\,M''_{ba}$$

$$- \frac{L\,L_1}{2\,I'_C}\,M'_{ba} - \frac{L\,L_1}{3\,I'_C}\,(D_b - D_a) \sum_1^a H_w \ldots\ldots\ldots\ldots\,(37)$$

Referring to Fig. 5(*b*), the angular displacement of Point D with respect to Point C is:

$$E\,\Delta''\,\theta = \int \frac{M}{I}\,ds = \frac{1}{I_b}\int_0^{D_b} (M_{bw} - H_{bw}\,y)\,dy + \frac{1}{I''_C}\int_0^{L} (V''_{ab}\,x - M''_{ba})\,dx$$

$$+ \frac{1}{I_a}\int_0^{D_a} (H_{aw}\,y - M_{aw})\,dy \quad \ldots\ldots\ldots\ldots\ldots\ldots (38)$$

Integrating Equation (38):

$$E\,\Delta''\,\theta = \frac{D_b}{I_b} M_{bw} - \frac{D^2_b}{2\,I_b} H_{bw} + \frac{L^2}{2\,I''_C} V''_{ab} - \frac{L}{I''_C} M''_{ba} + \frac{D^2_a}{2 I_a} H_{aw} - \frac{D_a}{I_a} M_{aw} \cdot (39)$$

Referring to Fig. 6(*a*), the angular displacement of Point D with respect to Point C is:

$$E\,\Delta'\,\theta = \int \frac{M}{I}\,ds = \frac{1}{I'_C}\int_0^{L_t} (V'_{ab}\,x - H_{ab}\,y - M'_{ba})\,dL_t \ldots . (40)$$

Integrating Equation (40):

$$E\,\Delta'\,\theta = \frac{L\,L_t}{2\,I'_C} V'_{ab} - \frac{L_t}{2\,I'_C} (D_b - D_a)\,H_{ab} - \frac{L_t}{I'_C} M'_{ba} \ldots\ldots (41)$$

Equating Equations (39) and (41):

$$0 = -\frac{D^2_b}{2\,I_b} H_{bw} + \frac{D^2_a}{2\,I_a} H_{aw} + \frac{D_b}{I_b} M_{bw} - \frac{D_a}{I_a} M_{aw} + \frac{L^2}{2\,I''_C} V''_{ab} - \frac{L\,L_t}{2\,I'_C} V'_{ab}$$

$$-\frac{L}{I''_C} M''_{ba} + \frac{L_t}{I'_C} M'_{ba} + \frac{L_t}{2\,I'_C} (D_b - D_a) \sum_1^a H_w \ldots\ldots (42)$$

Equations (32), (37), and (42) are the fundamental expressions for a typical panel. A set of these formulas could be written for each panel and the series solved simultaneously to find the unknowns. Such a procedure, although possible, would be too laborious for practical use. However, by transforming these fundamental equations, as described subsequently, a workable solution may be obtained.

Solution for the H_w-Values.—First, the terms involving M_{aw} and M_{bw} may be eliminated from Equations (32), (37), and (42). This can be accomplished by multiplying Equation (37) by $\frac{1}{2\,L}\,(D_a - D_b)$; thus:

$$0 = -\left(\frac{D^3_a}{4} - \frac{D^2_a\,D_b}{4}\right)\frac{H_{aw}}{I_a} + \left(\frac{D^2_a}{2} - \frac{D_a\,D_b}{2}\right)\frac{M_{aw}}{I_a} - \left(\frac{L^2\,D_a}{6} - \frac{L^2\,D_b}{6}\right)\frac{V''_{ab}}{I''_C}$$

$$+\left(\frac{L\,L_t\,D_a}{6} - \frac{L\,L_t\,D_b}{6}\right)\frac{V'_{ab}}{I'_C} + \left(\frac{L\,D_a}{4} - \frac{L\,D_b}{4}\right)\frac{M''_{ba}}{I''_C} - \left(\frac{L_t\,D_a}{4} - \frac{L_t\,D_b}{4}\right)\frac{M'_{ba}}{I'_C}$$

$$-\frac{L_t}{6\,I'_C} (D_b - D_a)\,(D_a - D_b) \sum_1^a H_w \ldots\ldots\ldots\ldots\ldots (43)$$

Multiplying Equation (42) by $\frac{D_b}{2}$:

$$0 = -\frac{D^3_b}{4 I_b} H_{bw} + \frac{D_b D^2_a}{4 I_a} H_{aw} + \frac{D^2_b}{2 I_b} M_{bw} - \frac{D_a D_b}{2 I_a} M_{aw} + \frac{L^2 D_b}{4 I''_C} V''_{ab}$$

$$-\frac{L L_t D_b}{4 I'_C} V'_{ab} - \frac{L D_b}{2 I''_C} M''_{ba} + \frac{L_t D_b}{2 I'_C} M'_{ba} + \frac{L_t}{I'_C} (D_b - D_a) \frac{D_b}{4} \sum_1^a H_w \quad (44)$$

Subtracting the sum of Equation (43) and (44) from Equation (32) gives Equation (45), as follows:

$$0 = -\frac{D^3_b}{12 I_b} H_{bw} + \frac{D^3_a}{12 I_a} H_{aw} + \frac{L^2}{12 I''_C} (D_b + 2 D_a) V''_{ab} + \frac{L L_t}{12 I'_C} (D_b + 2 D_a) V'_{ab}$$

$$- \frac{L}{4 I''_C} (D_b + D_a) M''_{ba} - \frac{L_t}{4 I'_C} (D_b + D_a) M'_{ba}$$

$$+ \frac{L_t}{12 I'_C} (2 D^2_a - D^2_b - D_a D_b) \sum_1^a H_w \quad \text{............(45)}$$

Equation (45) may be simplified by substituting various statical relations. For equilibrium of the upper chord (see Fig. 6(a)), it is seen that:

$$V'_{ab} L - H_{ab} d = M'_{ab} + M'_{ba} \quad \text{...............(46a)}$$

For equilibrium of the lower chord (see Fig. 6(b)), it is seen that:

$$V''_{ab} L = M''_{ab} + M''_{ba} \quad \text{..................(46b)}$$

Let $\frac{M'_{ab} + M'_{ba}}{M''_{ab} + M''_{ba}} = \alpha$ and note that $H_{ab} = \sum_1^a H_w$; then, dividing Equation (46a) by Equation (46b):

$$V'_{ab} = \frac{d}{L} \sum_1^a H_w + \alpha V''_{ab} \quad \text{...................(47)}$$

Substituting $V'_{ab} = V_{ab} - V''_{ab}$ and $V''_{ab} = V_{ab} - V'_{ab}$ in Equation (47):

$$V'_{ab} = \frac{\alpha V_{ab}}{1 + \alpha} + \frac{\frac{d}{L} \sum_1^a H_w}{1 + \alpha} \quad \text{................(48a)}$$

and,

$$V''_{ab} = \frac{V_{ab}}{1 + \alpha} - \frac{\frac{d}{L} \sum_1^a H_w}{1 + \alpha} \quad \text{................(48b)}$$

Now, consider that part of the truss to the left of Panel Point b, as shown in Fig. 7. For equilibrium it is obvious that:

$$M_b - M'_{ba} - M''_{ba} - H_{ab}\, D_b = 0 \ldots\ldots\ldots\ldots\ldots (49)$$

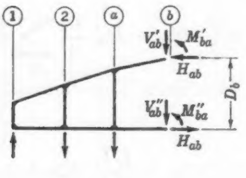

FIG. 7.

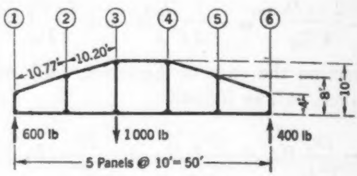

FIG. 8.

Let $\dfrac{M'_{ba}}{M''_{ba}} = \beta$ and note that $H_{ab} = \sum\limits_1^a H_w$; then, solving Equation (49), first for M'_{ba} and then for M''_{ba}:

$$M'_{ba} = \frac{\beta\, M_b}{1 + \beta} - \frac{\beta\, D_b \sum\limits_1^a H_w}{1 + \beta} \ldots\ldots\ldots\ldots\ldots (50a)$$

and,

$$M''_{ba} = \frac{M_b}{1 + \beta} - \frac{D_b \sum\limits_1^a H_w}{1 + \beta} \ldots\ldots\ldots\ldots\ldots (50b)$$

For reference purposes, designate the seven terms in Equation (45) by the letters, a to g, in order, from left to right. Substituting Equation (48b) in Term (c) gives:

$$\frac{L^2}{12\, I''_C}\,(D_b + 2\, D_a)\, V''_{ab} = \frac{L^2\,(D_b + 2\, D_a)}{12\, I''_C\,(1 + \alpha)}\, V_{ab}$$

$$- \frac{L\,(D_b + 2\, D_a)\,(D_b - D_a)}{12\, I''_C\,(1 + \alpha)} \sum_1^a H_w \ldots\ldots\ldots\ldots (51c)$$

Substituting Equation (48a) in Term (d), gives:

$$\frac{L\, L_1\,(D_b + 2\, D_a)}{12\, I'_C}\, V'_{ab} = \frac{\alpha\, L\, L_1\,(D_b + 2\, D_a)}{12\, I'_C\,(1 + \alpha)}\, V_{ab}$$

$$+ \frac{L_1\,(D_b + 2\, D_a)\,(D_b - D_a)}{12\, I'_C\,(1 + \alpha)} \sum_1^a H_w \ldots\ldots\ldots\ldots (51d)$$

Substituting Equation (50*b*) in Term (*e*) gives:

$$-\frac{L}{4\,I''_C}\,(D_b + D_a)\,M''_{ba} = -\frac{L\,(D_b + D_a)}{4\,I''_C\,(1+\beta)}\,M_b$$

$$+\frac{L\,D_b\,(D_b + D_a)}{4\,I''_C\,(1+\beta)}\sum_1^a H_w \quad\text{.................(51e)}$$

Substituting Equation (50*a*) in Term (*f*) gives:

$$-\frac{L_1}{4\,I'_C}\,(D_b + D_a)\,M'_{ba} = -\frac{\beta\,L_1\,(D_b + D_a)}{4\,I'_C\,(1+\beta)}\,M_b$$

$$+\frac{\beta\,L_1\,D_b\,(D_b + D_a)}{4\,I'_C\,(1+\beta)}\sum_1^a H_w \quad\text{...............(51f)}$$

From Equations (51*c*) to (51*f*), collect the terms containing V_{ab}, to form Term (*h*):

$$\frac{L^2\,(D_b + 2\,D_a)}{12\,I''_C\,(1+\alpha)}\,V_{ab} + \frac{\alpha\,L\,L_1\,(D_b + 2\,D_a)}{12\,I'_C\,(1+\alpha)}\,V_{ab}$$

$$= \frac{L^2\,(D_b + 2\,D_a)}{12\,I''_C}\left[\frac{1}{1+\alpha} + \frac{\dfrac{L_1\,I''_C}{L\,I'_C}\,\alpha}{1+\alpha}\right]V_{ab}$$

$$= \frac{L^2\,(D_b + 2\,D_a)}{12\,I''_C}\left(\frac{1+\phi\,\alpha}{1+\alpha}\right)V_{ab} \quad\text{...............(51h)}$$

in which ϕ = ratio of stiffness, top and bottom chords = $\dfrac{L_1\,I''_C}{L\,I'_C}$.

From the same group of terms, collect the ones containing M_b; thus, for Term (*i*):

$$-\frac{L}{4\,I''_C}\,\frac{(D_b + D_a)}{(1+\beta)}\,M_b - \frac{\beta\,L_1\,(D_b + D_a)}{4\,I'_C\,(1+\beta)}\,M_b$$

$$= -\frac{L}{4\,I''_C}\,(D_b + D_a)\left[\frac{1}{1+\beta} + \frac{\dfrac{L_1\,I''_C}{L\,I'_C}\,\beta}{1+\beta}\right]M_b$$

$$= -\frac{L}{4\,I''_C}\,(D_b + D_a)\left(\frac{1+\phi\,\beta}{1+\beta}\right)M_b \quad\text{..............(51i)}$$

From the same group of terms, collect the ones containing $\sum_1^a H_w$, for Term (*j*):

$$-\frac{L\,(D_b^2 + D_b\,D_a - 2\,D_a^2)}{12\,I''_C\,(1+\alpha)}\sum_1^a H_w + \frac{L_1\,(D_b^2 + D_b\,D_a - 2\,D_a^2)}{12\,I'_C\,(1+\alpha)}\sum_1^a H_w$$

$$+\frac{L\,D_b\,(D_b + D_a)}{4\,I''_C\,(1+\beta)}\sum_1^a H_w + \frac{\beta\,L_1\,D_b\,(D_b + D_a)}{4\,I'_C\,(1+\beta)}\sum_1^a H_w$$

$$= \left[\frac{L\,(2\,D_a^2 - D_b\,D_a - D_b^2)}{12\,I''_C}\left(\frac{1-\phi}{1+\alpha}\right) + \frac{L\,D_b\,(D_b + D_a)}{4\,I''_C}\left(\frac{1+\phi\,\beta}{1+\beta}\right)\right]\sum_1^a H_w \text{.(51j)}$$

Adding Term (j) to Term (g), Term (k) equals:

$$\text{Term } (j) + \frac{L_t}{12\, I'_C} (2\, D^2_a - D_a\, D_b - D^2_b) \sum_1^a H_w$$

$$= \text{Term } (j) + \frac{\phi\, L}{12\, I''_C} (2\, D^2_a - D_a\, D_b - D^2_b) \sum_1^a H_w$$

$$= \left[\frac{L\,(2\, D^2_a - D_a\, D_b - D^2_b)}{12\, I''_C} \left(\frac{1 + \phi\, \alpha}{1 + \alpha} \right) + \frac{L\, D_b\,(D_b + D_a)}{4\, I''_C} \left(\frac{1 + \phi\, \beta}{1 + \beta} \right) \right] \sum_1^a H_w \quad \text{.............(51}k\text{)}$$

By these transformations, Terms (c) + (d) + (e) + (f) + (g) have been reduced to the three terms, (h) + (i) + (k). With these changes, Equation (45) becomes:

$$0 = -\frac{D^3_b}{12\, I_b} H_{bw} + \frac{D^3_a}{12\, I_a} H_{aw} + \frac{L}{12\, I''_C} \left[(2\, D^2_a - D_a\, D_b - D^2_b) \left(\frac{1 + \phi\, \alpha}{1 + \alpha} \right) + 3\, D_b\,(D_b + D_a) \left(\frac{1 + \phi\, \beta}{1 + \beta} \right) \right] \sum_1^a H_w - \frac{L}{4\, I''_C} (D_b + D_a) \left(\frac{1 + \phi\, \beta}{1 + \beta} \right) M_b + \frac{L^2}{12\, I''_C} (D_b + 2\, D_a) \left(\frac{1 + \phi\, \alpha}{1 + \alpha} \right) V_{ab} \quad \text{.............(52)}$$

Transposing the term containing H_{bw} and dividing through by its coefficient gives:

$$H_{bw} = \frac{D^3_a}{D^3_b} \frac{I_b}{I_a} H_{aw} + \frac{L}{D^3_b} \frac{I_b}{I''_C} \left[3\, D_b\,(D_b + D_a) \left(\frac{1 + \phi\, \beta}{1 + \beta} \right) + (2\, D^2_a - D_a\, D_b - D^2_b) \left(\frac{1 + \phi\, \alpha}{1 + \alpha} \right) \right] \sum_1^a H_w - \frac{3\, L}{D^3_b} \frac{I_b}{I''_C} (D_b + D_a) \left(\frac{1 + \phi\, \beta}{1 + \beta} \right) M_b + \frac{L^2}{D^3_b} \frac{I_b}{I''_C} (D_b + 2\, D_a) \left(\frac{1 + \phi\, \alpha}{1 + \alpha} \right) V_{ab} \quad \text{.............(53)}$$

Equation (53) is the fundamental expression for determining the H_w-values. No approximations have been made in its derivation, except to neglect deflections due to axial stresses. The effect of these deflections is considered subsequently. For the case of parallel chords and constant moment of inertia, Equation (53) reduces to Equation (11). It may be used for parallel-chord trusses with members having different moments of inertia.

After evaluating the coefficients of each term of Equation (53), it reduces to the simple form of Equation (13). In this case, however, the coefficients depend not only on the truss dimensions, but also upon α and β, which are ratios of the bending moments in the upper chord to those in the lower chord.

In order to evaluate the coefficients it is necessary to assume values for these ratios. It can be shown that, in most cases, choosing widely different values for these ratios effects the H_w-values only slightly. Hence, by assuming any reasonable values for α and β, a close approximation to the true values of H_w is obtained upon solving the equation.

For the particular case in which the moments of inertia are such that $\phi = \frac{L_t}{L} \frac{I''_C}{I'_C} = 1$, the factors involving α and β reduce to unity and the solution becomes exact. For values of ϕ close to unity, the factors involving α and β will be nearly equal to unity for any values of these ratios and, therefore, in such case, little error is introduced in assuming these ratios.

The following examples illustrate the method of solution and the effect on the H_w-values of assuming different magnitudes for α and β.

Example 3.—Consider a truss with dimensions and loads as shown in Fig. 8. For this example assume that the moments of inertia are of such values that $I_a = I_b = I''_C = I'_C \frac{L}{L_t}$. Then, for this case, ϕ will equal 1, and Equation (53) reduces to:

$$H_{bw} = \frac{D^3_a}{D^3_b} H_{aw} + \frac{2\,L}{D^3_b} (D^2_a + D_a\,D_b + D^2_b) \sum_1^a H_w - \frac{3\,L}{D^3_b} (D_b + D_a)\,M_b$$

$$+ \frac{L^2}{D^3_b} (D_b + 2\,D_a)\,V_{ab} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (54)$$

Apply Equation (54) to each panel in the left half of the truss. Then, after evaluating the coefficients, the following series of equations is obtained:

$$H_{1w} = H_{1w} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (55a)$$

$$H_{2w} = 0.125\,H_{1w} + 4.37\,H_{1w} - 0.702\,M_2 + 3.12\,V_{12} \ldots\ldots\ldots (55b)$$

$$H_{3w} = 0.512\,H_{2w} + 4.88\,(H_{1w} + H_{2w}) - 0.54\,M_3 + 2.60\,V_{23} \ldots (55c)$$

and,

$$H_{4w} = 1.00\,H_{3w} + 6.00\,(H_{1w} + H_{2w} + H_{3w}) - 0.60\,M_4 + 3.00\,V_{34} . (55d)$$

For the loading given: $M_2 = 6\,000$ ft-lb; $M_3 = 12\,000$ ft-lb; $M_4 = 8\,000$ ft-lb; $V_{12} = 600$ lb; $V_{23} = 600$ lb; and, $V_{34} = -400$ lb. Substituting these values in Equations (55) and then expressing each value of H_w in terms of H_{1w}:

$$H_{1w} = H_{1w} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (56a)$$

$$H_{2w} = 4.495\,H_{1w} - 2\,340 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (56b)$$

$$H_{3w} = 0.512\,H_{2w} + 4.88\,(H_{1w} + H_{2w}) - 4\,920 = 29.117\,H_{1w} - 17\,537 . (56c)$$

and,

$$H_{4w} = 1.00\,H_{3w} + 6.00\,(H_{1w} + H_{2w} + H_{3w}) - 6\,000$$

$$= 236.789\,H_{1w} - 142\,799 \ldots\ldots\ldots\ldots\ldots\ldots (56d)$$

Now consider the truss reversed in position, as shown in Fig. 9. The prime mark, ('''), will be used to designate terms for this position. Moments

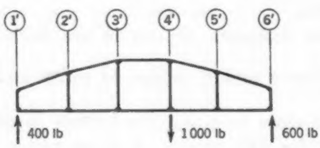

FIG. 9.

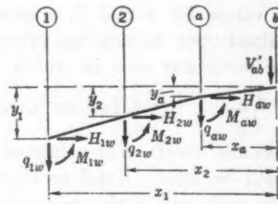

FIG. 10.

and shears for the left half of the truss are: $M'''_2 = 4\,000$ ft-lb; $M'''_3 = 8\,000$ ft-lb; $V'''_{12} = 400$ lb; and $V'''_{23} = 400$ lb. Substituting these values in Equations (55) and then expressing each value of H'''_w in terms of H'''_{1w}:

$$H'''_{1w} = H'''_{1w} \quad \ldots\ldots (57a)$$

$$H'''_{2w} = 4.495\ H'''_{1w} - 1\,560 \quad \ldots\ldots (57b)$$

and,

$$H'''_{3w} = 0.512\ H'''_{2w} + 4.88\ (H'''_{1w} + H'''_{2w}) - 3\,280$$

$$= 29.117\ H'''_{1w} - 11\,692 \quad \ldots\ldots (57c)$$

Since it is obvious from their identity that $H_{4w} = -\ H'''_{3w}$: $236.789\ H_{1w} - 142\,799 = -\ 29.117\ H'''_{1w} + 11\,692$; and,

$$H'''_{1w} = -\ 8.13233\ H_{1w} + 5\,305.87 \quad \ldots\ldots (58)$$

For equilibrium:

$$H_{1w} + H_{2w} + H_{3w} + H_{4w} - H'''_{2w} - H'''_{1w} = 0 \quad \ldots\ldots (59)$$

Substituting for each value of H_w in Equation (59), its value in terms of H_{1w}: $271.401\ H_{1w} - 162\,676 - 5.495\ H'''_{1w} + 1\,560 = 0$; $271\,401\ H_{1w} - 162\,676 - 5.495\ (-\ 8.13233\ H_{1w} + 5\,305.87) + 1\,560 = 0$; and, $H_{1w} = 601.96$. Substituting this value for H_{1w} in Equations (56), (57), and (58): $H_{2w} = 366$ lb; $H_{3w} = -\ 10$ lb; $H_{4w} = -\ 262$ lb; $H_{5w} = -\ H'''_{2w} = -\ 285$ lb; and, $H_{6w} = -\ H'''_{1w} = -\ 411$ lb.

Example 4.—Consider the same truss as in Example 3, but assume that $I_a = I_b = I''_C = I'_C$. In this case, in order to evaluate the coefficients, it is necessary to assume values for α and β. To show how slightly these values affect the magnitudes of the H_w, it will be assumed that $\alpha = \beta = 2$. This is a highly improbable value, of course, and is chosen only for purposes of illustration. A more reasonable assumption would give more accurate results.

Referring to Equation (53), the factors, $\frac{1 + \phi\,\alpha}{1 + \alpha}$ and $\frac{1 + \phi\,\beta}{1 + \beta}$, become $\frac{1 + \frac{10.77 \times 2}{10}}{1 + 2} = 1.051$ for the first panel; $\frac{1 + \frac{10.2 \times 2}{10}}{1 + 2} = 1.013$ for the second panel; and $\frac{1 + \frac{10 \times 2}{10}}{1 + 2} = 1$ for the third panel. The coefficients for this example will equal those in Example 3 multiplied by these factors, except for the H_{aw}-term, which remains the same. Performing this multiplication yields the following series of equations:

$$H_{1w} = H_{1w} \quad \ldots\ldots (60a)$$

$$H_{2w} = 0.125\ H_{1w} + 4.59\ H_{1w} - 0.738\ M_2 + 3.28\ V_{12} \quad \ldots\ldots (60b)$$

$$H_{3w} = 0.512\ H_{2w} + 4.94\ (H_{1w} + H_{2w}) - 0.547\ M_3 + 2.63\ V_{23} \quad \ldots\ldots (60c)$$

and,

$$H_{4w} = 1.00\ H_{3w} + 6.00\ (H_{1w} + H_{2w} + H_{3w}) - 0.600\ M_4 + 3.00\ V_{34} \quad (60d)$$

Substituting the values for the moments and shears and solving as was done in Example 3: $H_{1w} = 600$; $H_{2w} = 369$; $H_{3w} = -10$; $H_{4w} = -262$; $H_{5w} = -H'''_{2w} = -287$; and, $H_{6w} = H'''_{1w} = -409$. Comparing these values with those of Example 3, it is seen that the two assumptions give nearly the same results, even though α and β in this example were chosen far greater than their probable value.

Determination of Chord Moments and Shears

After the H_w-values have been determined from Equation (53), the next step is to solve for the M_w and q_w-values. This is done by transforming the fundamental equations, as follows: Multiplying Equation (37) by $\frac{3}{L}$ and adding the result to Equation (42), gives:

$$-\frac{D^2_b}{2\,I_b}\,H_{bw} - \frac{D^2_a}{I_a}\,H_{aw} + \frac{D_b}{I_b}\,M_{bw} + \frac{2\,D_a}{I_a}\,M_{aw} - \frac{L^2}{2\,I''_c}\,V''_{ab} + \frac{L\,L_1}{2\,I'_c}\,V'_{ab}$$
$$+ \frac{L}{2\,I''_c}\,M''_{ba} - \frac{L_1}{2\,I'_c}\,M'_{ba} - \frac{L_1}{2\,I'_c}\,(D_b - D_a) \sum_1^a H_w = 0 \quad \ldots (61)$$

Substituting the statical relations, $V''_{ab} = V_{ab} - V'_{ab}$ and $M''_{ba} = M_b - M'_{ba} - D_b \sum_1^a H_w$, in Equation (61) and collecting terms:

$$-\frac{D^2_b}{2\,I_b}\,H_{bw} + \frac{D^2_a}{I_a}\,H_{aw} + \frac{D_b}{I_b}\,M_{bw} + \frac{2\,D_a}{I_a}\,M_{aw} - \frac{L^2}{2\,I''_c}\,V_{ab} + \frac{L^2}{2\,I''_c}\,(1 + \phi)\ V'_{ab}$$
$$+\frac{L}{2\,I''_c}\,M_b - \frac{L}{2\,I''_c}\,(1 + \phi)\ M'_{ba} + \left[\frac{L_1\,D_a}{2\,I''_c} - \frac{L\ D_b}{2\,I''_c}\,(1 + \phi)\right] \sum_1^a H_w = 0 \quad .. (62)$$

Fig. 10 shows the forces acting on the upper chord to the left of Panel Point b. For equilibrium:

$$M'_{ba} = -\sum_{1}^{a} M_w - \sum_{1}^{a} (q_w x) - \sum_{1}^{a} (H_w y) = -\sum_{1}^{a} M_w$$

$$+ \sum_{1}^{a} (V' L) - \sum_{1}^{a} (H_w y) \dots\dots\dots\dots\dots\dots (63)$$

Equation (63) may be written:

$$M'_{ba} = -M_{aw} - \sum_{1}^{(a-1)} M_w + V'_{ab} L + \sum_{1}^{(a-1)} (V' L) - \sum_{1}^{a} (H_w y) \quad \dots (64)$$

From the geometry of the truss it is seen that $H_w \, y = H_w \, D_b - H_w \, D$. Substituting this value in Equation (64):

$$M'_{ba} = -M_{aw} - \sum_{1}^{(a-1)} M_w + V'_{ab} L + \sum_{1}^{(a-1)} (V' L)$$

$$- \sum_{1}^{a} (H_w D_b) + \sum_{1}^{a} (H_w D) \dots\dots\dots\dots\dots\dots (65)$$

Substituting Equation (65) in Equation (62) and collecting terms:

$$\frac{D_b}{I_b} M_{bw} = -\left[\frac{2\,D_a}{I_a} + \frac{L}{2\,I''_c}(1+\phi)\right] M_{aw} - \frac{L}{2\,I''_c}(1+\phi) \sum_{1}^{a-1} M_w$$

$$+ \frac{L^2}{2\,I''_c}(1+\phi) \sum_{1}^{a-1} V' + \frac{D^2_b}{2\,I_b} H_{bw} + \frac{D^2_a}{I_a} H_{aw} + \frac{L^2}{2\,I''_c} V_{ab} - \frac{L}{2\,I''_c} M_b$$

$$- \frac{L_t\,D_a}{2\,I'_c} \sum_{1}^{a} H_w + \frac{L}{2\,I''_c}(1+\phi) \sum_{1}^{a} (H_w D) \quad \dots\dots\dots (66)$$

For the first panel Equation (66) reduces to:

$$\frac{D_2}{I_b} M_{2w} = -\left[\frac{2\,D_1}{I_a} + \frac{L}{2I''_c}(1+\phi)\right] M_{1w} + \left[\frac{D^2_1}{I_a} + \frac{L\;D_1}{2\,I''_c}\right] H_{1w} + \frac{D^2_2}{2\,I_b} H_{2w} \dots (67)$$

Substituting the same statical relations in Equation (37) and simplifying:

$$\frac{L^2}{6\,I''_c}(1+\phi)\,V'_{ab} = \left[\frac{D_a}{I_a} + \frac{L}{2\,I''_c}(1+\phi)\right] M_{aw} + \frac{L}{2\,I''_c}(1+\phi) \sum_{1}^{a-1} M_w$$

$$- \frac{L^2}{2\,I''_c}(1+\phi) \sum_{1}^{a-1} V' - \frac{D^2_a}{2\,I_a} H_{aw} - \frac{L^2}{3\,I''_c} V_{ab} + \frac{L}{2\,I''_c} M_b$$

$$+ \frac{L_t}{6\,I'_c}(D_b + 2\,D_a) \sum_{1}^{a} H_w - \frac{L}{2\,I''_c}(1+\phi) \sum_{1}^{a} (H_w D) \dots (68)$$

For the first panel Equation (68) reduces to:

$$\frac{L^2}{6\,I''_C}\,(1+\phi)\,V'_{12} = \left[\frac{D_1}{I_a} + \frac{L}{2\,I''_C}\,(1+\phi)\right] M_{1w}$$

$$-\left[\frac{D^2_1}{2\,I_a} - \frac{L_1}{6\,I'_C}\,(D_2 + 2\,D_1) + \frac{L\,D_1}{2\,I''_C}\,(1+\phi)\right] H_{1w} + \frac{L^2}{6\,I''_C}\,V_{12} \;\ldots\ldots(69)$$

Equations (66), (67), (68), and (69) furnish the necessary relations for solving for each value of M_w and V'. Each value of q_w, of course, is determined directly from the V'-values.

Equations (66) to (69) appear somewhat involved but, after substituting numerical values for the truss dimensions and for the previously calculated H_w-values, they reduce to:

$$C_1\,M_{bw} = C_2\,M_{aw} + C_3 \sum_{1}^{a-1} M_w + C_4 \sum_{1}^{a-1} V' + C_5 \;\ldots\ldots\ldots(70)$$

which corresponds to Equation (66);

$$C_6\,M_{2w} = C_7\,M_{1w} + C_8 \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots(71)$$

which corresponds to Equation (67);

$$C_9\,V'_{ab} = C_{10}\,M_{aw} + C_{11} \sum_{1}^{a-1} M_w + C_{12} \sum_{1}^{a-1} V' + C_{13} \;\ldots\ldots(72)$$

which corresponds to Equation (68); and,

$$C_{14}\,V'_{12} = C_{15}\,M_{1w} + C_{16} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots(73)$$

which corresponds to Equation (69).

The general method of solution is to apply Equations (66) and (68) to each panel in turn. This gives a series of expressions which may be solved simultaneously to obtain the magnitude of each unknown function. It will be noted that the equations for any given panel involve the moments, M_w, and shears, V', for the preceding panels only. Hence, by starting with the equations for the end panel and substituting, successively, in the equations for the following panels, each M_w may be expressed in terms of M_{1w} and the entire series is then readily solved.

This method of solution is best explained by solving an example. Accordingly, Equations (66) to (69) will be applied to find the values of M_w and V' for the truss used in Example 3.

Example 5.—For this example, the moments and shears will be computed for the truss of Example 3, using the H_w-values obtained in that example. For this case it should be noted that $\phi = 1$ and that $\frac{L_1}{I'_C} = \frac{L}{I''_C}$. Then, for this

particular problem, Equations (66) to (69) become:

For Equation (66):

$$D_b M_{bw} = -(2D_a + L) M_{aw} - L \sum_1^{a-1} M_w + L^2 \sum_1^{a-1} V' + \frac{D^2_b}{2} H_{bw}$$

$$+ D^2_a H_{aw} + \frac{L^2}{2} V_{ab} - \frac{L}{2} M_b - \frac{L D_a}{2} \sum_1^a H_w + L \sum_1^a (H_w D) \quad \text{..(74)}$$

For Equation (67):

$$D_2 M_{2w} = -(2D_1 + L) M_{1w} + \left(D^2_1 + \frac{L D_1}{2}\right) H_{1w} + \frac{D^2_2}{2} H_{2w} \quad \text{...(75)}$$

For Equation (68):

$$\frac{L^2}{3} V'_{ab} = (D_a + L) M_{aw} + L \sum_1^{a-1} M_w - L^2 \sum_1^{a-1} V' - \frac{D^2_a}{2} H_{aw} - \frac{L^2}{3} V_{ab}$$

$$+ \frac{L}{2} M_b + \frac{L}{6} (D_b + 2D_a) \sum_1^a H_w - L \sum_1^a (H_w D) \quad \text{......(76)}$$

and, for Equation (69):

$$\frac{L^2}{3} V'_{12} = (D_1 + L) M_{1w} - \left[\frac{D^2_1}{2} - \frac{L}{6}(D_2 + 2D_1) + L D_1\right] H_{1w} + \frac{L^2}{6} V_{12} \quad \text{.(77)}$$

Applying Equations (75) and (77) to the first panel gives:

$$8M_{2w} = -(2 \times 4 + 10) M_{1w} + \left(4^2 + \frac{10 \times 4}{2}\right)(602) + \frac{8^2}{2}(366); \text{ or,}$$

$$M_{2w} = 4\,173 - 2.25 M_{1w} \quad \text{..................(78)}$$

and, $\frac{10^2}{3} V'_{12} = (4 + 10) M_{1w} - \left[\frac{4^2}{2} - \frac{10}{6}(8 + 2 \times 4) + 10 \times 4\right](602)$

$+ \frac{10^2}{6}(600)$; or,

$$V'_{12} = 0.420 M_{1w} - 86 \quad \text{....................(79)}$$

Applying Equations (74) and (76) to the second panel gives:

$10 M_{3w} = -(2 \times 8 + 10) M_{2w} - 10 M_{1w} + 10^2 V'_{12} + \frac{10^2}{2}(-10)$

$+ 8^2 (366) + \frac{10^2}{2}(600) - \frac{10}{2}(12\,000) - \frac{10 \times 8}{2}(602 + 366) + 10\,(602 \times 4$

$+ 366 \times 8)$; or,

$$M_{3w} = -2.6 M_{2w} - M_{1w} + 10 V'_{12} + 759 \quad \text{..........(80)}$$

and, $\frac{10^2}{3} V'_{23} = (8 + 10)\, M_{2w} + 10\, M_{1w} - 10^2\, V'_{12} - \frac{8^2}{2}(366) - \frac{10^2}{3}(600)$
$+ \frac{10}{2}(12\,000) + \frac{10}{6}(10 + 2 \times 8)\,(602 + 366) - 10\,(602 \times 4 + 366 \times 8)$; or,

$$V'_{23} = 0.54\, M_{2w} + 0.3\, M_{1w} - 3\, V'_{12} + 508 \ldots\ldots\ldots\ldots (81)$$

Applying Equations (74) and (76) to the third panel gives: $10\, M_{4w} = -\,(2 \times 10 + 10)\, M_{3w} - 10\,(M_{2w} + M_{1w}) + 10^2\,(V'_{23} + V'_{12}) + \frac{10^2}{2}(-\,262) + 10^2\,(-\,10) + \frac{10^2}{2}(-\,400) - \frac{10}{2}(8\,000) - \frac{10 \times 10}{2}(602 + 366 - 10) + 10\,(602 \times 4 + 366 \times 8 - 10 \times 10)$; or,

$$M_{4w} = -\,3\, M_{3w} - M_{2w} - M_{1w} + 10\, V'_{23} + 10\, V'_{12} - 6\,964 \ldots (82)$$

and, $\frac{10^2}{3} V'_{34} = (10 + 10)\, M_{3w} + 10\,(M_{2w} + M_{1w}) - 10^2\,(V'_{23} + V'_{12}) - \frac{10^2}{2}(-\,10) - \frac{10^2}{3}(-\,400) + \frac{10}{2}(8\,000) + \frac{10}{6}(602 + 366 - 10)\,(10 + 2 \times 10) - 10\,(602 \times 4 + 366 \times 8 - 10 \times 10)$; or,

$$V'_{34} = 0.6\, M_{3w} + 0.3\, M_{2w} + 0.3\, M_{1w} - 3\, V'_{23} - 3\, V'_{12} + 1\,481 \ldots (83)$$

Substituting Equations (78) and (79) in Equations (80) and (81):

$$M_{3w} = 9.05\, M_{1w} - 10\,960 \ldots\ldots\ldots\ldots (84a)$$

and,

$$V'_{23} = 3\,021 - 2.175\, M_{1w} \ldots\ldots\ldots\ldots (84b)$$

Substituting Equations (78), (79), and (84), in Equations (83) and (82):

$$M_{4w} = 51\,090 - 43.45\, M_{1w} \ldots\ldots\ldots\ldots (85a)$$

and,

$$V'_{34} = 10.32\, M_{1w} - 12\,648 \ldots\ldots\ldots\ldots (85b)$$

By means of these substitutions, all the values of M_w and V' are expressed in terms of M_{1w}.

Now, consider the truss turned end for end as shown in Fig. 9, and write a corresponding series of expressions, beginning with the first panel on the left, as before. Functions for the truss in this reversed position will be designated by the prime mark (′ ″). The coefficients for all terms will be the same as for the truss in its original position. The only difference in the calculations is that the values of H_w, M_b, and V_{ab}, of course, must be those for the reversed position. Because of this similarity, the detailed calculations are

omitted in this case and only the final equations are given. Applying Equations (75) and (77) to the first panel, gives:

$$M'''_{2w} = 2\,990 - 2.25\, M'''_{1w} \qquad \text{(86a)}$$

and,

$$(V'_{12})''' = 0.42\, M'''_{1w} - 63.04 \qquad \text{(86b)}$$

Applying Equations (74) and (76) to the second panel:

$$M'''_{3w} = -\,2.6\, M'''_{2w} - M'''_{1w} + 10\,(V'_{12})''' + 2\,274 \qquad \text{(87a)}$$

and,

$$(V'_{23})''' = 0.54\, M'''_{2w} + 0.3\, M'''_{1w} - 3\,(V'_{12})''' + 245 \qquad \text{(87b)}$$

Applying Equations (74) and (76) to the third panel, gives:

$$M'''_{4w} = -\,3\, M'''_{3w} - M'''_{2w} - M'''_{1w} + 10\,(V'_{23})''' + 10\,(V'_{12})''' + 420 \qquad \text{(88a)}$$

and,

$$(V'_{34})''' = 0.6\, M'''_{3w} + 0.3\, M'''_{2w} + 0.3\, M'''_{1w} - 3\,(V'_{23})''' - 3\,(V'_{12})''' + 481 \qquad \text{(88b)}$$

Substituting Equations (86) in Equations (87):

$$M'''_{3w} = 9.05\, M'''_{1w} - 6\,130 \qquad \text{(89a)}$$

and,

$$(V'_{23})''' = 2\,049 - 2.175\, M'''_{1w} \qquad \text{(89b)}$$

Substituting Equations (86) and (89) in Equations (88):

$$M'''_{4w} = 35\,680 - 43.45\, M'''_{1w} \qquad \text{(90a)}$$

and,

$$(V'_{34})''' = 10.32\, M'''_{1w} - 8\,258 \qquad \text{(90b)}$$

It is obvious that $M_{3w} = -\,M'''_{4w}$ and that $M_{4w} = -\,M'''_{3w}$. Equating the values for these functions as given in Equations (84), (85), (89a), and (90a):

$$9.05\, M_{1w} - 10\,960 = -\,35\,680 + 43.45\, M'''_{1w} \qquad \text{(91a)}$$

and,

$$51\,090 - 43.45\, M_{1w} = -\,9.05\, M'''_{1w} + 6\,130 \qquad \text{(91b)}$$

Solving Equations (91a) and (91b) the following values are obtained: $M_{1w} = 1\,206$; and, $M'''_{1w} = 820$. The remaining moments and shears may now be found by substituting these values in Equations (78), (79), (84), (85), (86), and (89). This gives the following results: $M_{2w} = 1\,460$; $M_{3w} = -\,50$; $M_{4w} = -\,M'''_{3w} = -\,1\,290$; $M_{5w} = -\,M'''_{2w} = -\,1\,150$; $V'_{12} = 420$; $V'_{23} = 399$; $V'_{34} = -\,205$; $V'_{45} = -\,(V'_{23})''' = -\,265$; and, $V'_{56} = -\,(V'_{12})''' = -\,281$.

The q_w-values are determined directly from the V'-values, giving: $q_{1w} = -420$; $q_{2w} = 21$; $q_{3w} = 604$; $q_{4w} = 60$; $q_{5w} = 16$; and $q_{6w} = -281$. This completes the analysis of the truss. With the values of H_w, M_w, and V' known, the stresses at all points in the truss may be calculated.

SPECIAL APPROXIMATIONS

Only general methods of solution have been illustrated in Examples 1 to 5. There are various places where short-cut methods of computation or, in special cases, further simplifications may be applied. Furthermore, the general equations may be solved by successive approximations.

For example, the values of H_w may be obtained by successive approximations, as follows: Equations (10) and (53) are of the form shown in Equation (13). Assume the location of the points of contraflexure in Panel bc and calculate the value of H_{bc}. Then, substituting the relation, $H_{bw} = H_{bc} - \sum_{1}^{a} H_w$, into Equation (13) an expression of the form, $H_{aw} = C' \sum_{1}^{a-1} H_w + C''$, is obtained. Starting with an end panel, an equation of this form may be set up and solved for each panel in turn, since $\sum_{1}^{a-1} H_w$ is known from the preceding calculations. The operations may then be repeated using for H_{bc} the results of the first approximation. Similarly, Equations (66) and (68) may be solved by successive approximations by assuming a value for M_{bw}. A good assumption for a first approximation is $M_{bw} = \frac{1}{2} D_b H_{bw}$.

Professor Vierendeel uses an approximate method for calculating the chord moments and shears[12] which is very rapid. Equations (48) and (50) are expressions for these functions. After determining the values of the H_w-values from Equation (53), the only unknowns in these expressions are α and β. By assuming values for these ratios, the desired moments and shears may be obtained quickly. Professor Vierendeel uses the assumption that $\alpha = \beta = \frac{I'_C}{I''_C} \frac{L}{L_i}$. It is obvious that this assumption greatly simplifies the work in comparison with the method used in Example 5. Experience in analyzing many trusses has shown that this approximation gives results which are sufficiently accurate for most designs. The only serious errors that occur as a result of using this method are in the values for the moments and shears in one or two panels at the ends of some trusses. For such cases a close approximation may be secured by combining the general method presented in this paper with Vierendeel's method; that is, use the former to obtain the moments and shears in the first two panels and the latter for the remainder of the truss.

EFFECT OF AXIAL STRESS

The effect of deformation due to axial stress in the chord members upon the H_w-values may be taken into account by the addition of two terms

[12] "Cours de Stabilité des Constructions", Tome IV, by Arthur Vierendeel, Louvain, 1920.

to Equation (53). Refer to Equation (21) which is the expression for the horizontal deflection in the lower part of a typical panel. The deflection due to direct stress in the lower chord is obviously $\frac{H_{ab}\,L}{A''\,E} = \frac{L\sum\limits_1^a H_w}{A''\,E}$. The total deflection is obtained by adding this term to Equation (21).

Similarly, for the upper chord, the horizontal deflection due to direct stress is $-\left(\frac{L\,H_{ab}}{A'\,E} + \frac{V'_{ab}\,d}{A'\,E}\right)\frac{L}{L_t}$. Substituting for V'_{ab} its value from Equation (48), these terms become:

$$-\left[\frac{L\sum\limits_1^a H_w}{A'\,E} + \frac{\alpha\,(D_b - D_a)}{(1+\alpha)\,A'\,E}\,V_{ab} + \frac{(D_b - D_a)^2}{(1+\alpha)\,L\,A'\,E}\sum_1^a H_w\right]\frac{L}{L_t}$$

Adding these terms to Equation (27), the total horizontal deflection for the upper chord is obtained.

Adding these terms to Equations (21) and (27) and carrying them through all the operations to Equation (53), they become, in the final stage:

$$\frac{12\,I_b}{A'\,D^3_b}\left\{\sum_1^a H_w\left[\frac{L\,A'}{A''} + \frac{L^2}{L_t} + \frac{(D_b - D_a)^2}{L_t\,(1+\alpha)}\right] + V_{ab}\left[(D_b - D_a)\frac{L}{L_t}\left(\frac{\alpha}{1+\alpha}\right)\right]\right\}$$

By adding this expression to the right-hand side of Equation (53), the effect of direct stress is included in the solution. This is equivalent to slightly increasing the numerical values of the coefficients of the original terms, involving $\sum\limits_1^a H_w$ and V_{ab}. In most cases, the change is small and may be neglected. In applying the foregoing term, it should be noted that I and A must be in the same units as D and L.

For trusses with symmetrical chords the effect of axial stresses may be included in a similar manner.

The deformation of the web members due to axial stress could be included in Equation (37), but this effect is generally so slight as to be negligible.

Conclusions

In summary, the following conclusions regarding this method of analyzing Vierendeel trusses and its limitations are noted:

(1) All the equations derived are based upon the principles of virtual work and are, therefore, "exact"; that is, they include no more assumptions or limitations than the basic elastic theory;

(2) The solution of the equations for trusses with symmetrical chords requires no assumptions and is, therefore, "exact";

(3) The solution of the equations for trusses with inclined upper chords involves an assumption of values for α and β, and, therefore, is approximate;

(4) The method of analysis presented in this paper, although not extremely rapid or simple, is reasonably so, and gives results that are sufficiently accurate for good design; and,

(5) A large part of the labor involved in the analysis is in the evaluation of the coefficients and setting up an equation for each panel. This part of the solution depends only upon the truss dimensions. Therefore, in investigating the effect of different loadings to obtain influence lines, this part of the analysis is the same for all cases, and so need be performed only once.

In any particular solution, the numerical effect of Assumption (3) upon the value of the coefficients is immediately evident and its effect upon the results may be estimated. In cases where the assumption has a large effect upon coefficient values, this method should be used with caution. In designing it is possible to assume such relative values for the moments of inertia of the members that the effect of the assumption is negligible or even nil.

ACKNOWLEDGMENTS

Grateful acknowledgment is due Professor Arthur Vierendeel for his kind assistance in investigating this form of truss and for furnishing much invaluable data regarding the bridges which he has designed.

APPENDIX I

NOTATION

The following symbols, defined where first introduced in the paper, are re-arranged herein for convenience of reference: In general, single primes denote upper chord values; double primes denote lower chord values; and triple primes denote values for the truss in a reversed position.

A = area; A' = cross-sectional area of an upper chord member; A'' = cross-sectional area of a lower chord member;

a = a subscript; Subscripts a, b, and c, denote three successive panel points (see Fig. 1), and are used to designate the location of the various functions; for example, V'_{ab} = vertical shear in the upper chord between Panel Points a and b; M''_{bc} = bending moment at Point b in the lower chord member, bc; that is, the member extending between Panel Points b and c; M_b = external moment at Point b; H_{aw} = shear in web member at Panel Point a;

b = a subscript (see a);

C = a constant; as a subscript to the moment of inertia, C denotes "chord member";

c = a subscript (see a);

D = depth of a truss at a given panel point (designated by subscript); length of a web member transverse to the longitudinal axis of a truss;

d = drop in chord between panel points; for trusses with only the upper chord inclined, $d = D_b - D_a$; for trusses with symmetrical chords, $d = \frac{1}{2}(D_b - D_a)$;

E = modulus of elasticity;
H = in general, a horizontal force; a horizontal component of axial compression or tension in a chord member; H_w = the total transverse shear in a web member; $\sum_1^a H_w$ = the sum of the H_w-values from Panel Point 1 to Panel Point a, inclusive; H_{aw} = the shear in a web member at Point a;
I = moment of inertia; I'_C and I''_C = moments of inertia of the upper and lower chord members, respectively; I_a and I_b = moments of inertia of the web members at Panel Points a and b, respectively;
i = a subscript denoting "inclined";
L = length of a panel; L_i = length of an inclined chord member;
M = external moment, considered positive when the external forces on that part of the truss to the left of the point of moments have a clockwise moment about that point. Internal moments and forces are considered positive when they act in the direction shown in the illustrations; M' and M'' = bending moments in the upper and lower chord members, respectively; M_{aw} = bending moment at Point C on the upper end of web member (at the panel point, a); M_{bw} = bending moment at Point D on the upper end of web member (at the panel point, b);
P = an external, concentrated load; P_a, P_b, and P_c, are, respectively, loads suspended from Panel Points a, b, and c;
q_w = total axial tension or compression in a web member;
V = total external shear; V'_{ab} = vertical shear in the upper chord between Panel Points a and b; V'' = vertical shear for the lower chord; the external shear, V, is considered positive when the resultant of the external forces on that part of the truss to the left of the point under consideration, acts upward. Internal moments and forces are considered positive when they act in the direction shown in the illustrations;
w = a subscript denoting "web";
x = a distance measured parallel to the X-axis;
y = a distance measured parallel to the Y-axis;
α = a measure of bending moment ratios $= \dfrac{M'_{ab} + M'_{ba}}{M''_{ab} + M''_{ba}}$;
β = a measure of bending moment ratios $= \dfrac{M'_{ba}}{M''_{ba}}$;
Δ = deflection; Δ_x = horizontal deflection; Δ_y = vertical deflection:
θ = angular deflection; θ_A = angular deflection at Point A;
ϕ = ratio of stiffness, top and bottom chords $= \dfrac{L_i I''_C}{L I'_C}$.

DISCUSSION

L. J. MENSCH,[13] M. AM. SOC. C. E. (by letter).—From his splendid analysis of open-web trusses and bents Professor Vierendeel developed practical design formulas which relieve the structural engineer from the necessity of deep thinking when designing such structures. Why then has this practical method been ignored by American engineers, and by many European engineers? Professor Young's paper gives an answer to this question. The analysis is difficult to follow; there is a bewildering number of unknowns shown in Fig. 2, and in Fig. 5; in the absence of adequate explanations the directions of the unknown moments and shears are difficult to trace; and the reason for Δx being zero is rather difficult to find. The most serious obstacle to the proper understanding of the analysis is the omission of diagrams showing the deformation of the truss members under the assumed loading. The fact that Professor Young begins with a rather difficult case is another impediment.

The object of this discussion is to make it easy for the young engineer to grasp Professor Vierendeel's thoughtful conception by describing step by step how the simple open-web truss with symmetrical parallel chords deforms. Fig. 11(a) shows the typical deformation of every member of such a truss or bent, and the reader who has followed the latest discussions on wind-bracing bents will be surprised by the coincidence of the deformations. On account of the symmetry it is not difficult to see that the point of contraflexure of the web members must be in the center of the spans. As a rule, the points of contraflexure of the chords will not be in the center of the panels, but will be near the support or free ends, farther from the end than the center line of the panel, and will be found farther to the left in the panels near the center line of the truss or near a fixed end, as will be shown in detail subsequently.

Fig. 11(b) shows part of a half truss cut along the horizontal center line. In order to re-establish equilibrium it is necessary to apply, at each point of contraflexure of the web members, one-half the force acting at each panel point, this force being in the direction of the web member; and in order to prevent confusion in the signs of these forces, all forces, P, have been assumed to act in the same direction as in a wind-bracing bent. At the same points of contraflexure in the web members it is also necessary to apply the shear forces, H_1, H_2, H_a, etc., in a direction such that they will cause a curvature of the web member, as shown in Fig. 11(a).

By inspecting Fig. 11(b) one can readily see that all longitudinal forces and bending moments in each member may be found, after the statically unknown forces, H_1, H_2, etc., are known. The assumption that the longitudinal deformations of the chord members are so small that they may be neglected safely, leads peremptorily to the conclusion that the distance between the points of contraflexure of the web members is the same after, as before, the deformation of the truss.

[13] Civ. Engr. and Constructor, Chicago, Ill.

At a section, k, an infinitesimal distance from Point a in Fig. 11(b), the left part of the truss or bent will exert the following forces and moments:

A longitudinal compression $= H_1 + H_2 = \sum_{1}^{a-1} H$; a shear in an upward

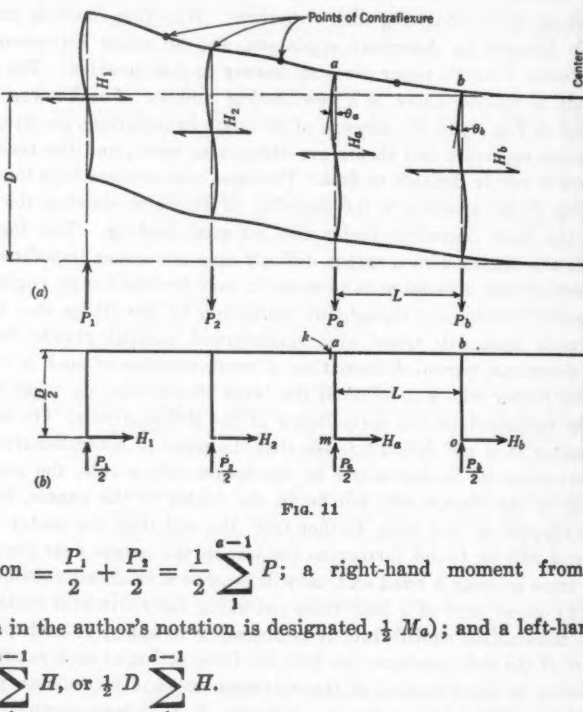

FIG. 11

direction $= \frac{P_1}{2} + \frac{P_2}{2} = \frac{1}{2} \sum_{1}^{a-1} P$; a right-hand moment from $\frac{1}{2} \sum_{1}^{a-1} P$ (which in the author's notation is designated, $\frac{1}{2} M_a$); and a left-hand moment from $\sum_{1}^{a-1} H$, or $\frac{1}{2} D \sum_{1}^{a-1} H$.

Fig. 12 shows an exaggerated picture of the deformed half-panel, a-b. If the deformation of the chords may be neglected, one may assume that m-o = m'-o'. The lines, b'-o'' and a'-m'', are drawn at right angles to the tangents at the chords at these points, and a'-m''' was drawn parallel to b'-o''.

Angles θ_a and θ_b are the rotations of the chord at a' and b', respectively, and $\theta_a - \theta_b$ is the change of angle of these rotations due to the moments acting in the chord, a-b, which may be found by the well-known formula:

$$\theta_a - \theta_b = \frac{1}{E\, I_c} \int_a^b M\, dx \dots\dots\dots\dots\dots\dots (92)$$

in which M is the moment acting at any point distant x from Point a.

The expression for M is found by adding to the moment acting at Section k: (a) The moment from the shear force acting at k, or $\frac{x}{2} \sum_{1}^{a-1} P$;

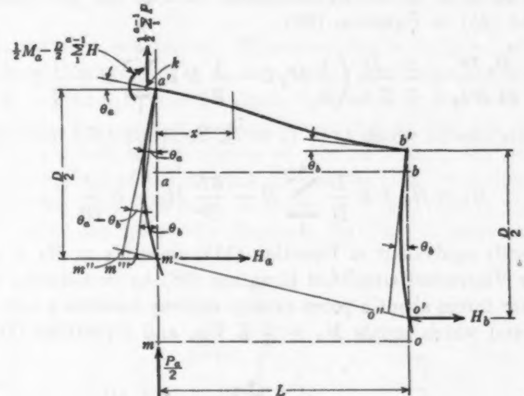

FIG. 12

(b) the moment from $\frac{1}{2} P_a$, or $\frac{1}{2} P_a x$; and (c) the moment from H_a, or $\frac{1}{2} D H_a$, which acts in the opposite direction. Moments (a) and (b) may be contracted to $\frac{x}{2} \sum_{1}^{a} P$, so that:

$$M = \frac{1}{2} M_a - \frac{1}{2} D \sum_{1}^{a-1} H + \frac{x}{2} \sum_{1}^{a} P - \frac{1}{2} D H_a$$

$$= \frac{1}{2} M_a - \frac{1}{2} D \sum_{1}^{a} H + \frac{x}{2} \sum_{1}^{a} P \quad \ldots\ldots\ldots\ldots\ldots (93)$$

and,

$$\theta_A - \theta_B = \frac{1}{E I_c} \int_0^L \left(\frac{1}{2} M_a - \frac{1}{2} \sum_{1}^{a} H + \frac{x}{2} \sum_{1}^{a} P \right) dx \; \ldots . (94)$$

In the author's notation, $\sum_{1}^{a} P = V_{ab}$, and,

$$\theta_A - \theta_B = \frac{1}{E I_c} \left(\frac{L}{2} M_a - \frac{D L}{2} \sum_{1}^{a} H + \frac{1}{2} V_{ab} \frac{L^2}{2} \right) \ldots\ldots (95)$$

For the movements, o'-o'' and m'-m'', the author gives the correct values in Equations (2), and the elastic equation which enables one to find the indeter-

minate values of the horizontal shear forces is obtained by,

$$m'\text{-}m'' = m''\text{-}m''' + m'''\text{-}m' = \frac{1}{2}\, D\,(\theta_A - \theta_B) + o'\text{-}o'' \quad \ldots\ldots(96)$$

o'-o'' being equal to m'-m''' by inspection of Fig. 12. Substituting Equations (2) and (95) in Equation (96):

$$\frac{H_a\, D^3}{24\, E\, I_a} = \frac{H_b\, D^3}{24\, E\, I_b} + \frac{1}{2}\,\frac{D}{E\, I_c}\left(\frac{1}{2}\, M_a\, L - \frac{1}{2}\, D\, L \sum_1^a H + \frac{1}{2}\, L^2\, \frac{1}{2}\, V_{ab}\right) \ldots(97)$$

In the rare case in which $I_a = I_b = I_c$, Equation (97) reduces to:

$$H_b = H_a + 6\,\frac{L}{D}\sum_1^a H - \frac{6\,L}{D^2}\, M_a - 3\,\frac{L^2}{D^2}\, V_{ab} \quad \ldots\ldots\ldots(98)$$

which is exactly equivalent to Equation (11), since $M_b = M_a + L\, V_{ab}$.

Professor Vierendeel simplified Equation (98) by introducing the moment of the exterior forces about a point exactly midway between a and b, which he called $M^b{}_a$, and which equals $M_a + \frac{1}{2}\, L\, V_{ab}$, and Equations (11) and (98) reduce to:

$$H_b = H_a + 6\,\frac{L}{D}\sum_1^a H - \frac{6\, L\, M^b{}_a}{D^2} \quad \ldots\ldots\ldots\ldots\ldots(99)$$

For the more practical case in which the moments of inertia of the various members are different as long as the I-value of the chords in each particular panel are alike due to the assumption of symmetry, the writer has used the equation:

$$\frac{I_a}{I_b}\, H_b = H_a + 6\, n \sum_1^a H - 6\,\frac{n}{D}\, M^b{}_a \quad \ldots\ldots\ldots\ldots(100)$$

which he derived from Equation (97) by introducing the relative stiffness of the web member to the chord in Panel ab:

$$n = \frac{I_a}{D} \div \frac{I_c}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(101)$$

The writer remembers that, when he first studied Professor Vierendeel's analysis, he had some difficulties with the statement that H is to be set to zero at the base of a fixed bent, even where no shear member exists. Fig. 12 shows that, in this particular case, Point o'' returns to Point o'; Point m''' returns to Point m'; and Equation (96) must be replaced by:

$$m'\text{-}m'' = \frac{1}{2}\, D\, \theta_a \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(102)$$

The first term is, again, $\dfrac{H_a\, D^3}{24\, E I_a}$, and the second term is given again by Equation (95). Therefore, it is clear that the term of H_b must really be set equal to zero in Equations (11), (97), (98), (99), etc., when it is used in the lowest panel of a fixed bent even where no web member exists.

Another difficulty encountered by students when they first try to apply this analysis occurs at the base when the ends are hinged; the solution is easy as the sum of all H-values must be equal to the reaction, which, in this particular case, is given by $\frac{M_b}{D}$. Often, there are solid walls as web members at the support of open web trusses. This case, also, is easily solved by omitting the first term in Equation (97), I_a being many hundred times larger than I_b.

American engineers should be vitally interested in Professor Vierendeel's analysis as it is the quickest method known for finding the moments and shears in the top and bottom stories of a wind-bracing bent, in which the points of contraflexure of the columns may not be near the middle of the story height or may be entirely absent, as shown in Fig. 11(a) in the panel near the center line of the truss. To illustrate, let Fig. 13 represent a six-story

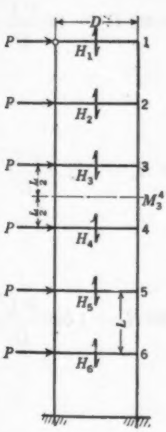

FIG. 13

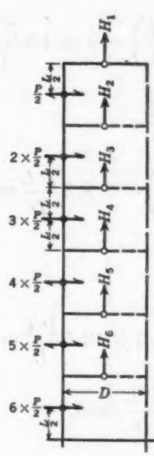

FIG. 14

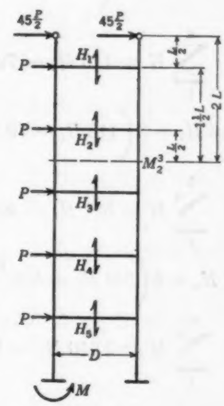

FIG. 15

wind-bracing bent. A force, P, is acting at each floor and the assumption is made that all columns have the same length, L, and the same moment of inertia, I_c, and that all girders have the same moment of inertia, I_a. Equation (100) becomes,

$$H_b = H_a + 6\,n \sum_{1}^{a} H - 6\,\frac{n}{D}\,M^b{}_a \ldots\ldots\ldots\ldots\ldots (103)$$

When the relative stiffness of girders and columns is $n = \frac{1}{2}$, for example,

$$H_b = H_a + 3 \sum_{1}^{a} H - \frac{3}{D}\,M^b{}_a \ldots\ldots\ldots\ldots\ldots\ldots (104)$$

The values of M'_a for the various panels from the top down are easily found as $P\,L$ times 0.5, 2, 4.5, 8, 12.5, and 18, and one can write the elastic equations as follows:

$$H_2 = H_1 + 3\,H_1 - \frac{3\,P\,L}{2\,D} = 4\,H_1 - 1.5\,\frac{P\,L}{D} \;\ldots\ldots\ldots (105a)$$

and, $\sum_1^2 H = 5\,H_1 - 1.5\,\frac{P\,L}{D};$

$$H_3 = H_2 + 3\left(5\,H_1 - 1.5\,\frac{P\,L}{D}\right) - \frac{6\,P\,L}{D} = 19\,H_1 - 12\,\frac{P\,L}{D} \,.\,(105b)$$

and, $\sum_1^3 H = 24\,H_1 - 13.5\,\frac{P\,L}{D};$

$$H_4 = H_3 + 3\left(24\,H_1 - 13.5\frac{P\,L}{D}\right) - 3 \times 4.5\,\frac{P\,L}{D} = 91\,H_1 - 66\,\frac{P\,L}{D} \,.\,(105c)$$

and, $\sum_1^4 H = 115\,H_1 - 79.5\,\frac{P\,L}{D};$

$$H_5 = H_4 + 3\left(115\,H_1 - 79.5\,\frac{P\,L}{D}\right) - 3 \times 8\,\frac{P\,L}{D} = 436\,H_1 - 328.5\,\frac{P\,L}{D} \,.\,(105d)$$

and, $\sum_1^5 H = 551\,H_1 - 408\,\frac{P\,L}{D};$

$$H_6 = H_5 + 3\left(551\,H_1 - 408\frac{P\,L}{D}\right) - 3 \times 12.5\frac{P\,L}{D} = 2\,089\,H_1 - 1\,590\,\frac{P\,L}{D} \,.\,(105e)$$

and, $\sum_1^6 H = 2\,640\,H_1 - 1\,998\,\frac{P\,L}{D}$; and,

$$H_7 = 0 = H_6 + 3\left(2\,640\,H_1 - 1\,998\,\frac{P\,L}{D}\right) - 3 \times 18\,\frac{P\,L}{D}$$

$$= 10\,009\,H_1 - 7\,638\,\frac{P\,L}{D} \;\ldots\ldots\ldots\ldots\ldots\ldots (105f)$$

Whence,

$$H_1 = 7\,638\,\frac{P\,L}{10\,009\,D} = 0.76311\,\frac{P\,L}{D} \;\ldots\ldots\ldots\ldots\ldots (106)$$

Substituting Equation (106) in Equations (105a) to (105f), the other indeterminate shear values, H_2, H_3, etc., may be found quickly.

Values of H $\left(\text{to be multiplied by } \frac{P\,L}{D}\right)$ in a six-story bent, for ratios of $n = \frac{1}{10}, \frac{1}{6}, \frac{1}{2}$, and 1, are given in Table 1.

TABLE 1.—VALUES OF H IN TERMS OF $\frac{PL}{D}$

Relative stiffness, n	H_1	H_2	H_3	H_4	H_5	H_6
$\frac{1}{10}$	1.282	1.75	2.38	2.91	3.08	2.42
$\frac{1}{8}$	1.09	1.68	2.45	3.17	3.56	3.01

Common theory	0.50	1.50	2.50	3.50	4.50	5.50

It will be interesting to compare the shear values found by Professor Vierendeel's analysis with those computed by the common theory which is based upon the assumption that the point of contraflexure of the columns is at the mid-story height. Fig. 14 illustrates this assumption and by taking moments about the juncture of column and girder the following statical equations may be written, from the top downward:

$$\frac{1}{2}P \times \frac{1}{2}L = H_1 \times \frac{1}{2}D; \text{ or, } H_1 = \frac{1}{2}\frac{PL}{D}$$

$$\frac{1}{2}P \times \frac{1}{2}L + 2 \times \frac{1}{2}P \times \frac{1}{2}L = H_2 \times \frac{1}{2}D; \text{ or, } H_2 = 1.5\frac{PL}{D}$$

$$2 \times \frac{1}{2}P \times \frac{1}{2}L + 3 \times \frac{1}{2}P \times \frac{1}{2}L = H_3 \times \frac{1}{2}D; \text{ or, } H_3 = 2.5\frac{PL}{D}$$

$$3 \times \frac{1}{2}P \times \frac{1}{2}L + 4 \times \frac{1}{2}P \times \frac{1}{2}L = H_4 \times \frac{1}{2}D; \text{ or, } H_4 = 3.5\frac{PL}{D}$$

$$4 \times \frac{1}{2}P \times \frac{1}{2}L + 5 \times \frac{1}{2}P \times \frac{1}{2}L = H_5 \times \frac{1}{2}D; \text{ or, } H_5 = 4.5\frac{PL}{D}$$

and,

$$5 \times \frac{1}{2}P \times \frac{1}{2}L + 6 \times \frac{1}{2}P \times \frac{1}{2}L = H_6 \times \frac{1}{2}D; \text{ or, } H_6 = 5.5\frac{PL}{D}$$

Comparing the values given in Table 1 it will be noted that the shear, H_1, for the top girder is entirely too small as derived by the common theory, whereas H_2 computed by the common theory nearly agrees with the values found by this analysis for $n = \frac{1}{2}$ and 1 and is only 16% at variance for $n = \frac{1}{10}$. For H_3, which is only two panels down from the top (a point of singularity), the agreement is quite remarkably close. The great variation of stiffness has scarcely any influence on the value of H_3 and it is quite permissible to compute it by the common theory. Another point of singularity is found at the bottom of the structure where the discrepancies in the shear values of H_6 are as great as for H_1 at the top. The irregularity at the bottom extends for three panels in the case of $n = \frac{1}{10}$ and $n = \frac{1}{8}$, and for two panels, or even only one panel, in the case of $n = \frac{1}{2}$ and $n = 1$.

It is interesting to compute the moment at the base of the columns for the case, say, of $n = \frac{1}{10}$. The sum of all H-values is found from Table 1 to be $13.83 \frac{P L}{D}$, whereas the moment of one-half the exterior forces about the base is $10.5\, PL$; that is, the moment at the base:

$$M = 10.5\, P L - \frac{1}{2} D \times 13.83 \frac{P L}{D} = 3.59\, P L \ldots\ldots\ldots (107)$$

which is very much larger than the value of $6 \times \frac{1}{2} P \times \frac{1}{2} L$ found by inspection of Fig. 14 by using the common theory.

The shear at the base being only $3\, P$, it requires a leverage of more than the story height to produce a moment of $3.59\, P\, L$. Therefore, there is no point of contraflexure in the lowest story for this particular case ($n = \frac{1}{10}$).

From the foregoing considerations it follows that, in a tall building bent with many stories, the shears in the girders (except, possibly, two stories at the top and two to six stories at the bottom) may be computed by the common theory; that is, by assuming ideal hinges in the columns at their mid-story heights. For the computation of H_1 and H_2 the writer uses the following short-cut: Write the elastic equations for H_2 and H_3 by using Equation (103); then compute H_3 by the common theory; and equate the two values. For example, in the case of the six-story frame, shown in Fig. 13, for $n = \frac{1}{2}$, Equation (105*b*), $H_3 = 19\, H_1 - 12 \frac{P L}{D}$, which must be equal to the value of $H_3 = 2.5 \frac{P L}{D}$ found by the common theory as given in Table 1. Therefore, $2.5 \frac{P L}{D} = 19\, H_1 - 12 \frac{P L}{D}$; and $H_1 = 0.763 \frac{P L}{D}$, which is nearly the same as the value given in Table 1.

For computing the girder shears in the lowest stories of tall bents (say, of 50 stories), the following procedure will save considerable time: At each point of contraflexure of the columns, just above the fifth story (see Fig. 15), apply one-half the wind load $\left(\text{namely, } 45 \frac{P}{2}\right)$, and then write the elastic equations of the type of Equation (103). Assuming that $n = \frac{1}{10}$, Equation (103) becomes:

$$H_b = H_a + 0.6 \sum_{1}^{a} H - 0.6 \frac{M^b{}_a}{D} \ldots\ldots\ldots\ldots\ldots (108)$$

and the values of $M^b{}_a$ for the various stories from the fifth story down, are found as $P\, L$ times 45.5, 92, 139.5, 188, and 237.5, respectively, or,

$$H_2 = H_1 + 0.6\, H_1 - 0.6 \times 45.5 \frac{P L}{D} = 1.6\, H_1 - 27.3 \frac{P L}{D} \ldots (109a)$$

$$H_3 = H_2 + 0.6\left(2.6\,H_1 - 27.3\,\frac{P\,L}{D}\right) - 0.6 \times 92\,\frac{P\,L}{D}$$

$$= 3.16\,H_1 - 98.88\,\frac{P\,L}{D} \quad \text{(109b)}$$

$$H_4 = H_3 + 0.6\left(5.76\,H_1 - 126.2\,\frac{P\,L}{D}\right) - 0.6 \times 139.5\,\frac{P\,L}{D}$$

$$= 6.616\,H_1 - 258.3\,\frac{P\,L}{D} \quad \text{(109c)}$$

$$H_5 = H_4 + 0.6\left(12.376\,H_1 - 384.5\,\frac{P\,L}{D}\right) - 0.6 \times 188\,\frac{P\,L}{D}$$

$$= 14.04\,H_1 - 601.6\,\frac{P\,L}{D} \quad \text{(109d)}$$

and,

$$0 = H_6 = H_5 + 0.6\left(26.42\,H_1 - 985.1\,\frac{P\,L}{D}\right) - 0.6 \times 237.5\,\frac{P\,L}{D}$$

$$= 29.9\,H_1 - 1\,335.2\,\frac{P\,L}{D} \quad \text{(109e)}$$

Hence,

$$H_1 = 1\,335.2\,\frac{P\,L}{29.9\,D} = 44.6\,\frac{P\,L}{D} \quad \text{(110)}$$

Equation (110) substituted in Equations (109) results in: $H_2 = 44.1\,\frac{P\,L}{D}$; $H_3 = 42.1\,\frac{P\,L}{D}$; $H_4 = 39\,\frac{P\,L}{D}$; and, $H_5 = 24.6\,\frac{P\,L}{D}$. By the common theory, the shear for the fifth floor girder is obtained by the equation, $H_1 \times \frac{1}{2}\,D = 22.5\,P \times \frac{1}{2}\,L + 23\,P \times \frac{1}{2}\,L$; or,

$$H_1 = 45.5\,\frac{P\,L}{D} \quad \text{(111)}$$

which varies only by 2% from the value in Equation (110).

The study of the two-column bent may be safely used in estimating the shear values in the girders of the upper two stories and those of the lowest two to six stories of a bent with three, four, or more columns. For this purpose an estimate of the column shears of the outside columns must be obtained by any valid method, such, for example, as the writer has indicated elsewhere.[14] Twice this shear must be considered as the load on the two-column bent and the girder shears may be computed for the irrgular panels at the top and bottom, as shown previously herein.

[14] *Journal*, Am. Concrete Inst., February, 1932; see, also, p. 438.

The shears thus found in the girders will differ from those found by the common theory, and the shears in the corresponding girders of the inside bays may be changed in the same proportion, provided there is not too great a change in the value of the corresponding value of n. Some objections may be raised to the use of the formulas for a symmetrical two-column bent to the case of a bay cut from a regular wind-bracing bent where the two columns may not be of the same stiffness. The writer has studied, thoroughly, the two-column bent with columns of different stiffness (the unsymmetrical bent), and has found that, except for the top and bottom stories, the following relation holds:

$$\frac{X_1}{X_2} = \frac{(6 + n'')}{(6 + n')} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (112)$$

in which X_1 is the shear at the left column; X_2 is the shear at the right column; n' is the relative stiffness between the girder and the left column; and n'' is the stiffness in relation to the right column. From Equation (112) one may observe at once that the shears in the columns will vary only a little when the values of n' and n'' are small, even where they differ from each other by as much as 100 per cent. For $n' = \frac{1}{8}$ and $n'' = \frac{1}{4}$, $\frac{X_1}{X_2} = 1.022$, from which it may be concluded that no great errors will be made in most cases of unsymmetrical frames when a corresponding symmetrical frame is analyzed first and the possible variation is studied later.

For end conditions the factor, 6, had better be replaced by 1 in Equation (112). If the author is correct in stating (see heading "Special Approximations") that Professor Vierendeel uses the assumption:

$$\alpha = \beta = \frac{I'_c\, L}{I''_c\, L_t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (113)$$

then the writer is convinced that Professor Vierendeel's students did not accept his analysis seriously or they would have analyzed many examples and would have found that Equation (113) "falls far from the mark"; although it does not seem to effect the results in Example 4 of the paper.

Professor Young's paper is an important contribution to American literature on structural engineering. However, it is no improvement on the 40-yr old method introduced by Professor Vierendeel. In fact, many of his practical simplifications have been omitted. The paper deserves the earnest discussion of the keenest talent in the United States because this analysis is susceptible of great simplification to the vast benefit of structural engineers, especially at this time when arithmetical methods are lauded as being preferable to a clear understanding and scientific processes.

Of course, Professor Young's analysis is not "exact" even in his own sense. He does not say whether clear spans or center-to-center spans should be used in the calculations and there is certainly a difference of at least 20% from this source alone, in most cases. There are considerable "roundings" at all the

junctures of web members and chords, and they may change the results 5 to 10 per cent. If to this is added the serious error made in all textbook rules for the design of members subject to combined loading (which are often 50% in error), it is quite probable that an investigator who tests a model to destruction which has been designed by Professor Young's "exact" method may find it 100% too strong and will declare Professor Young's method a "safe" guide.

Fig. 16 shows a 100 000-gal sprinkling tank on a 80-ft tower, built in 1911 for the Chicago City Railway Company, Chicago, Ill., and Fig. 17 shows one

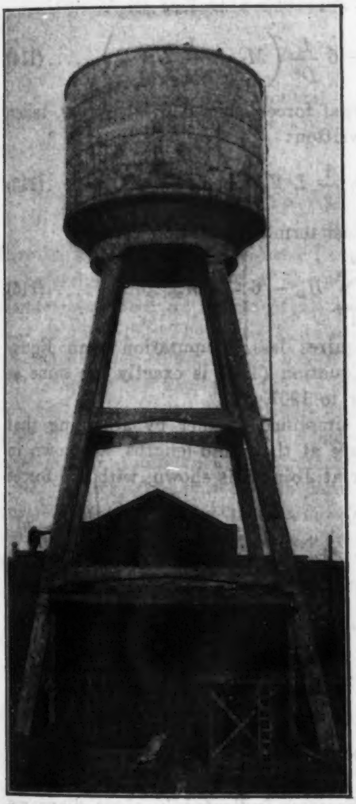

FIG. 16—VIEW OF 100 000-GALLON SPRINKLING TANK ON 80-FOOT TOWER, CHICAGO, ILL.

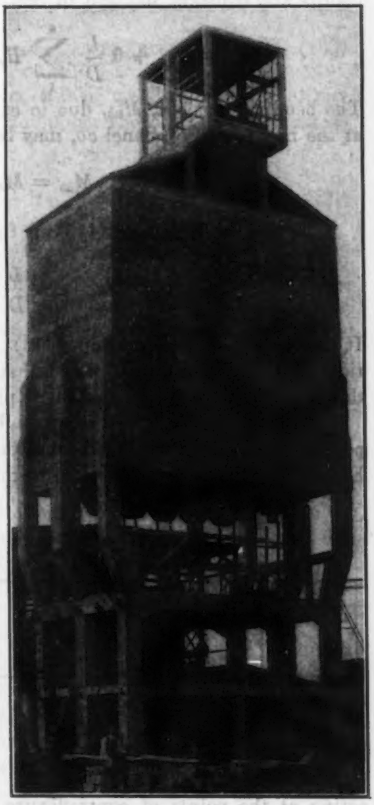

FIG. 17—VIEW SHOWING ONE OF SEVERAL OPEN-BENT STRUCTURES, COAL-BIN OF 1 900-TON CAPACITY, GRANITE CITY, ILL.

of several open-bent structures (a coal-bin of 1 900-ton capacity, 142 ft high) built for the St. Louis Coke and Chemical Company, in 1919, at Granite City, Ill. The latter is probably the most unusual Vierendeel type of structure ever built. A large number of open-bent structures have been built in the United States.

A. A. EREMIN,[15] ASSOC. M. AM. SOC. C. E. (by letter).—Although little has been written on this subject in English, the distribution of stresses in Vierendeel trusses has been studied extensively abroad. An exact computation of these stresses is a forbidding task and, therefore, various simplified methods of computation have been developed. The advantage of a Vierendeel truss is that, for all practical purposes, stresses can be computed with reasonable accuracy for assumptions as to distribution.

The method described by the author is not simple, although it can easily be simplified. For example, in the case of a Vierendeel truss with parallel chords and constant moment of inertia, Equation (11) may be written:

$$H_{bw} = H_{aw} + 6\,\frac{L}{D}\sum_{1}^{a} H_w - 6\,\frac{L}{D^2}\left(M_b + \frac{1}{2}\,L\,V_{ab}\right) \quad \ldots\ldots (114)$$

The bending moment, M_{ab}, due to external forces carried by the truss, taken at the mid-length of Panel ab, may be written:

$$M_{ab} = M_b + \frac{1}{2}\,L\,V_{ab} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (115)$$

Substituting Equation (115) in the last term of Equation (114):

$$H_{bw} = H_{aw} + 6\,\frac{L}{D}\sum_{1}^{a} H_w - 6\,\frac{L}{D^2}\,M_{ab} \quad \ldots\ldots\ldots\ldots (116)$$

It is evident that Equation (116) requires less computation than Equation (11). It may also be noted that Equation (116) is exactly the same as that developed by Dr. F. Gebauer[16] prior to 1907.

Computation for this case may be simplified further by assuming that points of contraflexure in all members are at their mid-lengths, as shown in Fig. 18. In Fig. 19 the vertical member at Joint b is shown, with the forces

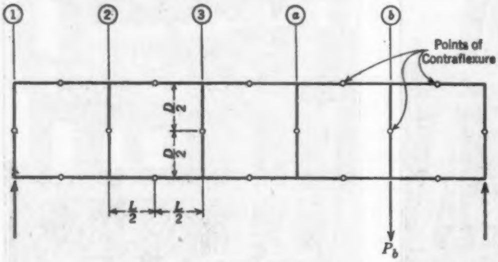

FIG. 18

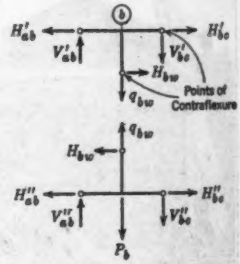

FIG. 19

acting at the points of contraflexure. Stresses indicated in these diagrams may be determined by statics. Using the author's notation, direct stresses in the chords are:

$$H'_{ab} = -\,H''_{ab} = \frac{M_a + M_b}{2\,D} \quad \ldots\ldots\ldots\ldots\ldots (117)$$

[15] Assoc. Bridge Designing Engr., Div. of State Highways, Sacramento, Calif.
[16] *Beton und Eisen*, 1907, p. 252.

The shear stresses, V'_{ab}, at the points of contraflexure in the chords at Panel ab are:

$$V'_{ab} = V''_{ab} = \frac{1}{2} V_{ab} \qquad (118)$$

The shear stresses, H_{bw}, at the point of contraflexure in vertical members at Joint b are:

$$H_{bw} = H_{bc} + H_{ab} \qquad (119)$$

The direct stress, q_{bw}, in the vertical member at Joint b is,

$$q_{bw} = V_b - P_b \qquad (120)$$

The sum of the bending moments at the ends of members meeting at any joint is equal to zero; thus, for Joint b at the upper chord, an expression may be written (see Fig. 19):

$$V'_{ab} \frac{L}{2} + V'_{bc} \frac{L}{2} - H_{bw} \frac{D}{2} = 0 \qquad (121)$$

Equation (121) may also be used for checking the computations.

Referring to Example 1 of the paper, the shear stress at the end vertical member computed by means of Equation (117) is, $H_{1w} = 750$ lb; likewise, $H_{sw} = 1\,000$ lb. Therefore, it is evident that the shear stress at the end vertical member computed by means of Equation (117) differs slightly from that computed by Equation (11). The error increases toward mid-span, but will be less in Vierendeel trusses with a large number of panels. Furthermore, there is generally a greater factor of safety in verticals toward the mid-span, due to architectural requirements that vertical members be uniform.

If, in Vierendeel trusses with parallel chords, the moment of inertia of the upper chord is I_t, and the moment of inertia of the lower chord is I_b, the assumed distances of points of contraflexure in vertical members to top chords are:

$$a = D \frac{1}{1 + \dfrac{I_b}{I_t}} \qquad (122)$$

Equation (122) is similar to the formula for locating points of contraflexure developed by Professor R. Saliger.[27]

In the case of a Vierendeel truss with a curved top chord and straight bottom chord (see Fig. (5a)), a limitation of the author's method is that the true values of α and β can not be computed. In practice, the values of α and β differ slightly from unity. Furthermore, the probable error in the computation of the stresses (even with the help of modern mechanical calculating machines) is always greater than the difference between the true values of α and β and the values assumed. This is especially true in the case of Vierendeel trusses with a large number of panels.

---

[27] "Der Eisenbetonbau", 6 Aufl., Leipzig, 1933.

Equation (54) is reasonably simple and may be used for the general cases in practice. However, the computation of the moments, M_w, and the shear stresses, V', may be simplified. Assume that the points of contraflexure are at the middle of the vertical members and that the shear stress, H_w, is applied at those points. Then, the maximum bending moment, M_{aw}, in the vertical member at Joint a, is,

$$M_{aw} = H_{aw} \frac{D_a}{2} \qquad (123)$$

In Example 3 of the paper, the moments in the vertical members as computed by Equation (123) are: $M_{1w} = 601.96 \times 2 = 1\,203.92$; $M_{2w} = 366 \times 4 = 1\,464$; $M_{3w} = -10 \times 5 = -50$; $M_{4w} = -262 \times 4 = 1\,048$; and, $M_{5w} = -411 \times 2 = 822$.

The shear stress, V', may be computed from Equation (48*a*), assuming $\alpha = 1$; thus:

$$V'_{ab} = \frac{1}{2}\left(V_{ab} + \frac{d}{L}\sum_{1}^{a} H_w\right) \qquad (124)$$

Shear stresses computed by Equation (124) are: $V'_{12} = \frac{1}{2}(600 + 0.4 \times 600) = 420$; $V'_{23} = \frac{1}{2}[600 + 0.2 \times (600 - 369)] = 396.9$; $V'_{34} = -\frac{1}{2}(400) = -200$; $V'_{45} = -\frac{1}{2}[400 + 0.2\,(409 + 287)] = -269.6$; and $V'_{56} = -\frac{1}{2}[400 + 0.4\,(409)] = -281.8$.

It is evident that the moments and shear stresses determined by Equations (123) and (124), respectively, differ slightly from those computed by Equations (75) and (77) of the paper. The labor involved, however, is considerably reduced. The author is to be congratulated for his valuable and interesting contribution.

LEON BLOG,[18] ASSOC. M. AM. SOC. C. E. (by letter).—Formulas for analyzing several of the more familiar types of Vierendeel trusses are presented in this paper. As the largest part of the paper is devoted to the analysis and solution of problems dealing with the case of an inclined upper chord, the writer has confined his discussion to that phase.

Whether one will prefer to use the formulas presented by the author or the approximate equations derived by Professor Vierendeel, depends upon the exigencies of one's practice. Some engineers prefer to use formulas approximate to a known degree of accuracy and affording a speedy solution. They know full well that a liberal correction must be made to compensate for causes which make the theoretical stresses unattainable.

The main difference between the analyses of Professors Vierendeel and Young is that the former develops accurate formulas at the beginning of his study, demonstrates that they are too unwieldy for speedy solution, and, after making certain assumptions which carry conviction, evolves formulas which, although admittedly approximate, have a simple nomenclature, are easy to

[18] Asst. Chf. Structural Engr., Div. of Bridges and Structures, City of Los Angeles, Los Angeles, Calif.

apply, and, above all, are direct. No "cut-and-try" process is required. Professor Young evolves a formula for horizontal shear in the vertical members which is theoretically exact according to the postulates stipulated; but it is difficult to apply because it is not simple. It is expressed in terms of unknowns. It can only be made simple by assuming certain convenient relations between the moments of inertia of the truss members, the fulfillment of which, in practice, would be purely fortuitous. How often will ϕ equal 1? When it does not, the various moments of inertia remain in Equation (53) and the fractions containing α and β must be evaluated before that formula can be solved. The difficulty of evaluating α is indicated subsequently under the heading "Comparison of Formulas."

Using Professor Vierendeel's equations[19] the writer has made a check of the solution of Example 3 which the author solved by use of the formulas of the paper. The results of this solution are compared with that of the author in Fig. 20. All the forces are in pounds and the moments are in foot-pounds.

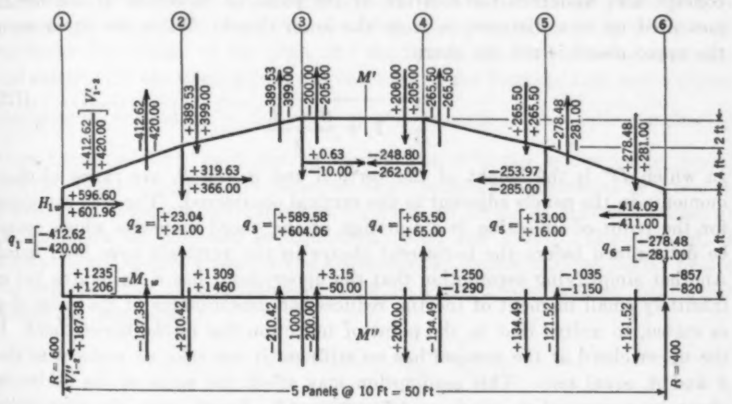

FIG. 20

Shear in the lower part of the vertical members balances the shears that are shown, and the writer's values are placed above, and to the left of, those determined by the author.

In the writer's opinion, the author did not depart essentially from the method of analysis used by Professor Vierendeel for the inclined upper chord truss. He arrived at different formulas by using the tool of least work to evaluate the relative displacements of the junctions of the verticals with the chords for two successive verticals. Professor Vierendeel based his method upon the linear and angular displacements of a point in the axis of an arch of flat curvature. He applied the formulas for these displacements to find the relative displacements of two successive verticals above a plane passed through them between the chords, and equated the displacements for the same points in the verticals below the plane. The result was an exact expression for

[19] "Cours de Stabilite des Constructions", Tome IV, by Arthur Vierendeel, Louvain, 1920, Equation (16); Equation (3) p. 194; Equation (4) p. 183; and Equations (8) and (9), p. 188.

the horizontal shear in any vertical which the author deemed to be too complex for easy and speedy solution. Making use of the relation which he had previously proved, that $\frac{M'}{M''} = \frac{I' \, dx}{I'' \, ds}$, in which M' and I' are the internal bending moment and the moment of inertia at any section of the upper chord and M'' and I'' refer to a point in the lower chord in that same section; and since $\frac{dx}{ds}$ is the cosine of the angle of slope of the panel in which the section is taken, then, letting $\frac{I' \, dx}{I'' \, ds} = \beta$, $M' = \beta \, M''$; that is, either chord moment is known when the other is known. This is the fundamental concept which underlies the derivations of formulas for the chord shears and horizontal shears through the verticals evolved by Professor Vierendeel. It is based upon the tenable assumption that the length of the verticals remains constant. This concept also underlies the location of the point of inflection of the vertical measured up to a distance, y, from the lower chord. When the curvature of the upper chord is not too sharp:

$$y = \frac{D}{1 + \frac{\beta + \beta_1}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (125)$$

in which D[20] is the height of the vertical and β and β_1 are ratios of chord moments in the panels adjacent to the vertical considered. The true expression for the point of inflection is a function of the chord moments which cannot be determined before the horizontal shears in the verticals have been found. Another simplifying assumption that the upper chord has a finite area but an infinitely small moment of inertia, reduces the denominator of the value of y, as stated, to unity; that is, the point of inflection lies in the upper chord. If the upper chord at the vertical has no stiffness it can take no moment so that β and β_1 equal zero. This assumption may affect the value of the horizontal shear in a vertical as much as 5.5 per cent.[21] Based upon the simplifying assumptions made, and proceeding from the exact analysis for the horizontal shear in a vertical, Professor Vierendeel evolved the following formula:[22]

$$H_{r+1} = \frac{H_r \, D^2_r \, (3 \, D_{r+1} - D_r)}{2 \, D^3_r} + \frac{L \, (3 \, D_r \, D_{r+1} + d^2)}{D^3_{r+1}} \sum_1^r H$$
$$- \frac{3 \, L \, (D_r + D_{r+1}) \, M_{r+1}}{2 \, D^3_{r+1}} + \frac{L^2 \, (2 \, D_r + D_{r+1}) \, V_r}{2 \, D^3_{r+1}} \quad \ldots\ldots (126)$$

The subscript, r, denotes the left-hand panel point whereas $r + 1$ denotes the one immediately to the right; H denotes the horizontal shear in the vertical; D, its height; d, the difference in heights of two successive verticals; L, the panel length; and, M and V, the external bending moment and shear, respec-

[20] "Cours de Stabilite des Constructions", Tome IV, by Arthur Vierendeel, Louvain, 1920, p. 186.

[21] *Loc. cit.*, p. 179.

[22] *Loc. cit.*, Equation (16), p. 194.

tively. Note the absence of all symbols except dimensions or forces in Equation (126) and the freedom from terms which themselves involve unknowns. Regardless of the value of H_r, $\sum_1^r H$, M_{r+1} or V_r, their coefficients are always the same and need be computed but once. Professor Vierendeel also reverses the position of the load in order to derive all the shears, as did the author.

Comparison of Formulas.—Vierendeel wrote a formula[23] for horizontal shear in vertical members as follows:

$$H_{bw} = \frac{D^3_a H_{aw}}{2 D^3_b} (3 D_b - D_a) + \frac{L}{D^3_b}\left[(3 D_b D_a) + (D_b - D_a)^2\right] \sum_1^a H_w$$

$$- \frac{3 L (D_b + D_a)}{2 D^3_b} M_b + \frac{L^2 (D_b + 2 D_a)}{2 D^3_b} V_a \text{ ....(127)}$$

in which the notation is that of the paper. It is obvious that Equation (127) is more simple than Equation (53), involving fewer terms, and including only the linear dimensions of the truss and the known external bending moments and shears. All the assumptions are involved in the formula and, assumptions that $\phi = 1$, or that $I_a = I_b = I''_c = I'_c \frac{L}{L_1}$, such as the author makes to solve Equation (53), need not be made The difficulty about using Equation (53) is that H_{bw} involves unknown chord moments represented by α and β. These chord moments are expressed, in turn, in terms of themselves and of H_w as shown by reference to Equations (50*a*) and (50*b*). The ratio, β, is known from the properties of the truss, but H_w must still be found before the moments can be determined. This is a circuitous process. Professor Vierendeel suggested[23]:

$$M''_{ba} = -\frac{M_{ba}}{1 + \beta} + \frac{D_b \sum_1^a H_w}{1 + \beta} \text{ ....(128)}$$

It is to be noted that Equation (128) differs from Equation (50*b*) in the sign convention and that $\beta = \frac{M'_{ab}}{M''_{ab}}$.

The author's formulas for chord shears, Equation (48*a*) and Equation (48*b*), are complex because they involve the upper and lower chord moments of two adjacent panels which must first be found from Equation (53) and Equation (50*b*). Such moments need not be found when using the Vierendeel formulas[24],

$$V'_{ab} = \frac{V_{ab}}{1 + \beta} + \frac{\frac{d}{L} \sum_1^a H_w}{1 + \beta} \text{ ....(129)}$$

[23] "Cours de Stabilite des Constructions", Tome IV, by Arthur Vierendeel, Louvain, 1920, Equation (9), p. 188.

[24] *Loc. cit.*, Equations (3) and (4), p. 183.

and,

$$V''_{ab} = \frac{V_{ab}}{1+\beta} - \frac{\frac{d}{L}\sum_{1}^{a} H_w}{1+\beta} \quad \ldots\ldots\ldots\ldots\ldots\ldots (130)$$

because $\frac{M'_{ab}}{M''_{ab}} = \beta = \frac{I'\,dx}{I''\,ds}$, which is a known constant and, when substituted for the easily found ΣH_w, readily yields V'_{ab} and V''_{ab}.

Discussion of Results in Fig. 20.—Fig. 20 shows a comparison of all the values found by the author with those found by the Vierendeel formulas. In addition, the writer computed the shears in the lower chord by the Vierendeel formula, Equation (130). The sum of the shears in both chords in any panel must equal the external shear at that point and yields a check on the underlying evaluations.

The maximum shear variation in the upper chord occurs in Panel 3–4 and is 2.50% less than the value given by the author. The maximum significant horizontal shear variation in any vertical occurs in q_4 and is 12.50% less than the author's value. The maximum variation in direct stress in any vertical occurs in q_5 and is 18.70% less than the author's value. The maximum significant moment variation in any vertical occurs in q_2 and is 10.30 per cent.

The term, significant, is used to exclude the values for horizontal shear and bending moment in q_3. For shear, the writer obtained + 0.63 as against the author's − 10.00. These values are both small and of opposite signs. In any practical design, they would be allowed a factor of error because of the proximity to zero which might be due to the sensitivity of both methods to the underlying assumptions. For instance, in the author's solution of Examples 3 and 4, H_{3w} each time equals − 10 lb despite his different relations between the moments of inertia. For the moments in q_3, the writer's value is + 3.15 and that of the author, − 50.00 ft-lb. The ratio of these shears and moments is about 15.9 to 1. Except for the values for q_3, the agreement between the two solutions is close.

Under the heading, "Special Approximations", the author states that "Professor Vierendeel uses an approximate method for calculating the chord moments and shears[13] which is very rapid. Equations (48) and (50) are expressions for these functions." He should have made it clear that Equations (48) and (50) are his own expressions. The corresponding Vierendeel formulas are Equations (128), (129), and (130).

Referring to Conclusion (3) of the paper, the writer agrees that the solution for a truss with an inclined upper chord although proceeding from an exact formula, must, in the last analysis, be approximate. As to Conclusion (4), the formulas proposed cannot be as rapid as those of Professor Vierendeel because the simplifying assumptions required to be made with regard to moments of inertia, ϕ, and values of α to arrive at a simpler formula (Equation (54) from Equation (53)) will not, in general, correspond

with the conditions of the problem. These difficulties are eliminated by Professor Vierendeel, who makes rational assumptions during the development of his final simple and direct formulas. The author's remarks in Conclusion (5) apply to the Vierendeel formulas, but the numerical effect of Assumption (3) is not immediately evident except for those happily selected cases, such as for $\phi = 1$, unless a solution is made by another method as a check. Appreciable errors can be made when the slopes of the upper chord vary considerably from panel to panel. Equation (53) contains too many unknowns for a rapid solution having any assured degree of accuracy. How much error is involved when ϕ does not $= 1$ and when α and β are assumed?

To those who are interested in the subject of Vierendeel trusses, the writer recommends reference to Professor Vierendeel's comprehensive treatment of trusses of various shapes and purposes as well as the design of panel joints.[12] An analysis of Vierendeel trusses by the combined Cross and Grinter methods was presented in an able paper before the International Association for Bridge and Structural Engineers.[35]

From the standpoint of rapid design, the writer does not consider the author's formulas as rapid, or as unfailingly accurate, as those presented by Professor Vierendeel.

A. W. Fischer,[36] Esq. (by letter).—The author has certainly contributed a valuable paper to the Engineering Profession on the analysis of the Vierendeel truss with either symmetrical or inclined upper chords. At first glance the theory seems rather long, but after it is studied and understood it is very simple (as are the final general equations) in application, if the theory from which they were developed is understood.

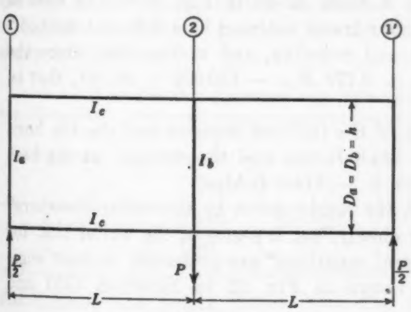

Fig. 21

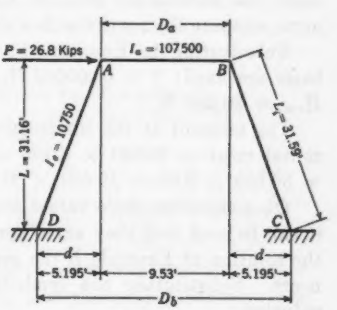

Fig. 22

Equation (10) is a general formula and solves symmetrical structures with either parallel or inclined chords in a short time.

[35] Rept. of the International Assoc. for Bridge and Structural Engrs., Vol. 3, 1935, by L. C. Maugh, Assoc. M. Am. Soc. C. E.

[36] Care, Pennsylvania Sugar Co., Philadelphia, Pa.

Example A.—For example, consider a symmetrical quadrangular bridge truss as shown in Fig. 21 which is a two-span Vierendeel truss, with parallel chords. Substituting in Equation (10):

$$H_{2w} = \frac{I_b\,H_{1w}}{I_a} + \frac{6\,L\,I_b\,H_{1w}}{h\,I_c} - \frac{6\,L\,I_b\,M_2}{h^2\,I_c} + \frac{3\,L^2\,I_b\,V_{12}}{h^2\,I_c} \quad \ldots.(131)$$

From the symmetry of the loading in this particular case, it is obvious that $H_{2w} = 0$; $M_2 = 0.5\,PL$; and $V_{12} = 0.5\,P$. Substituting in Equation (131):

$$\frac{H_{1w}}{I_a} + \frac{6\,L\,H_{1w}}{h\,I_c} - \frac{3\,L^2\,P}{h^2\,I_c} + \frac{1.5\,L^2\,P}{h^2\,I_c} = 0 \quad \ldots\ldots\ldots\ldots(132)$$

Reducing Equation (132):

$$H_{1w} = \frac{1.5\,P\,\phi\,\dfrac{L}{h}}{1 + 6\,\phi} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(133)$$

in which $\phi = \dfrac{I_a\,L}{I_c\,h}$.

The moment at the intersection of the end vertical and the top chord,

$$M = 0.5\,H_{1w}\,h = \frac{0.75\,P\,\phi\,L}{1 + 6\,\phi} \quad \ldots\ldots\ldots\ldots\ldots\ldots(134)$$

which is the same value as that given elsewhere.[27] The moments at the other joints can now readily be computed by statics.

Example B.—As another example the writer will use the top story of the bent analyzed as Example 2 in the paper and will assume the bases fixed, so as to form a symmetrical frame with inclined legs. In Equation (10) the change of the length of the various members is considered zero. Instead of using the dimensions given in Fig. 4, those shown in Fig. 22 will be used so as to compare the results with a similar frame analyzed by a different method.[28]

Substituting in Equation (10) and reducing, and noting that, since the bases are fixed: $0 = 0.005602\,H_{1w} + 2.770\,H_{1w} - 150\,900 - 66\,560$; that is, $H_{1w} = 30\,390$ lb.

The moment at the intersection of the inclined member and the top horizontal strut $= 30\,390 \times 4.765 = 144.8$ ft-kips and the moment at the base $= 30\,390 \times 9.96 - 13\,400 \times 31.16 = -\,114.8$ ft-kips.

On comparing these values with the results given by the writer elsewhere[28] it can be seen that they agree very closely, but it seems to the writer that for the solution of Example *B* the general equations[29] are preferable to most engineers. Substituting the symbols shown in Fig. 22 in Equation (10) and reducing:

$$M_{AD} = -\,\frac{P\,D_a\,\phi_t\,L\,(3\,D_a + 4\,d)}{2\left\{D_a^2\,(1 + 6\,\phi_t) + 12\,D_a\,\phi_t\,d + 8\,\phi_t\,d^2\right\}} \quad \ldots\ldots\ldots(135)$$

[27] "The Design of Steel Mill Buildings", by the late M. S. Ketchum, Hon. M. Am. Soc. C. E., Fourth Edition, Rewritten, Equation (56), p. 303.

[28] See pp. 362–364.

[29] See Equations (41) and (42), p. 364.

and,

$$M_{DA} = -\frac{P D_a L \left\{ D_a (1 + 3\phi_i) + 2\phi_i d \right\}}{2 \left\{ D_a^2 (1 + 6\phi_i) + 12 D_a \phi_i d + 8 \phi_i d^2 \right\}} \quad \ldots\ldots\ldots(136)$$

in which $\phi_i = \dfrac{I_a L_i}{D_a I_c}$.

All calculations in Example B were carried to four significant figures. If they had been carried to ten significant figures the moments would have been 144 699 ft-lb and − 115 089 ft-lb, respectively. As the results differ by a very small amount the results to four significant figures are satisfactory and, therefore, a 20-in. slide-rule will give results that are reliable.

In Example C the truss shown in Fig. 23 is analyzed to show how the results by the author's analysis for a truss with an inclined upper chord

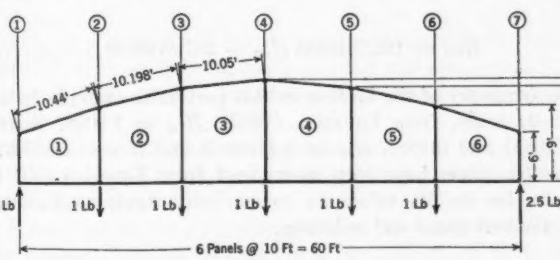

FIG. 23

compares with the results as calculated by relative deflections as proposed by Professor H. Yu.[30] The moments of inertia for all the members are equal.

The values of α and β are not known for an original design, but as the moments in the top and bottom chords have been determined by Professor Yu, these values have been used for determining the bending moment ratios, as shown in Table 2.

TABLE 2.—FACTORS FOR THE SOLUTION OF EXAMPLE C

Panel No.	Values of:				
	α	β	ϕ	$\dfrac{1+\phi\alpha}{1+\alpha}$	$\dfrac{1+\phi\beta}{1+\beta}$
1............	0.9839	0.9802	1.044	1.022	1.022
2............	1.003	0.9954	1.0198	1.010	1.010
3............	1.011	1.0	1.005	1.003	1.003

Substituting the proper values from Fig. 23, and the proper factors from Table 2, in Equation (53), and reducing:

$$H_{1w} = H_{1w} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(137a)$$

$$H_{2w} = 0.2963\, H_{1w} + 4.795\, H_{1w} - 0.6309\, M_2 + 2.944\, V_{12} \ldots.(137b)$$

[30] "Stresses in Statically Indeterminate Structures", by Prof. H. Yu, National Wuhan Univ., Wuchang, Hupeh, China, Second Edition, 1935, pp. 486–494.

$$H_{3w} = 0.5477\, H_{2w} + 4.568\, (H_{1w} + H_{2w}) - 0.4553\, M_3 + 2.201\, V_{23} . \text{(137c)}$$

and,

$$H_{4w} = 0.7703\, H_{3w} + 4.609\, (H_{1w} + H_{2w} + H_{3w}) - 0.4005\, M_4 + 1.973\, V_{34} . \text{(137d)}$$

For the loading shown in Fig. 23: $M_2 = 25$ ft-lb; $M_3 = 40$ ft-lb; $M_4 = 45$ ft-lb; $V_{12} = 2.5$ lb; $V_{23} = 1.5$ lb; and, $V_{34} = 0.5$ lb. Substituting these values in Equations (137) and then expressing each value of H_w in terms of H_{1w}:

$$H_{1w} = H_{1w} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(138a)}$$

$$H_{2w} = 5.0913\, H_{1w} - 8.4125 \ldots\ldots\ldots\ldots\ldots\ldots \text{(138b)}$$

$$H_{3w} = 30.61356341\, H_{1w} - 57.94632625 \ldots\ldots\ldots\ldots \text{(138c)}$$

and,

$$H_{4w} = 192.7543434\, H_{1w} - 367.5198853 \ldots\ldots\ldots\ldots \text{(138d)}$$

From the symmetry of the loading in this particular example, it is obvious that $H_{4w} = 0$; hence, from Equation (138*d*), $H_{1w} = 1.90667$ lb and, from Equations (138*b*) and (138*c*), $H_{2w} = 1.29493$ lb and $H_{3w} = 0.423637$ lb.

After the H_w-values have been determined from Equation (53) the next step is to solve for the M_w-values for comparison. Applying Equations (67) and (69) to the first panel and reducing:

$$M_{2w} = 19.81 - 2.469\, M_{1w} \ldots\ldots\ldots\ldots\ldots\ldots \text{(139)}$$

and,

$$V'_{12} = 0.4761\, M_{1w} - 1.171 \ldots\ldots\ldots\ldots\ldots\ldots \text{(140)}$$

Applying Equations (66) and (68) to the second panel and reducing:

$$M_{3w} = -\, 2.554\, M_{2w} - 0.9181\, M_{1w} + 9.181\, V'_{12} + 8.349 \ldots\ldots \text{(141)}$$

and,

$$V'_{23} = 0.5674\, M_{2w} + 0.3\, M_{1w} - 3\, V'_{12} + 0.6575 \ldots\ldots \text{(142)}$$

Applying Equation (66) to the third panel and reducing:

$$M_{4w} = -\, 2.669\, M_{3w} - 0.8354\, M_{2w} - 0.8354\, M_{1w} + 8.354\, V'_{12}$$
$$+\, 8.354\, V'_{23} + 5.907 \ldots\ldots\ldots\ldots\ldots\ldots \text{(143)}$$

The value of V'_{34} is not required for evaluating M_{1w}, M_{2w}, and M_{3w}, and is, therefore, not given. Substituting Equations (139) and (140) in Equations (141) and (142):

$$M_{3w} = 9.759\, M_{1w} - 53.00 \ldots\ldots\ldots\ldots\ldots\ldots \text{(144a)}$$

and,

$$V'_{23} = 15.41 - 2.529\, M_{1w} \ldots\ldots\ldots\ldots\ldots\ldots \text{(144b)}$$

Substituting Equations (139), (140), and (144) in Equation (143):

$$M_{4w} = -41.969495\, M_{1w} + 237.953072 \ldots\ldots\ldots\ldots (145)$$

From the symmetry of the loading in this particular example, it is obvious that $M_{4w} = 0$; hence, from Equation (145), $M_{1w} = 5.6697$ ft-lb. The value determined by Professor Yu is 5.6695 ft-lb. Substituting the value of M_{1w} in Equation (139) gives $M_{2w} = 5.8115$ ft-lb; Professor Yu[30] found it to be 5.8115 ft-lb. Substituting the value of M_{1w} in Equation (144a) $M_{3w} = 2.3306$ ft-lb; Professor Yu reported 2.3298 ft-lb.

From the foregoing values it is seen that the author's general equations give results that agree with those found by other methods; and they should agree, because no approximations are assumed except that in all the analysis in this discussion the change in the length of the members is considered equal to zero.

The value of M_{3w} as given is not the absolute maximum because, if there is no unit load at Panel Point 2, but unit loads at Panel Points 3, 4, 5, and 6, then the value of M_{3w} will be larger and the value given by Professor Yu is 3.3355 ft-lb.

For the symmetrical loading assumed, $M_{4w} = 0$; but if unit loads are placed at Panel Points 2 and 3, M_{4w} no longer $= 0$, and the value given by Professor Yu is -2.1459 ft-lb.

If it is assumed that the H_w-values act at the center of the vertical members, the moments are as follows: $M_{1w} = 1.90667 \times 3 = 5.7200$ ft-lb; $M_{2w} = 1.29493 \times 4.5 = 5.8272$ ft-lb; and $M_{3w} = 0.423637 \times 5.5 = 2.3300$ ft-lb. The corresponding values given by Professor Yu are: 5.7122 ft-lb; 5.8398 ft-lb; and, 2.3316 ft-lb, respectively. In this case, again, the two different methods agree very closely.

To solve for the maximum moments in all the members of a Vierendeel truss is a rather lengthy process no matter what method is used, but it appears that the author's method is as short as any.

L. C. Maugh,[31] Assoc. M. Am. Soc. C. E. (by letter).—In the United States the use of Vierendeel trusses has been opposed consistently (in print at least) for such reasons as lack of rigidity and economy or for the difficulties that are involved in the analysis, design, and construction of such monolithic structures. In actual practice, however, structures of this type have been built or, more frequently, designed as a more standardized type, such as in the bowstring and open spandrel arch, when the Vierendeel truss arrangement would sometimes be the simpler solution. This simplicity is especially noticeable when welded or reinforced concrete construction is used. The present trend in the adoption of various structural types indicates that there will be an increasing use of the quadrangular panel system by those engineers who appreciate both its advantages and disadvantages (because it certainly has both). For this reason a general discussion of some of the methods that are

[31] Asst. Prof. of Civ. Eng., Univ. of Michigan, Ann Arbor, Mich.

applicable to the analysis of the quadrangular framework will be pertinent at this time.

In the analysis of the Vierendeel truss, as in any hyperstatic frame, the engineer has the choice of two different methods of approach: One involving the strain energy of the system or its counterpart, internal and external work, and the other, the various deformation methods that use the displacement of the joints. In this paper the author has used the first method to obtain a general form for the three algebraic expressions that will provide a system of minimum strain energy, these equations being expressed in terms of the resultant internal forces acting on the vertical members. Ordinarily, there will be three of these unknown forces in each of the strain equations but, by ingenious algebraic arrangement, certain groups of equations are expressed in terms of the horizontal components of the vertical members as the only forces, and two variables, α and β, that represent the ratio between the unknown end moments of the top and bottom chords. This algebraic arrangement, which is a characteristic feature of the method of Professor Vierendeel and Professor Young, is probably as convenient and simple as any results that can be obtained by the use of energy or work theorems. In fact, the author has done exceptionally well in the development and application of this method of approach. By assuming various values of α and β, the horizontal components of stress, H, in the vertical members can be computed with sufficient accuracy; but what is true for the H and V-components, the writer believes, is not necessarily true for the bending moments in the chord members.

Small errors made in the calculation of the H and V-values (errors that can easily be made because of the necessity of carrying the computations out to many decimals, or due to the rather indeterminate quantities, α and β) may produce relatively large errors in the end moments acting on the chord members Thus, for example, in Fig. 8, the author obtained values of $H_{1w} = 601.96$ lb and $V_{12} = 420$ lb, which, if applied at the mid-point of the first vertical, gives a moment at the right end of the chord member equal to: $M_{21} = (420)\ (10) - (601.96)\ (6) = 588$ ft-lb. If an error of -3% is assumed in H_{1w} and of $+3\%$ in V'_{12}, the computed value of the chord moment will be: $M'_{21} = (1.03)\ (420)\ (10) - (0.97)\ (601.96)\ (6) = 823$ ft-lb, or an increase of 40 per cent.

In view of the fact that, for structures with top and bottom chords of different rigidity, the values of α and β are affected by this variation of the chord moments, the writer believes that it would be difficult to obtain accurate numerical results. When the top and bottom chords in the same panel have the same $\frac{I}{l}$-value, then $\phi = \alpha = \beta = 1$, and a direct solution can be made regardless of the inclination of the chord members.

For Vierendeel trusses or for any rigid frame in which the members have considerable variation in rigidity and in which the joints undergo relatively large linear displacements as well as rotation, the writer has frequently combined the use of deformation equations with auxiliary force systems to obtain a direct method of solution. With this method of approach, the various forms of successive approximations, such as the method of iteration or moment

distribution, can be incorporated. Various forms of the deformation methods are in general use, but the advantage of introducing auxiliary force systems to control the motion of the structure does not seem to be so well known.

To illustrate the use of auxiliary forces, the truss shown in Fig. 8 will be subjected to various systems that will allow only one linear displacement at a time. Thus, in Fig. 24(*a*), there is one vertical displacement Δ_1, and in

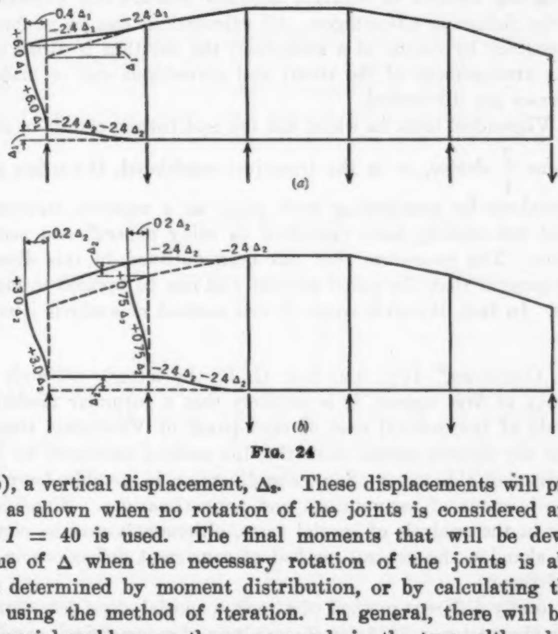

FIG. 24

Fig. 24(*b*), a vertical displacement, Δ_2. These displacements will produce end moments as shown when no rotation of the joints is considered and when a value of $I = 40$ is used. The final moments that will be developed for each value of Δ when the necessary rotation of the joints is allowed can easily be determined by moment distribution, or by calculating the angular rotation, using the method of iteration. In general, there will be as many of these special problems as there are panels in the truss although advantage can be taken of symmetry, as in the truss used by the author only three problems need be solved.

After the values of the moments that are consistent with each value of Δ have been obtained, an equilibrium equation for the moments in each panel for any desired load can be written easily. For the truss considered, with $I = 40$, the writer obtained the following set of equilibrium equations:

$$-15.62\,\Delta_1 - 1.53\,\Delta_2 - 0.276\,\Delta_3 + 0.044\,\Delta_4 - 0.004\,\Delta_5 + 6\,000 = 0 \quad (146a)$$

$$-1.65\,\Delta_1 - 7.64\,\Delta_2 + 1.64\,\Delta_3 - 0.261\,\Delta_4 + 0.042\,\Delta_5 + 6\,000 = 0 \quad (146b)$$

$$-0.272\,\Delta_1 + 1.6\,\Delta_2 - 5.96\,\Delta_3 + 1.6\,\Delta_4 - 0.272\,\Delta_5 - 4\,000 = 0 \quad (146c)$$

$$+0.042\,\Delta_1 - 0.261\,\Delta_2 + 1.64\,\Delta_3 - 7.64\,\Delta_4 - 1.65\,\Delta_5 - 4\,000 = 0 \quad (146d)$$

and,

$$-0.004\,\Delta_1 + 0.044\,\Delta_2 - 0.276\,\Delta_3 - 1.53\,\Delta_4 - 15.62\,\Delta_5 - 4\,000 = 0 \quad (146e)$$

Equations (146) satisfy all the requirements for quick convergence when solved by the method of iteration. The following values were obtained after performing the numerical calculations for five cycles: $\Delta_1 = 337$; $\Delta_2 = 583$; $\Delta_3 = -696$; $\Delta_4 = -652$; and $\Delta_5 = -180$. These relative displacements are, of course, E times the actual values. For different applied loads the only change in Equations (146) is in the constant terms.

The foregoing method of solution requires considerable numerical work, but it has the following advantages: All calculations can be performed with sufficient accuracy by means of a slide-rule; the solution is direct and accurate for any arrangement of the truss; and corrections can be made quickly whenever errors are discovered.

For the Vierendeel truss in which the top and bottom chords in each panel have the same $\frac{I}{l}$-factor, as in the truss just considered, the writer prefers to make the analysis by considering each panel as a separate structural unit. This method has already been explained in other papers[32] and need not be repeated here. The procedure that has been outlined in this discussion is much more general than the panel method and can be applied to many types of problems. In fact, the wide scope of this method of analysis is not always appreciated.

JOHN E. GOLDBERG,[33] JUN. AM. SOC. C. E. (by letter).—Slightly complex though it may at first appear, it is unlikely that a formular method for the exact analysis of the general case of open-panel or Vierendeel truss can be simplified to any greater extent than the fine method presented by Professor Young in his creditable paper Some simplification is possible, however, when cautious use is made of assumptions and approximations. Simplification is also possible in the analysis of special cases, although it may be necessary or desirable to abandon the general method of consistent deflections in favor of some special theory

Using a totally different method of attack, a special slope deflection method developed by the writer in 1933 for the analysis of symmetrical, parallel chord bents and trusses, a perfect check of Professor Young's Example 1, the frame shown in Fig. 3, was obtained. The basis of the writer's method is an exact and easily set-up working equation which gives the rotation, θ_n, of the nth panel points in terms of the rotations of the two adjacent panel points:

$$\theta_n \left(6 \frac{I_n}{D} + \frac{I'_{mn}}{L_{mn}} + \frac{I'_{no}}{L_{no}} \right) = \frac{V_{mn} L_{mn} + V_{no} L_{no}}{2} + \frac{I'_{mn}}{L_{mn}} \theta_m + \frac{I'_{no}}{L_{no}} \theta_o \quad \text{..(147)}$$

In actual use, an equation of this type is set up for each panel point along one chord, the resulting simultaneous equations then being solved by algebraic methods or by successive approximations. When successive approximations are used, the equations are reduced to the form:

$$\theta_n = A + B\,\theta_m + C\,\theta_o \quad \text{....................(148)}$$

[32] "The Analysis of Vierendeel Trusses by Successive Approximations", Publications of the International Assoc. of Bridge and Structural Engrs., Vol. 3, (1935).

[33] With Dept. of Buildings, Chicago, Ill.

For Points 1 and 2 (Fig. 3) Equation (147) yields:

$$\theta_1 (6 + 1) = \frac{1.5\ (10)}{2} + 1\ (\theta_2) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (149)$$

and,

$$\theta_2 (6 + 1 + 1) = \frac{1.5\ (10) + 0.5\ (10)}{2} + 1\ (\theta_1) \quad \ldots\ldots\ldots (150)$$

in which the shears are in kips. The simultaneous solution of Equations (149) and (150) (although the method of successive approximations using the form of Equation (148) would have been practically as easy) gives: $\theta_1 = 1.272$; and $\theta_2 = 1.409$. Final chord and cross-member moments are obtained by substituting the θ-values in the appropriate equations. For the moment at the end, n, of the chord member, n-m:

$$M_{nm} = \frac{V_{nm}\, L_{nm}}{4} + \frac{I'_{nm}}{L_{nm}} \frac{(\theta_m - \theta_n)}{2} \quad \ldots\ldots\ldots\ldots\ldots (151)$$

and, for the moment at either end of the nth cross-member:

$$M_n = -3\, \frac{I_n}{D}\, (\theta_n) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (152)$$

Thus, by Equation (152), the moment at each end of the first cross-member is $-3(1.272) = -3.816$ kip-ft, and at each end of the second cross-member, $-3(1.409) = -4.227$ kip-ft. Respective shears are, therefore, $\frac{2\ (3.816)}{10} = 0.763$ kips, and $\frac{2\ (4.227)}{10} = 0.845$ kips, which check exactly Professor Young's calculations.

Louis Baes,[34] Esq. (by letter).—The author develops the equations of his problem very skilfully, but he states, under the heading "Conclusions", that his method is based upon the principles of virtual work. The writer does not discern anywhere in the paper that these principles are involved. On the other hand, Equations (1), (21), (27), (33), and (38), which are the fundamental formulas, are merely the Bresse formulas, relating to the deflection of the mean fiber of curved members, applied to the case of rigid frames (polygonal members).

Under the heading, "Introduction to Stress Analysis", the author states that his aim is to describe a method of analysis less laborious than others actually in use in the United States. In Belgium, where a great number of Vierendeel trusses have already been built, methods of analysis much simpler than that of the paper are being used. Among others, there is a method developed by Professor Vierendeel himself and another by Professors Keelhoff and Magnel. These methods are exact, in the usual sense of this word, for symmetrical trusses; they include simplifying assumptions for non-symmetrical trusses, which is also true for the author's method.

---

[34] Prof. of Civ. Eng., Univ. of Brussels, Brussels, Belgium.

The simplifying assumptions in the paper involve the reasonable selection of the values of the two coefficients which are, in fact, the ratios between the bending moments taken by the upper chord and by the lower chord. The author rightly shows that the value reasonably assumed for these ratios only slightly affects the results. This is only true within the customary limits, but not in a general way. In fact, the author recalls that Professor Vierendeel uses the assumption that,

$$\alpha = \beta = \frac{I'_c L}{I''_c L_t} \quad \text{.......................(153)}$$

and that this assumption greatly simplifies the work. The assumptions generally made in Belgium refer to the location of the point of contraflexure in the vertical members of the truss.

The methods by Professor Vierendeel and Professors Keelhoff and Magnel assume the location of these points of contraflexure to be known and, this location being given, make the truss statically determinate in cutting it into two great combs separated from each other at the points of contraflexure in each vertical. This leads them to one equation which is the equivalent of Equation (53), but instead of the long Equations (66) and (68), they obtain only simple formulas. This results from the fact that the author does not take advantage of the location of contraflexure points, except in the case of symmetrical trusses. Consequently, he finds himself confronted by three systems of equations of the type of Equations (53), (66), and (68)

These three systems are rather long and difficult to solve and require (as has been recognized in Belgium) either very long direct numerical computations, or the use of the method of successive approximations (see Example 4 or Example 5). In fact, the results are derived from the difference between two very great numbers which differ slightly, so that if one does not compute by successive approximations, one might obtain entirely erroneous numerical results. Thus, the method suggested by Professor Young seems to be longer than those developed by Professor Vierendeel or by Professors Keelhoff and Magnel.

The writer has proved[35] that the location of the points of contraflexure in the verticals can be found with great precision by a single formula, which has been checked by more than fifty photo-elastic tests conducted on fifteen models of non-symmetrical trusses. These tests cover a considerable field, extending beyond all the needs of bridge construction, and show the points of contraflexure in the verticals remarkably well. They reveal that these points are actual physical elements on which it is logical to base the method of analysis.

Finally, the writer has shown[35] that Kriso's method may be generalized to all cases. In this method, contrary to what has been done by Professor Vierendeel or by Professor Keelhoff, the system is made statically determinate by cutting a section in one of the chords in each panel. This generalized method leads to one equation for every group of two or three successive panels separated by two successive verticals. The other equations are elementary.

[35] "La Poutre Vierendeel—Généralisation de la methode de calcul par ouverture des mailles par sectionnement d'une des membrures—Controles par la photo-élasticité", par L. Baes, *l'Ossature Metallique* (Brussels, Belgium), No. 10, October, 1936.

The only long computation is in the solution of the system of these special equations, which are equal to the number of panels. This solution, however, does not involve any difficulty and the equations may well be compared to the three-moment equations of the continuous beams.[36] Each unknown is obtained by an expression in which all the terms have the same sign. This is very important in that it permits computation by slide-rule. On the other hand, it is impossible to make any error in sign. In fine, it must be noted that by this method the designers very easily, can determine the influence lines of all the variables in the problem. For the ordinary cases of bridges, influence lines show that computations may be limited to the case of one or two conditions of loading.

To the writer, this is the shortest method; it is "exact" for symmetrical trusses, and almost "exact" for the others since from experimental proofs[35] of this essential fact, the location of the points of contraflexure is known quite accurately.

E. C. INGALLS,[37] ESQ., AND RALPH B. PECK,[37a] JUN. AM. SOC. C. E. (by letter). —It is unusual to find a paper so carefully prepared that the derivations can be followed step by step without need for pencil and paper. The author is to be complimented for the excellent presentation of the development of his working equations.

The writers have used Professor Young's method to analyze the truss shown in Fig. 25. The relative moments of inertia assumed are indicated at

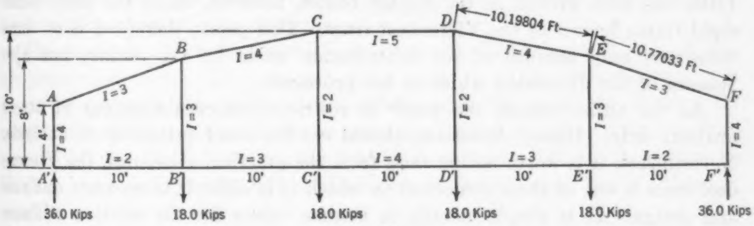

FIG. 25.

the mid-point of each member. The quantities, α and β, were each assumed to unity. The symmetry of both the truss and the loading made the labor involved comparatively slight.

To obtain a more correct analysis, involving no assumption of α and β, the writers analyzed the truss using the slope-deflection equations. Although the solution of the simultaneous equations makes the labor great, so that the writers do not recommend the slope-deflection method as a practical means of solving this truss, the problem is more general than any which they have seen solved by slope deflection. It includes a modified form

[36] "Calcul d'une poutre élastique reposant, sur des appuis inégalement espaces", par M. Clapeyron, *Comptes Rendus* des l'Académié des Sciences, Paris, Tome 45, 1857, pp. 1076 à 1080.

$M_{AA'}$ ...	−73.0	−75.4	M_{AB} ...	+73.0	+75.4	$M_{A'B'}$.	+61.8	+61.6	V'_1....	24.5	25.8
$M_{A'A}$ ...	−61.8	−61.6	M_{BA} ...	+47.6	+46.1	$M_{B'A'}$.	+42.9	+39.9	V'_2....	13.9	13.9
$M_{BB'}$ ...	−63.6	−62.2	.....	....	....	......	....	....	....	....	....

A detailed discussion of alternate methods is beyond the scope of discussion; but a comparison of results obtained by the slope-deflection method for the truss of Fig. 25, with those obtained by Professor Young's method, assuming $\alpha = \beta = 1$, is given in Table 2. The agreement is quite satisfactory.

HAROLD E. WESSMAN,[38] ASSOC. M. AM. SOC. C. E. (by letter).—There have been considerable additions in recent years to the literature of multi-story rigid frames, namely, the steel or reinforced concrete building skeleton. Little has been written in the United States, however, about the multi-panel rigid frame known as the Vierendeel truss. This paper, therefore, is of some value not only because of the contribution made by the author, but also because of the discussion which it has provoked.

As the author states, the paper is restricted to considerations of stress analysis only. Hence, discussion should confine itself primarily to analysis. Nevertheless, it is worth noting that, from the practical viewpoint, the Vierendeel truss is one of those structures in which it is difficult to separate analysis and design. It is simple enough to assume values for the relative stiffness of chords and web members in order to make an analysis of the shears, bending moments, and direct stresses; but when the designer proportions the various members on the basis of this analysis and in accordance with limiting unit stresses established by specification, and then makes a new analysis based on correct values of relative stiffness, he finds that the resulting shears, moments, and direct stresses may be radically different from those obtained in the first analysis. The normal procedure is to revise the design in accordance with the new values, but then, when the process of analysis is again repeated, considerable variations may again be found. In other words, the analysis is so sensitive to changes in sections, that it is almost impossible to obtain the final design in one or two trials, unless it is recognized that excess section must be used for some members.

[38] Associate Prof. of Structural Eng. and Mechanics, Coll. of Eng., Univ. of Iowa, Iowa City, Iowa.

Here, again, the designer faces the questions: "From where does one start? Can one use the same limiting unit stresses in all members or must one 'waste' material in order to get a design that conforms to the analysis?" This particular problem is another one which emphasizes the need for research in preliminary design methods, research in which analysis and design are more closely correlated.

From the standpoint of elementary mechanics, the author's paper is of value in illustrating the statics of free body diagrams. From the standpoint of advanced structural analysis, the paper is of value in illustrating the application of virtual work equations to satisfy the condition that there must be no relative translation, horizontally or vertically, or any relative rotation at a cut section in a continuous structure. The writer feels, however, that the author's presentation could have been improved at certain points, although he realizes the limitations imposed by condensing a paper. For example, Equation (1) would be much clearer if the author had noted that the origin of co-ordinates for the first integral on the right side is at Point B (see Fig. 2(a)) and that the origin of co-ordinates for the second integral is at the upper right-hand corner. It is also worth noting that, although the displacement of Point B is found with respect to Point A, the absolute base of reference is the upper left-hand corner in Fig. 2(a). By fixing this corner and drawing all moment diagrams as if there were two cantilevered members, one extending down to Point A and the other extending to the right and then down to Point B, the basic equation may be easily visualized in terms of area moments.

The same criticism also applies to Professor Young's treatment of the unsymmetrical case. In Equation (21), origins of co-ordinates are not the same for each integral. In connection with this equation, it may be stated that students using area moments blindly are prone to omit the first term, $E\,\theta_c\,(D_b - D_a)$. In solving for the movement of Point D relative to Point C, the rotation of the end, C, when it is not on the same level as Point D must be considered, of course.

In the development of his equations the author emphasizes one method for the analysis of rigid frames. It is a method which is based fundamentally on setting up independent equations for all the unknowns and solving them simultaneously. Presumably, it is an "exact" method; nevertheless, in attacking the unsymmetrical case, certain approximations must be made in order to obtain a solution readily. These approximations, as the author indicates, are not necessary in the symmetrical case. It is evident from the work done by Professor Young and from the equations set up by various other investigators that the computations necessary in order to reach a final design by this method are over-burdening, especially when several analyses are required.

The writer much prefers another method for the solution of the multipanel rigid frame. It is moment and shear distribution facilitated by superimposing arbitrary joint rotations in order to hasten convergence. There

Panel Shear 500
Panel Moment 5 000

Fig. 26.

is nothing new[39] about the method, although it does not seem to be widely known, at least in the accurate sense.

The solution of the symmetrical case (see Example 1) by this method is shown in Fig. 26, in which, consistent with the notation of the paper, M_R = the moment from joint rotation; M_V = the moment from shear; M_B = the balancing moment; M_C = the moment carried over; and, ΣM = the summation of moments. Note the rapid convergence of values. For all practical purposes, the procedure could have been terminated after two cycles and the results would be sufficiently accurate. If the arbitrary joint rotations had not been superimposed upon the shear translations, however, the convergence would be much slower.

The process will not be explained in detail in this discussion. It is worth noting, however, that a sketch of panel distortions due to joint translations acts as a guide in indicating the sense of the arbitrary joint rotations. It is not necessary to impose equal rotations at all joints; it is not necessary to make all of them of the same sense; moreover, one does not need to know the actual rotation as long as the arbitrary moments at each end of each member due to rotation bear the proper ratio to one another. If the ratio is correct, geometrical continuity is preserved.

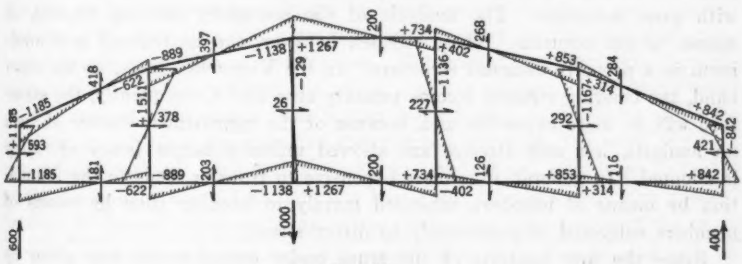

FIG. 27.

Fig. 27 shows the results from three cycles of computations when this process is applied to the author's unsymmetrical case (see Example 3). All calculations were made on a slide-rule.

This paper demonstrates to the writer that a slide-rule, combined with the proper method of attack, is a rather useful and universal instrument; it is much less expensive than a computing machine and its effect on the eyes not nearly so severe as a nine-place logarithmic table. Even if the author's results are obtained by the so-called "exact" solution of simultaneous equations, it must be kept in mind that his work also involved certain approximations. Moreover, when certain values depend upon small differences between two large values, it is evident that the large values must be determined with extreme precision to a great number of significant places in

[39] "Continuous Frames of Reinforced Concrete", by Hardy Cross and N. D. Morgan, Members, Am. Soc. C. E., pp. 229–283; in particular, footnote at bottom of p. 283.

order to obviate errors in the final result. That is one serious drawback to methods such as that used by Professor Young.

As long as procedure is scientific, however, the most important matter is not "what method was used", but rather, "how shall one interpret the results in the light of the actual design."

The alternate method cited by the writer[39] may also be used in the analysis of wind stresses in multiple-story buildings. It greatly facilitates convergence and obviates the need for extending a mathematical series to obtain the final answer.

A. Floris,[40] Esq. (by letter).—The classical methods used by the author in the analysis of the Vierendeel truss will undoubtedly divert the attention of engineers, somewhat, from the so-called arithmetical methods which have almost dominated the technical literature since the introduction by Hardy Cross, M. Am. Soc. C. E., of the moment distribution method.

The author sidesteps, wisely, the question of the merits of this type of structure. This question, however, is of great importance in practical problems involving safety and economy. Unfortunately, the Vierendeel truss is fundamentally inferior to trusses with diagonals, for the following obvious reasons. In the ordinary truss the primary direct stresses can be calculated with great accuracy. The analysis of the secondary bending stresses, of course, is less accurate. These stresses, however, can be reduced to a minimum in a properly designed structure. In the Vierendeel truss, on the other hand, the bending stresses become primary stresses. Consequently, the structure will be more expensive and, because of the approximate nature of such an analysis, less safe stresses are allowed unless a larger factor of safety is adopted. In general, it is more expensive to transfer loads to the foundation by means of members subjected mainly to bending than by means of members subjected preponderately to direct stress.

Since the first analysis of the truss under consideration was given by Professor Vierendeel[41], the problem has attracted, widely, the attention of theorists. This is obviously due to the desire to simplify the complicated, although not necessarily difficult, calculations. Theoretically, the analysis of statically indeterminate structures does not present essential difficulties. Any one familiar with such an analysis can write down the necessary equation with ease. However, the time consumed in the derivation of these expressions and their subsequent tedious numerical evaluation are serious obstacles to their use in practice.

Following the trend for greater simplicity and expediency the author gives an approximate (and, for practical purposes, sufficiently accurate) method of analyzing the Vierendeel truss. The writer does not intend to enter into a detailed discussion of this excellent paper. For a proper appreciation of the work done and the efforts made in this direction by the author and

[40] Dipl.-Ing., Los Angeles, Calif.

[41] "Longerons en treillis et longerons à arcades", par Arthur Vierendeel, Paris, 1897.

others, the available extensive literature on the subject should be studied carefully.[42]

KIMBALL R. GARLAND,[43] ESQ. (by letter).—A series of equations is presented in this paper that should be of great aid in analyzing Vierendeel trusses, and the author deserves much credit for having presented the method and results in such complete form that they can be followed through and checked. Exact methods for solving this type of truss have been lacking in American literature, and a need for such methods (which this paper will help to supply) is growing. It is unfortunate that, in spite of the careful analysis which has been made of this type of truss, the solution is still extremely laborious. In the case of the truss with horizontal bottom chords and inclined top chords, even with the equations presented, and with the simple example which was solved in the text, the labor of obtaining a result is considerable. In the case of practical design, where many other complications must be considered, and several trial designs made, many American offices, in the writer's opinion, would consider the difficulty of solution as a weighty argument against its use.

Some years ago, the writer made some comparative designs for a building foundation which was intended to be rigid enough to resist the effects of unequal soil-bearing pressure, utilizing the entire basement story as a framework. The Vierendeel truss seemed to be the proper type of design for this purpose, so that the basement might be free from the obstruction of diagonal members. On this occasion, a set of equations, such as the author has presented, would have been of great value. Not having any literature immediately available on the subject, the writer made a number of solutions based on the method of moment distribution, and found that results could be obtained of sufficient accuracy for the purpose, although the work involved was rather laborious. One design which was studied had very large haunches at the top and bottom joints, and the horizontal members were also tapered between the haunches, for economy, being thinner near the middle of the panel

[43] Newton, Mass.

where the bending was assumed to be least. This introduced a complication, in that the axis of all the horizontal members was bent in a vertical plane, so that the bending moment in these members was dependent in part on the axial stress in the chord, as well as on the shear which the panel carried. The process followed was to plot what was assumed to be the axis of each member, and determine its stiffness coefficient as if its axis were straight. Then, for the first trial analysis, it was assumed that this axis was straight, extending between the points where vertical and horizontal members intersected, and a solution was made by the method of moment distribution. The resulting axial stresses in the chords produced additional moments due to the eccentricity of the thrust, and a second moment distribution was made to correct for this. This cycle, in turn, changed the chord stresses, requiring a third correction, which seemed to have carried the process far enough. The proper method in this case would have been to substitute for the bent axis of each chord a straight axis, located so that a thrust or a tension acting along it would produce no angular displacement in either end of the member; or, in other words, through the center of gravity of the values of $y \frac{ds}{EI}$ for that member. After this is done, one analysis by moment distribution should suffice to determine the true values. Once this shifting of the axis of the member is accomplished, the author's method might be applied, although this would require further investigation. In any case, it seems as if some kind of correction should be applied where trusses have large gussets.

One uncertainty which makes it unwise to strive for too great refinement in the stress analysis of Vierendeel trusses of concrete, is the lack of knowledge regarding the tension chord. Should the reinforcement alone be computed, where both top and bottom rods are in tension, or should some weight be given to the concrete, which must certainly carry some stress, and, therefore, must add to the stiffness of the member?

As a matter of curiosity, the writer made a solution of the truss which the author solved in Examples 3 and 5 by the method of moment distribution. He made the usual assumption that every joint is held from rotating, although it may be displaced horizontally or vertically. He assumed, furthermore, that Vertical No. 3 took no horizontal shear, but that the members to the left took up all the thrust to the left, and those to the right took all the thrust to the right, due to the distortion of the inclined chords. It was then possible to write the expressions for the moments and shears in the two left panels in two simultaneous equations, and solve for the values. The same could be done for the two panels at the right. The center panel, being rectangular, was solved by inspection. The method of moment distribution was then applied. The steps would be as follows: (1) Solve for unbalanced vertical shear (two sets of short simultaneous equations); (2) balance joints; (3) carry over moments; (4) distribute the unbalanced horizontal shear among web members; and, (5) find the unbalanced vertical shear in each panel, and solve again by simultaneous equations.

The writer found that the moments converged consistently by this method, and that in five repetitions the results checked fairly closely (about 1%) with the answers given in the problem. This method, of course, was laborious. After working through the solution given in the paper for the same problem by the general method, the writer thinks that probably, for only one condition of loading, and where an accuracy of 1% is sufficient, the moment-distribution method would be as rapid as the solution by the general equations. For complete analysis of all possible conditions of loading, the general solution would save time in the end, and would give the exact results.

J. D. Gedo,[44] M. Am. Soc. C. E. (by letter).—The novelty in Professor Young's solution is that equations similar to those of the theorem of three moments may be written for the column shears. Thus, before any other unknowns are solved, the horizontal stresses are obtained from Clapeyronic equations. This is a valuable contribution.

It is surprising, however, that he under-estimates the value of the basic formulas, Equations (32), (37), and (42), in that he states: "A set of these formulas could be written for each panel and the series solved simultaneously to find the unknowns. Such a procedure, although possible, would be too laborious for practical use." As a matter of fact, Professor Young does write the three equations for each panel. Were these 3 n-equations such that they contain the 3 n-unknowns, not only collectively but also individually, the solution would be impossible in all but the simplest cases. The success of his analysis is not due entirely to the manipulation of these valuable equations; the secret is that when integrating the product of the virtual stresses and real deformations the integrations do not cover the entire structure, they extend only to the panel. Professor Young does not make any effort to explain why this is permissible; nor does he emphasize the importance of this procedure. It is true, however, that he refers to the work of J. A. Van den Broek,[8] M. Am. Soc. C. E., which contains such explanations.

Professor Young is misled when he assumes that, by solving the series simultaneously, the procedure would be too laborious for practical use. The writer has computed many Vierendeel trusses with similar elastic equations, and he has always found that it is possible to compute the influence lines of 10-panel Vierendeel trusses with horizontal or inclined upper chords in two working days, provided the truss is symmetrical about a vertical axis. With Professor Young's contribution this time is shortened by two hours.

Statements with which the writer does not agree are: That Vierendeel trusses may be built of reinforced concrete and that the effect of axial deformation is so small that it may be neglected in most cases. The example in Table 3 was computed to "throw light" on these statements and also to compare the Vierendeel truss with the closely related pinned truss and riveted truss. In the diagram of Table 3, the moments are shown on the sagging side of the system axis. The frame was designed as a Vierendeel truss and

$E = 30\,000\,000$ lb per sq in.

the sections were retained in the case of the other trusses. Two analyses were made for the Vierendeel truss. In the second analysis the axial deformations were considered not only in the chords but also in the posts. Hence, the dissymmetry between top-chord and bottom-chord stresses. Comparing the two analyses it is evident that the effect of the direct forces on the moment distribution is far too great to be negligible. It is also evident that the truss in Table 3 can not be built of reinforced concrete. The direct tension in Member 10–12 is nearly 600 kips. This force alone would require about forty 1-in. square bars. The shear in Member 3–4 is about 200 kips. Allowing 100 lb per sq in. for shear, the area of the section would be 2 000 sq in. Thus, it is easy to see that reinforced concrete is not the proper material for a Vierendeel truss except, possibly, for very small ones.

Although the subject of this paper concerns only the stress analysis, the results can not be properly interpreted without comparing the Vierendeel truss with frames that resemble it. In Table 3 it is noticeable that the moments of the Vierendeel truss are much higher than the so-called "secondary stresses" of the riveted truss. The writer has not analyzed the riveted truss by the slope deflection method, the stresses were obtained by using the same reasonings as in the case of the Vierendeel truss. The direct forces are smallest in the Vierendeel truss, higher in the riveted truss, and highest in the pinned truss. Adding the diagonal material to the chords and posts, the sections thus increased may suffice for the higher stresses in the Vierendeel truss.

Furthermore, the stresses in the Vierendeel truss can be reduced by spacing the posts closer together near the supports and farther apart near the center. In other words, the ideal spacing for the posts is similar to that of the stirrups in a uniformly loaded reinforced concrete beam. In interpreting the relatively high deflections of the Vierendeel truss, it should be borne in mind that the dimensions of both the riveted and the pinned truss are greater than necessary, in the example. No doubt, many more comparative studies are needed to arrive at a definite conclusion. Nevertheless, it is certain that the Vierendeel truss has a great future. Professor Young's contribution, therefore, is doubly meritorious, although some of his minor statements are not quite exact.

Dana Young,[45] Assoc. M. Am. Soc. C. E. (by letter).—The discussions have revealed many interesting facts. Additional examples have been presented and checked, other methods of analysis have been recommended, and several "short-cut" procedures have been proposed.

Mr. Mensch has presented an instructive application of the method to a multi-storied bent. It may be noted that Equation (97) is simply a special case of Equation (53) and may be readily obtained from the latter. Table 1, which gives a comparison of H-values obtained by the general method with those from the approximate portal method, is helpful in showing the errors that may occur from using the latter method. Mr. Mensch has also given a "short-cut" method of applying the general

[45] Asst. Prof. of Eng., Connecticut State Coll., Storrs, Conn.

equations to a specific problem. This is a good illustration of the simplifications that are practical in many cases, as was noted in the paper under the heading, "Special Approximations."

Mr. Eremin has suggested that, for trusses with parallel chords and constant moment of inertia, it is sufficiently accurate to assume points of contraflexure in all members at their mid-lengths; that is, the portal method. However, it is well known that this method is often in serious error. This fact is clearly illustrated by Mr. Mensch in Table 1. Equation (122), which is given without proof, is readily derived from statics, using the assumption that $\frac{M'_{ba} + M'_{bc}}{M''_{ba} + M''_{bc}} = \frac{I'_c}{I''_c} = \frac{I_t}{I_b}$. Although this assumption is satisfactory in some cases, it may be shown that in trusses with large differences in the moments of inertia of the chords, the error will be considerable. The approximate formulas, Equation (123) and Equation (124), especially Equation (123), which Mr. Eremin proposes—are too inaccurate for general use. Although they give good results in the particular example given, they cannot always be relied upon to do so.

Mr. Blog has presented a summary of Professor Vierendeel's method of analysis and claims that this method is simpler and more accurate than that proposed in the paper. It is true that Equations (127) through (130), inclusive, are simpler than those in the paper, but that is because the former group is based upon several assumptions. Because of these assumptions, it is not true that the Vierendeel equations are as accurate as the others. The primary assumption in the Vierendeel method is that,

$$\frac{M'}{M''} = \frac{I'\,dx}{I''\,ds} \quad \text{..........................(154)}$$

Mr. Blog states that Professor Vierendeel proves that this relation is true. However, a careful check of this derivation[9] will show that it is based on the assumption that the vertical deflection of corresponding points on the upper and lower chords of a truss are equal throughout the length of the truss. This is not true except in special cases. The fact that Equation (154) is not exact may be readily shown by a numerical example in which the moments of inertia of the chord members are not equal. Such an example has been very conveniently solved by Messrs. Ingalls and Peck in their discussion. An inspection of their results, which are given in Table 2, shows this immediately. Another assumption which Professor Vierendeel makes, as stated by Mr. Blog, is that the upper chord has a finite area but an infinitely small moment of inertia. As a result Equations (127) to (130), inclusive, involve these assumptions and, therefore, must be used with caution.

Messrs. Fischer, Goldberg, and Ingalls and Peck have added materially to the paper by developing other examples and checking by other methods of analysis.

Several of the discussions have indicated other methods of analysis. Mr. Maugh has described an interesting method using deformation equations with auxiliary force systems, which may be solved either directly or by successive approximations. This discussion contains a numerical computation which purports to show that an error of -3% in H_{1w} and of $+3\%$ in V'_{12} might cause an error of 40% in M'_{n}. This example neglects the relation that exists between H_{1w} and V'_{12} which is given by Equations (77) and (79). From these equations, it is seen that, for the condition assumed by Mr. Maugh (that is, $M_{1w} = 2H_{1w}$), the error in V'_{12} must be in the same direction as that in H_{1w} and, hence the error in M'_{n} will be much smaller than shown in his calculation. Professor Baes has referred to an ingenious method based upon the experimental determination of the point of contraflexure in each vertical member. This method appears to be very promising since experience in analysis tends to show that the position of the point of contraflexure in the vertical members varies only slightly for considerable differences in the moments of inertia of the truss members. Professor Baes objects to the statement that the fundamental equations are based upon the principle of virtual work. Unfortunately, it is true that the names of the various principles in structural mechanics are not standardized throughout the world. If this were done, the mass of current engineering literature would be considerably easier to follow. In this particular case, it is believed that the designation used is consistent with general practice in the United States.

Messrs. Wessman and Garland have applied the moment distribution method to the examples given. As these discussers have shown, although there are certain troublesome details in applying this method to a truss with inclined chords, the method is perfectly possible. In this connection, it is to be noted that the general equations given in the paper may also be solved by successive approximations, as was indicated, and will be found to converge very rapidly. Professor Wessman has raised the question as to whether the analysis of the Vierendeel truss is not so sensitive to changes in sections of members, that it is impossible to obtain a final design in one or two trials. Although such a condition is a possibility, it has been the writer's experience that no difficulty occurs in this direction in actual cases. The writer heartily agrees with Professor Wessman that analysis and design go hand-in hand" and must be considered together to insure satisfactory results, as in all good engineering.

Mr. Floris has stated that the Vierendeel truss is fundamentally inferior to trusses with diagonals. Although it is outside the scope of the paper to enter an extended argument as to the utility of this type of construction, it may be stated that the most usual form of Vierendeel truss for bridges is the bowstring type, which is very similar to a bowstring or tied arch, and possesses the advantages of this form of structure. In such cases, as mentioned by Mr. Maugh, the Vierendeel truss arrangement is often a simpler design, particularly with welded steel or reinforced concrete construction.

Mr. Gedo has presented an interesting and helpful discussion. His comparison of stresses in Vierendeel, riveted, and pin-connected trusses is very instructive. However, as mentioned previously, it would be more appropriate to compare the Vierendeel truss with a tied arch design, in order to understand best the possibilities of this form of construction. Mr. Gedo provides a refreshing contrast to some of the other discussers in that he advocates the direct solution of the general equation.

SIMULTANEOUS EQUATIONS IN MECHANICS SOLVED BY ITERATION

By W. L. Schwalbe,[1] Esq.

With Discussion by Messrs. Garrett B. Drummond, A. W. Fischer, M. B. Gamet, Marvin A. Gray, John E. Goldberg, A. Floris, and W. L. Schwalbe.

Synopsis

Iteration (meaning "repetition") stands for the process of successive approximations applied to the solution of simultaneous equations. A set of simultaneous equations may be characterized by a single equation such as, for instance, the well known equation of three moments for a continuous beam. Such an equation, with given boundary values, is easily solved by elimination or by determinants when the number of unknowns is small, say, eight or less, but requires less unwieldy methods when the number of unknowns is greater than eight. In this paper the method of iteration is applied to the equation of three moments, the equation of three angles, and the equation of five angles. All these equations occur in structural mechanics, the first two in the theory of continuous beams, and the third one in the theory of continuous frames.

The purpose in writing this paper is not to present a new method (all the subject-matter can be found in the references listed in Appendix I); but rather to aid the student in civil engineering in making a co-ordinated progress from the theory of beams in the elementary course in strength of materials to the theory of frames in the more advanced courses in structural civil engineering.

The derivations of formulas introduced are outlined separately in Appendix II and a list of symbols is arranged for convenience of reference in

Note.—Published in August, 1936, *Proceedings*.

Appendix III. In this notation an effort has been made to conform essentially with "Symbols for Mechanics, Structural Engineering, and Testing Materials"[3] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932.

Equation of Three Moments

The equation of three moments, which relates the statically indeterminate moments at three consecutive supports of a continuous beam (supports fixed and modulus of elasticity of material constant), may be written in the form:

$$\frac{M_{x-1}}{K_x} + 2\,S_x\,M_x + \frac{M_{x+1}}{K_{x+1}} = U_x \qquad (1)$$

in which M_x = the bending moment at Support x; K = a stiffness ratio, $\frac{I}{L}$; S_x = a measure of stiffness $= \frac{1}{K_x} + \frac{1}{K_{x+1}}$; and U_x = a load factor in two adjacent spans, such that:

$$U_x = -\frac{6\,Q_{x-1}}{I_x\,L_x} - \frac{6\,Q_{x+1}}{I_{x+1}\,L_{x+1}} \qquad (2)$$

in which Q_{x-1} and Q_{x+1} are, respectively, the moments of the areas below the moment diagram in Spans L_x and L_{x+1} with respect to Supports $x - 1$ and $x + 1$. The span is regarded as simply supported under the given loads.

In order to solve Equation (1) by iteration, or successive approximations, the first approximation is computed for each support, x, as:

$$(M_x)_1 = \frac{U_x}{2\,S_x} \qquad (3)$$

Substituting this value back into Equation (1) the second approximation is found to be:

$$(M_x)_2 = (M_x)_1 - \frac{1}{2\,S_x}\left(\frac{(M_{x-1})_1}{K_x} + \frac{(M_{x+1})_1}{K_{x+1}}\right) \qquad (4)$$

and so on to the nth approximation ($n = 1, 2, \ldots$):

$$(M_x)_n = (M_x)_1 - \frac{1}{2\,S_x}\left[\frac{(M_{x-1})_{n-1}}{K_x} + \frac{(M_{x+1})_{n-1}}{K_{x+1}}\right] \qquad (5)$$

Added speed of convergence is obtained if corrected values are used as soon as they are obtained, for computing the next approximation. Thus, in working from left to right over the series of supports, Equation (5) may be written as:

$$(M_x)_n = (M_x)_1 - \frac{1}{2\,S_x}\left[\frac{(M_{x-1})_n}{K_x} + \frac{(M_{x+1})_{n-1}}{K_{x+1}}\right] \qquad (6)$$

That is, the nth approximation, $(M_{x-1})_n$, is used in computing $(M_x)_n$. The proof of convergence of Equations (5) and (6) to the solution of Equation (1) is given in Appendix II.

[3] A. S. A.—Z10a—1932.

According to Equation (6) the first approximation, which is computed from the load factor, U_x, is repeatedly corrected by the factor, $\frac{1}{2\,S_x}\left[\frac{(M_{x-1})_n}{K_x} + \frac{(M_{x+1})_{n-1}}{K_{x+1}}\right]$, until the computed values remain stationary to any required degree of approximation. The correction factor is easily remembered as the sum of the products of the corrected moments on each side of a support and their corresponding $\frac{1}{K}$ - values in the two adjacent spans, divided by twice the sum of the two $\frac{1}{K}$ - values.

Case 1.—An example of a continuous beam over five supports with end moments zero, is shown in Fig. 1, including the computed values of the

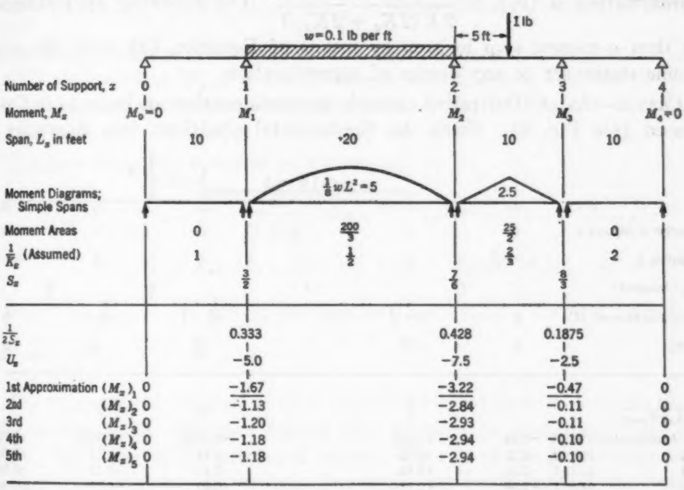

FIG. 1.

different quantities. To illustrate the use of Equation (6), the value, $(M_2)_2 = -2.84$, for $x = 2$, in Fig. 1, is computed as follows: The correction factor to the first approximation, -3.22, is $\left\{(-1.13 \times \frac{1}{2}) + (-0.47 \times \frac{2}{3})\right\} \times 0.428 = -0.38$. Then, $(M_2)_2 = -3.22 - (-0.38) = -2.84$.

As a check, the values of the three moments, computed by elimination from the three simultaneous equations which are found when Equation (1) is applied three times, are: $M_1 = -1.18$; $M_2 = -2.93$; and $M_3 = -0.10$.

EQUATION OF THREE ANGLES

The equation of three angles expresses the relation between the angles of rotation at three successive supports of a continuous beam. The equation is:

$$K_x\,\theta_{x-1} + 2\,(K_x + K_{x+1})\,\theta_x + K_{x+1}\,\theta_{x+1} = \frac{\Delta M'_x}{2\,E} \ldots\ldots (7)$$

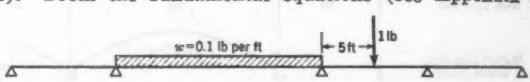
in which θ_x = angle of rotation of the beam at Support x (θ is plus (+) when clockwise); $\Delta M'_x$ = load factor = $(M'_x)_L - (M'_x)_R$; $(M'_x)_L$ = fixed-end moment at left of support, x, for the span, L_x, with given loads; $(M'_x)_R$ = fixed-end moment at right of support, x, for the span, L_{x+1}, with given loads; and E = modulus of elasticity of material.

The solution of Equation (7) by iteration proceeds in the same manner as that outlined for the equation of three moments. The approximating equation is written as:

$$(\theta_x)_n = (\theta_x)_1 - \frac{[K_x\,(\theta_{x-1})_n + K_{n+1}\,(\theta_{x+1})_{n-1}]}{2\,(K_x + K_{x+1})} \quad \ldots\ldots\ldots\ldots (8)$$

in which $(\theta_x)_n$ is the nth approximation (n = 1, 2, . . .), and the first approximation is $(\theta_x)_1 = \dfrac{\Delta M'_x}{2\,E\,(2\,K_x + 2\,K_{x+1})}$. The following approximations are then corrected step by step by means of Equation (8) until the values become stationary to any degree of approximation.

Case 2.—As an illustrative example the same continuous beam as in Case 1 is used (see Fig. 2). From the fundamental equations (see Appendix II,



Number of Support, x	0		1		2		3		4
Rotation, θ_x	$\theta_0 = -\frac{\theta_1}{2}$		θ_1		θ_2		θ_3		$\theta_4 = -\frac{\theta_3}{2}$

6th $2E(\theta_x)_6$	−0.393		+0.786		−0.493		−0.1361		+0.0681

FIG. 2.

Equations (24) and (25)), the boundary values, θ_0 and θ_4, are obtained under the assumption of no restraints at the ends, thus: $\theta_0 = -\dfrac{\theta_1}{2}$; and $\theta_4 = -\dfrac{\theta_3}{2}$.

Computed values are included in Fig. 2. For example, the value, $2\,E\,(\theta_1)_2 = +\,0.70$, is computed as follows: The correction factor is $\frac{1}{6}\left\{(-\,0.28 \times 1) + (-\,0.30 \times 2)\right\} = -\,0.15$; and then, $2\,E\,(\theta_1)_2 = +\,\underline{0.55} - (-\,0.15) = +\,0.70$. Some labor of computation is saved if the corrections are made roughly at first, say, to one decimal place; then, when the values become about stationary, to the second decimal place, etc. From Equations (24) and (25) in Appendix II, the moments at the supports are computed as, $M_1 = -\,1.18$; $M_2 = -\,2.93$; and $M_3 = -\,0.10$.

Equation of Five Angles; No Side-Sway

The equation of five angles is an expression of the equilibrium of a rigid joint in a continuous frame, relating the angle of rotation of the joint to the four neighboring angles and the loads on both vertical and horizontal members. For a frame with no side-sway (joints fixed in space), the equation is:

$$K_{x,y}\,\theta_{x-1,y} + K_{y,x}\,\theta_{y-1,x} + 2\,\Sigma K\,\theta_{x,y} + K_{x+1,y}\,\theta_{x+1,y} + K_{y+1,x}\,\theta_{y+1,x} = U_{x,y} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

in which $\theta_{x,y}$ = the angle of rotation at Joint x, y (see Fig. 9(a), Appendix II); $K_{x,y}$ = stiffness ratio for girder span; $K_{y,x}$ = stiffness ratio for column span; $\Sigma K = K_{x,y} + K_{x+1,y} + K_{y,x} + K_{y+1,x}$, $U_{x,y}$ = load factor $= \dfrac{1}{2E}\,(\Delta M'_{x,y} + \Delta M'_{y,x})$; $\Delta M'_{x,y}$ = difference, at Joint x, y, between the fixed-end moments of the girders with vertical loads, $[\Delta M'_{x,y} = (M'_{x,y})_L - (M'_{x,y})_R]$; and, $\Delta M'_{y,x}$ = the difference, at Joint x, y, between the fixed-end moments of the columns with horizontal loads, $[\Delta M'_{y,x} = (\Delta M'_{y,x})_L - (\Delta M'_{y,x})_R]$.

The approximating equation is written as:

$$(\theta_{x,y})_n = (\theta_{x,y})_1 - \frac{1}{2\,\Sigma K}\,[K_{x,y}\,(\theta_{x-1,y})_n + K_{x+1,y}\,(\theta_{x+1,y})_n + K_{y,x}\,(\theta_{y-1,x})_{n-1} + K_{y+1,x}\,(\theta_{y+1,x})_{n-1}] \ldots\ldots\ldots\ldots (10)$$

in which $(\theta_{x,y})_n$ = the nth approximation; and $(\theta_{x,y})_1$, the first approximation, $= \dfrac{U_{x,y}}{2\,\Sigma K}$.

The value of θ in Equation (10) that bears the index, n, depends on the order in which the correction factors (the quantity in parenthesis) are computed. The order is immaterial of course; any two of the four θ-values may be given the index, n. As written, Equation (10) indicates that the order of procedure is from left to right and from top to bottom. It expresses the fact that each value of $\theta_{x,y}$ is corrected, successively, by the sum of the products of the four neighboring θ-values and their K-factors, divided by twice the sum of the four K-values that meet at Point (x, y). The correction is always made from the first approximation, $(\theta_{x,y})_1$, which is first computed for each joint from the load factor. The proof of convergence for the procedure is indicated in Appendix II.

Case 3.—Fig. 3 shows a frame, two stories high (3)[8]. The values of the angles at the lower ends of the lower columns are assumed to be zero. For this example, $U_{x,y} = \dfrac{\Delta M'_{x,y}}{2\,E}$; and $\Delta M'_{y,x} = 0$, since there are no horizontal loads. To illustrate the application of Equation (10) the following values

[8] Numerals in parentheses refer to Appendix I.

for $2\,E\,\theta_{0,2}$ and $2\,E\,\theta_{1,2}$ are computed:

$$2\,E\,(\theta_{0,2})_1 = \frac{U_{x,y}}{2\,\Sigma K} = \frac{\Delta M'_{0,2}}{2\left(\frac{1}{6}+\frac{1}{3}\right)} = \frac{[0-(-3)]}{1} = +\,\underline{3.00};$$

$$2\,E\,(\theta_{0,2})_2 = +\,\underline{3.00} - \frac{1}{1}\left\{\left(-1.80\times\tfrac{1}{3}\right)+\left(0.00\times\tfrac{1}{6}\right)\right\} = +\,3.60;$$

and,

$$(\theta_{1,2})_2 = -\,\underline{1.80} - \frac{1}{\frac{5}{3}}\left\{\left(+\,3.60\times\tfrac{1}{3}\right)+\left(\underline{1.50}\times\tfrac{1}{6}\right)+\left(\tfrac{1}{3}\times\underline{1.80}\right)\right\} = -\,3.03$$

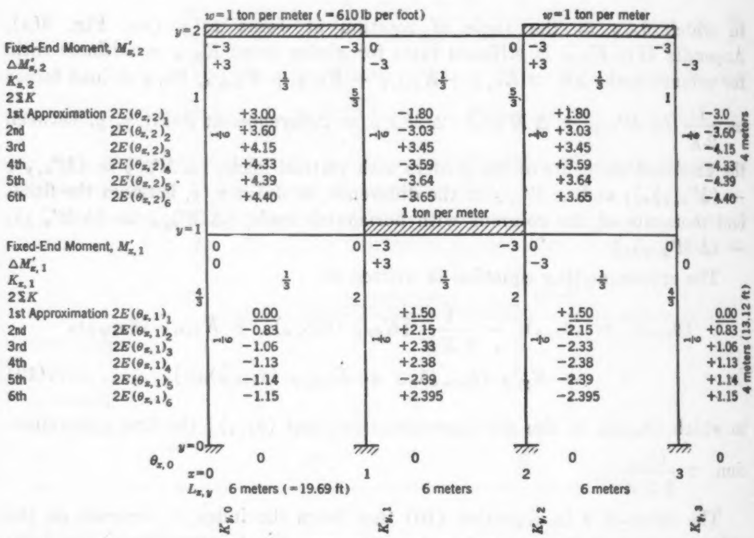

FIG. 3.—SUCCESSIVE APPROXIMATIONS FOR $2E\theta$

The procedure is continued until the values become stationary. On account of symmetry in this example computations for only one-half the joints need be made. The results shown in Fig. 3 check the values determined by elimination.

EQUATION OF FIVE ANGLES; SIDE-SWAY

For a continuous frame acted upon by horizontal loads, the rigid joints may undergo a horizontal displacement, or side-sway. The equation of five angles for this case is:

$$K\,(\theta) = U_{x,y} \qquad \text{(11)}$$

in which,

$$K\,(\theta) = K_{x,y}\,\theta_{x-1,y} + K_{y,x}\,\theta_{y-1,x} + 2(\Sigma K)\,\theta_{x,y} + K_{x+1,y}\,\theta_{x+1,y} + K_{y+1,x}\,\theta_{y+1,x} \qquad \text{(12)}$$

and,

$$U_{x,y} = \frac{\Delta M'_{y,x}}{2E} + 3\,K_{y,x}\,(\alpha_{y,x})_L + 3\,K_{y+1,x}\,(\alpha_{y+1,x})_L \ldots\ldots (13)$$

ΣK = sum of four K-values of members meeting at a joint; and $\Delta M'_{y,x}$ = difference in fixed-end moments for the column ends meeting at Joint x, y; and $(\alpha_{y,x})_L$ = angle of column rotation due to the horizontal displacement of the upper end, y, relative to the lower end, $y - 1$, of the column, $L_{y,x}$. The subscript, L, indicates that the angle is to the left of a joint when the observer is to the right of the column (Fig. 10(*a*), Appendix II).

For convenience in computing Angles θ and α, the former is written $\theta = \theta_b + \theta_s$. If θ_b represents the angle of rotation due to the bending action alone of the horizontal loads on the columns (side-sway being zero), and θ_s is the rotation due to the side-sway alone, Equation (11) may be replaced by:

$$K\,(\theta_b) = \frac{\Delta M'_{y,x}}{2E} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

and,

$$K\,(\theta_s) = 3\,K_{y,x}\,(\alpha_{y,x})_L + 3\,K_{y+1,x}\,(\alpha_{y+1,x})_L \ldots\ldots\ldots (15)$$

Since the angles, α, as well as the angles, θ_s, in Equation (15) are unknown, it is necessary to write an additional equation of equilibrium for the horizontal forces above each floor level; thus:

$$\sum_{y-1}^{y=k}\sum_{x=0}^{x=m} P_{y,x} - \sum_{x=0}^{x=m} (R_{y-1,x})_{o,R} + \sum_{x=0}^{x=m} \frac{(M'_{y-1,x})_R - (M'_{y,x})_L}{L_{y,x}}$$

$$= - \sum_{x=0}^{x=m} \frac{6\,E\,K_{y,x}}{L_{y,x}}\,[\theta_{x,y} + \theta_{y-1,x} - 2\,(\alpha_{y,x})_L] \ldots\ldots\ldots\ldots (16)$$

in which k = number of floor levels minus one; $P_{y,x}$ = horizontal load on the column, $L_{y,x}$; m = number of columns minus one; $(R_{y-1,x})_{o,R}$ = horizontal reaction at joint on the level, $y - 1$, due to given loads on the columns, with end moments equal to zero; and M' = fixed-end moment, either to the right or to the left of a joint, as indicated by the index, R, or L (Fig. 11, Appendix II).

Case 4.—As an example of the application of Equations (14), (15), and (16) to a frame with side-sway, the frame in Case 3 is subjected to horizontal loads, w, equal to 2 tons per m (1 220 lb per ft; see Fig. 4). The first part of the problem is the solution of Equation (14). This is accomplished as outlined in Case 3 for Equation (9). The fixed-end moments, $M'_{y,x}$, are $-\frac{1}{12}\,w\,L^2 = -\frac{8}{3}$ and the first approximation is, $2\,E\,(\theta_b)_1 = \frac{\Delta M'_{y,x}}{2\,\Sigma K}$. In Fig. 4 the first approximations are underlined and the succeeding ones are tabulated below the first.

For the solution of Equation (15), subject to the condition expressed by Equation (16), it is assumed that the angle of side-sway, α, is the same for

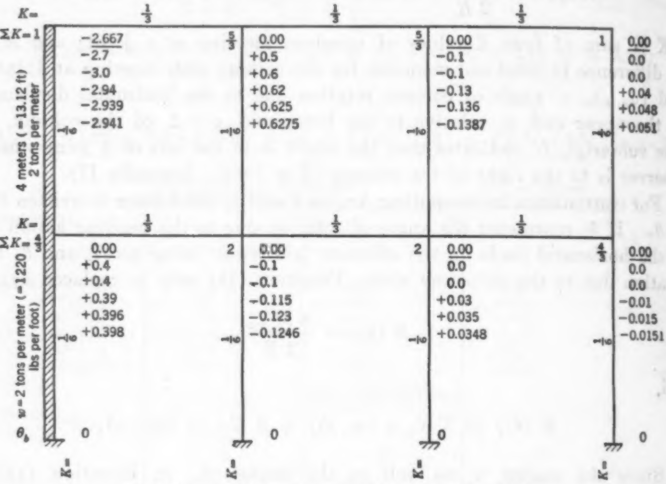

FIG. 4.—SUCCESSIVE APPROXIMATIONS FOR $2E\theta_b$

each column in any given story. Since, for this frame, $K_{y,x} = K_{y+1,x} = \frac{1}{3}$ for all columns, Equation (15) may be written:

$$K(\theta_s) = \frac{1}{2}(\alpha_{y-1})_L + \frac{1}{2}(\alpha_y)_L \ldots\ldots\ldots\ldots\ldots (17)$$

The joint rotation, θ_s, may be further divided into: $(\theta_s)_{y-1}$, the joint rotation corresponding to a side-sway $(\alpha_{y-1})_L$; and $(\theta_s)_y$, the joint rotation corresponding to a side-sway, $(\alpha_y)_L$. Consequently, for $y = 1, 2$ and $(\alpha_0)_L = 0$, Equation (17) may be replaced by:

$$K(\theta_s)_{y-1} = \frac{1}{2}(\alpha_1)_L = \frac{1}{2}\alpha_1 \ldots\ldots\ldots\ldots\ldots (18)$$

and,

$$K(\theta_s)_y = \frac{1}{2}(\alpha_1)_L + \frac{1}{2}(\alpha_2)_L = \frac{1}{2}\alpha_1 + \frac{1}{2}\alpha_2 \ldots\ldots\ldots\ldots (19)$$

Equations (18) and (19) are solved by iteration, as outlined in Case 3, first for the values, $\alpha_1 = \alpha_2 = \dfrac{1.00}{E}$. The results are shown in Figs. 5 and 6. These values, for $\alpha = 1$, are then used in solving Equation (16), which, for Case 4, reduces to:

$$\alpha_1 = \frac{1}{8}(\theta_{0,1} + \theta_{1,1} + \theta_{2,1} + \theta_{3,1}) + \frac{6}{E} \ldots\ldots\ldots\ldots (20)$$

at the first story; and,

$$\alpha_2 = \frac{1}{8}(\theta_{0,1} + \theta_{1,1} + \theta_{2,1} + \theta_{3,1} + \theta_{0,2} + \theta_{1,2} + \theta_{2,2} + \theta_{3,2}) + \frac{2}{E} \quad (21)$$

at the second story.

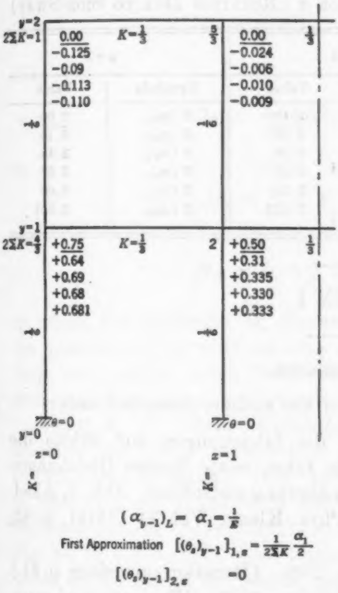

FIG. 5.—VALUES OF $2E(\theta_s)_{y-1}$

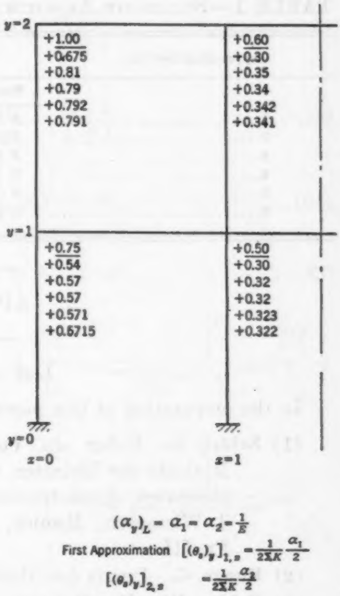

FIG. 6.—VALUES OF $2E(\theta_s)_y$

In solving Equations (20) and (21) the first approximation for the α-values is obtained by placing all the θ-values equal to zero or $(\alpha_1)_1 = \frac{6}{E}$ and $(\alpha_2)_1 = \frac{2}{E}$. These values are then corrected by multiplying the values of $(\theta_s)_{y-1}$ and $(\theta_s)_y$ for unit rotation, α, by the first approximation for α and using these new values of $(\theta_s)_{y-1}$ and $(\theta_s)_y$, together with the θ_b-values (see Fig. 4), for a second approximation of α according to Equations (20) and (21), etc. To illustrate, the second approximations are:

$$(\alpha_1)_2 = \frac{1}{8}\left[(0.681 + 0.333)\frac{6}{E} + (0.571 + 0.322)\frac{2}{E} + (0.398 - 0.125 + 0.035 - 0.015)\frac{1}{2E}\right] + \frac{6}{E} = \frac{7.002}{E}$$; and, $(\alpha_2)_2 = \frac{1}{8}\Big[(0.681 + 0.333 - 0.110$

$$- 0.009)\ \frac{7.002}{E} + (0.571 + 0.322 + 0.791 + 0.341)\ \frac{2}{E} + (0.398 - 0.125$$

$$+ 0.035 - 0.015 - 2.941 + 0.628 - 0.139 + 0.051)\ \frac{1}{2\,E}\Bigg] + \frac{2}{E} = \frac{3.16}{E}.$$

Successive values of α up to the sixth approximation are shown in Table 1.

TABLE 1.—SUCCESSIVE APPROXIMATIONS FOR α (ROTATION DUE TO SIDE-SWAY)

Approximation No.	$y = 1$		$y = 2$	
	Symbols	Value	Symbols	Value
1	$E\,(\alpha_1)_1$	6.00	$E\,(\alpha_2)_1$	2.00
2	$E\,(\alpha_1)_2$	7.00	$E\,(\alpha_2)_2$	3.16
3	$E\,(\alpha_1)_3$	7.26	$E\,(\alpha_2)_3$	3.48
4	$E\,(\alpha_1)_4$	7.33	$E\,(\alpha_2)_4$	3.57
5	$E\,(\alpha_1)_5$	7.35	$E\,(\alpha_2)_5$	3.60
6	$E\,(\alpha_1)_6$	7.353	$E\,(\alpha_2)_6$	3.601

APPENDIX II

Mathematical Derivations

The fundamental equations relating moments and slopes for a single simply supported span (Fig. 7) are:

$$\theta_A = (\theta_A)_0 + \frac{M_A L}{3 E I} + \frac{M_B L}{6 E I} \dots\dots\dots\dots\dots (22)$$

and,

$$\theta_B = -(\theta_B)_0 - \frac{M_B L}{3 E I} - \frac{M_A L}{6 E I} \dots\dots\dots\dots\dots (23)$$

or,

$$M_A = 2 E K (2 \theta_A + \theta_B) + M'_A \dots\dots\dots\dots\dots (24)$$

and,

$$M_B = -2 E K (2 \theta_B + \theta_A) + M'_B \dots\dots\dots\dots\dots (25)$$

in which the subscript, 0, denotes that the moments at the ends are zero. Rotations are positive when clockwise; and moments are positive as shown in Fig. 7.

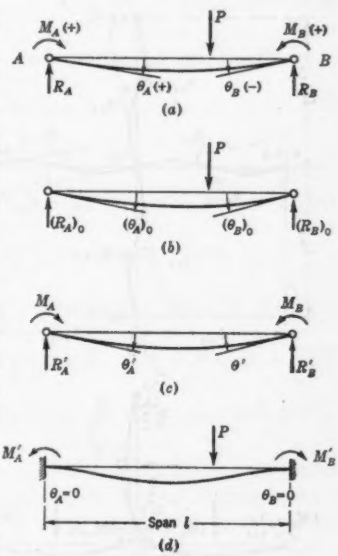

Fig. 7.

Equation of Three Moments.—The equation for three moments is found by applying Equations (22) and (23) to two adjacent spans in a continuous beam and making $(\theta_x)_L = (\theta_x)_R = \theta_x$ (see Fig. 8), in which $(\theta_x)_L$ is the angle of rotation at the left of Support x, and $(\theta_x)_R$ is the angle of rotation at the right of Support x. In a continuous beam these two rotations are equal. Expressing the angles, θ, in terms of the area-moments, Q_{x-1}, and Q_{x+1}, the equation of three moments becomes (7) (see Equation (1)):

$$\frac{M_{x-1}}{K_x} + 2 M_x \left(\frac{1}{K_x} + \frac{1}{K_{x+1}}\right) + \frac{M_{x+1}}{K_{x+1}} = -\frac{6 Q_{x-1}}{I_x L_x} - \frac{6 Q_{x+1}}{I_{x+1} L_{x+1}} \dots . (26)$$

Equation of Three Angles.—The equation of three angles is obtained in a manner similar to Equation (26) by applying Equations (24) and (25) to two adjacent spans (Fig. 8) and equating the moments on either side of Support x; that is,

$$(M_x)_L = (M_x)_R = M_x \dots\dots\dots\dots\dots\dots\dots (27)$$

in which $(M_x)_L$ is the moment at x in Member L_x to the left of x and $(M_x)_R$ is the moment at x in Member L_{x+1} to the right of x. Then (3) (see Equation (7));

$$K_x\ \theta_{x-1} + 2\ (K_x + K_{x+1})\ \theta_x + K_{x+1}\ \theta_{x+1} = \frac{\Delta\ M'_x}{2\ E}\ \text{.........(28)}$$

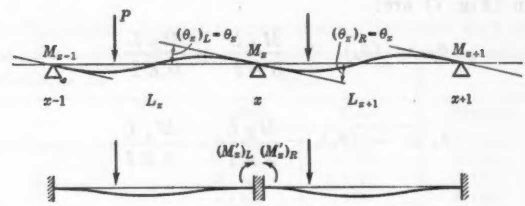

FIG. 8

in which $\Delta M'_x = (M'_x)_L - (M'_x)_R$ = the difference in fixed-end moments at x (see Fig. 8).

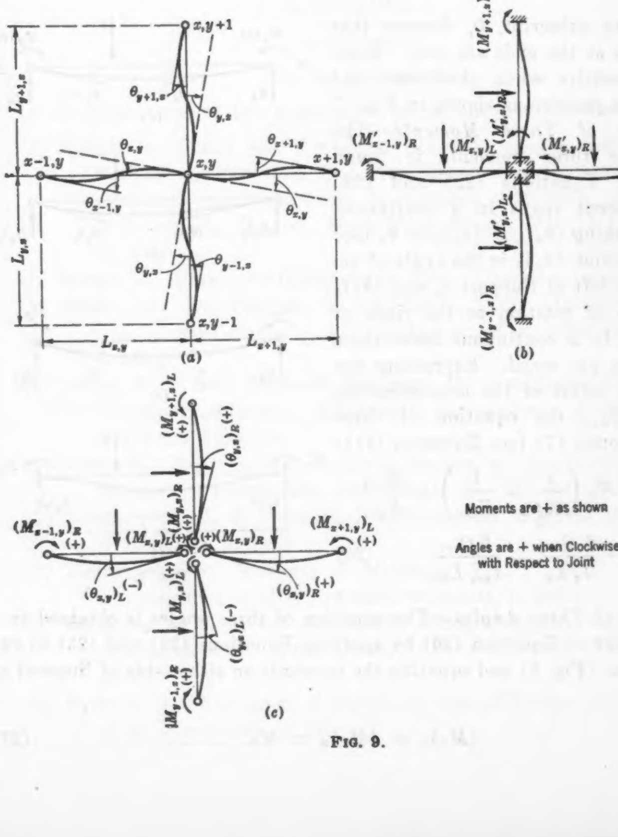

FIG. 9.

Equation of Five Angles: No Side-Sway.—Fig. (9*a*) shows Joint (x, y) rotated through a positive angle, $\theta_{x,y}$. Fig. 9(*b*) shows the fixed-end moments under the given loads. If Equations (24) and (25) are applied to the four spans joining at (x, y) (Fig. 9(*c*)), the following equations are obtained:

In Span $L_{x,y}$:

$$(M_{x,y})_L = -2\,E\,K_{x,y}\,[2\,(\theta_{x,y})_L + (\theta_{x+1,y})_R] + (M'_{x,y})_L \ldots (29)$$

In Span $L_{x+1,y}$:

$$(M_{x,y})_R = 2\,E\,K_{x+1,y}\,[2\,(\theta_{x,y})_R + (\theta_{x+1,y})_L] + (M'_{x,y})_R \ldots (30)$$

In Span $L_{y,x}$:

$$(M_{y,x})_L = -2\,E\,K_{y,x}\,[2\,(\theta_{y,x})_L + (\theta_{y-1,x})_R] + (M'_{y,x})_L \ldots (31)$$

and, in Span $L_{y+1,x}$:

$$(M_{y,x})_R = 2\,E\,K_{y+1,x}\,[2\,(\theta_{y,x})_R + (\theta_{y+1,x})_L] + (M'_{y,x})_R \ldots (32)$$

Substituting Equations (29) to (32) in the equilibrium equation,

$$(M_{x,y})_R + (M_{y,x})_R = (M_{x,y})_L + (M_{y,x})_L \ldots\ldots\ldots\ldots (33)$$

and, making use of the equality of angles at Joint x, y,

$$(\theta_{x,y})_R = (\theta_{x,y})_L = (\theta_{y,x})_L = (\theta_{y,x})_R = \theta_{x,y} \ldots\ldots\ldots (34)$$

the five-angle equation (3) (see Equation (9)), is obtained; thus:

$$K_{x,y}\,\theta_{x-1,y} + K_{y,x}\,\theta_{y-1,x} + 2\,\theta_{x,y}\,(K_{x,y} + K_{x+1,y} + K_{y,x} + K_{y+1,x})$$
$$+ K_{x+1,y}\,\theta_{x+1,y} + K_{y+1,x}\,\theta_{y+1,x} = \frac{1}{2\,E}\,[\Delta M'_{x,y} + \Delta M'_{y,x}] \ldots (35)$$

in which (see Fig. 9(*b*)): $\Delta M'_{x,y} = (M'_{x,y})_L - (M'_{x,y})_R$; and $\Delta M'_{y,x} = (M'_{y,x})_L - (M'_{y,x})_R$.

Equation of Five Angles: With Side-Sway.—It is assumed that no vertical loads act on the girders. Fig. 10(*a*) shows the horizontal displacement of Joints $x, y + 1$ and $x, y - 1$, relative to Joint x, y. The angles of displacement are $(\alpha_{y,x})_R$ to the right of Joint x, y, and $(\alpha_{y,x})_L$ to the left of Joint x, y. The other angles involved are shown in Fig. 10. Applying Equations (24) and (25) to the members in Fig. 10(*c*), the following equations are obtained:

In Span $L_{x,y}$:

$$(M_{x,y})_L = -2\,E\,K_{x,y}\,[2\,(\theta_{x,y})_L + (\theta_{x-1,y})_R] \ldots\ldots\ldots (36)$$

In Span $L_{x+1,\,y}$:

$$(M_{x,\,y})_R = 2\,E\,K_{x+1,\,y}\,[2\,(\theta_{x,\,y})_R + (\theta_{x+1,y})_L] \ldots\ldots\ldots (37)$$

In Span $L_{y,\,x}$:

$$(M_{y,\,x})_L = -\,2\,E\,K_{y,\,x}\,[2\,(\omega_{y,\,x})_L + (\omega_{y-1,x})_R] + (M'_{y,\,x})_L \ldots (38)$$

and, in Span $L_{y+1,\,x}$:

$$(M_{y,x})_R = 2\,E\,K_{y+1,x}\,[\,2\,(\omega_{y,\,x})_R + (\omega_{y+1,\,x})_L] + M'_{y,\,x})_R \ldots (39)$$

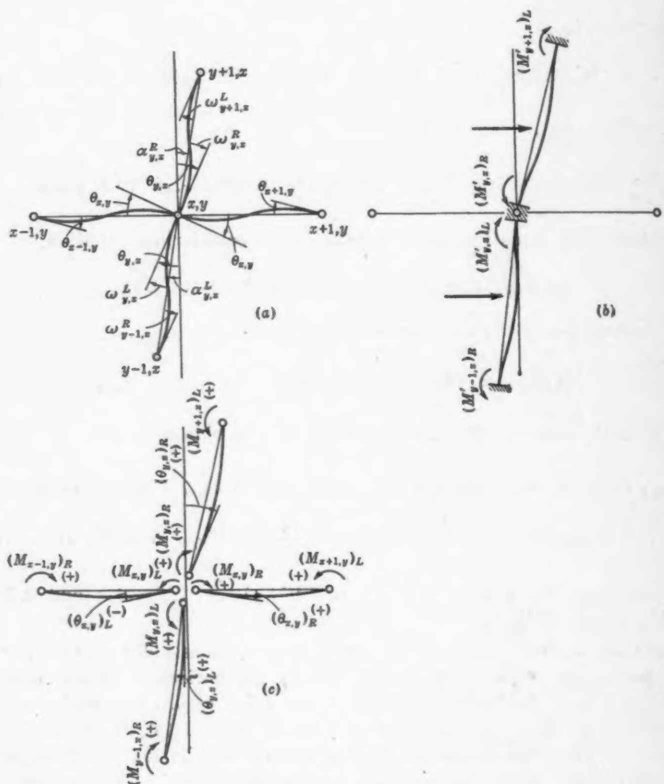

FIG. 10

By substituting Equations (36) to (39) into Equation (33), and making use of the relations, $(\omega_{y,\,x})_R = (\theta_{y,\,x})_R - (\alpha_{y,\,x})_R$; $(\omega_{y,\,x})_L = (\theta_{y,\,x})_L - (\alpha_{y,\,x})_L$ (see Fig. 10(a)); and, $(\theta_{x,\,y})_L = (\theta_{x,\,y})_R = (\theta_{y,\,x})_L = (\theta_{y,\,x})_R$

$= \theta_{x,y}$, the equation of five angles, for horizontal loads, with side-sway, is obtained; thus (see Equation (11)):

$$K_{x,y}\,\theta_{x-1,y} + K_{x+1,y}\,\theta_{x+1,y} + 2\,\theta_{x,y}\,(K_{x,y} + K_{y,x} + K_{x+1,y} + K_{y+1,x})$$

$$+ K_{y,x}\,\theta_{y-1,x} + K_{y+1,x}\,\theta_{y+1,x} = \frac{\Delta M'_{y,x}}{2\,E} + 3\,K_{y,x}\,(a_{y,x})_L + 3\,K_{y+1,x}\,(a_{y+1,x})_L \text{. (40)}$$

Equation (16) expressing the equilibrium of horizontal forces for the part of the frame above a horizontal section through any floor level is derived as follows: The fundamental relations between moments and reactions (see Fig. 7) are:

$$R_A = (R_A)_0 + \frac{M_B - M_A}{L} \dots\dots\dots\dots\dots\dots\dots (41)$$

and,

$$R_B = (R_B)_0 + \frac{M_A - M_B}{L} \dots\dots\dots\dots\dots\dots\dots (42)$$

If Equation (41) is applied to a single column (see Fig. 11(*a*)):

$$(R_{y-1,x})_R = (R_{y-1,x})_{0,x} + \frac{(M_{y,x})_L - (M_{y-1,x})_R}{L_{y,x}} \dots\dots\dots (43)$$

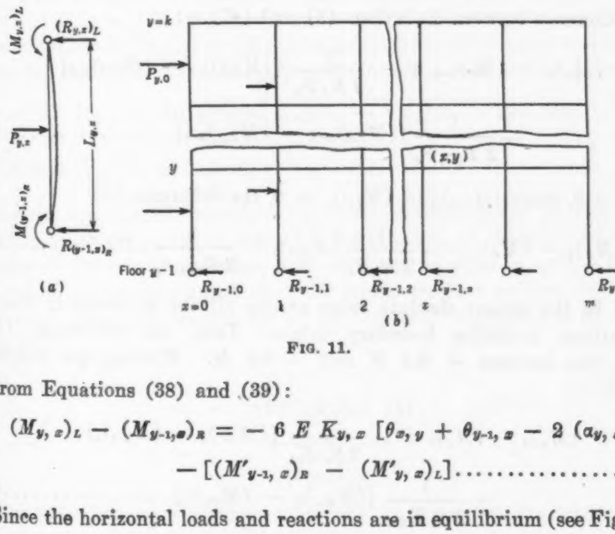

FIG. 11.

From Equations (38) and (39):

$$(M_{y,x})_L - (M_{y-1,x})_R = -\,6\,E\,K_{y,x}\,[\theta_{x,y} + \theta_{y-1,x} - 2\,(a_{y,x})_L]$$

$$-\,[(M'_{y-1,x})_R - (M'_{y,x})_L] \dots\dots\dots\dots\dots\dots\dots (44)$$

Since the horizontal loads and reactions are in equilibrium (see Fig. 11(*b*)):

$$\sum_{x=0}^{x=m}\sum_{y-1}^{y=k} P_{y,x} = \sum_{x=0}^{x=m} (R_{y-1,x})_R \dots\dots\dots\dots\dots\dots (45)$$

Finally, substituting Equations (43) and (44) into Equation (45) (see Equation (16)):

$$\sum_{x=0}^{x=m} \sum_{y-1}^{y=k} P_{y,x} = \sum_{x=0}^{x=m} (R_{y-1,x})_{o,R} - \sum_{x=0}^{x=m} \frac{6\,E\,K_{y,x}}{L_{y,x}} \left[\theta_{xy} + \theta_{y-1,x} - 2\,(\alpha_{y,x})_L\right]$$

$$- \sum_{x=0}^{x=m} \frac{(M'_{y-1,x})_R - (M'_{y,x})_L}{L_{y,x}} \qquad \text{.................. (46)}$$

Convergence Proof.—Equation of Three Moments.—That the sequence, $(M_x)_n$ (Equation (5)), is convergent for increasing integral values of n is demonstrated if it can be shown that the sequence of differences between successive approximations converges to zero. It is assumed that the coefficients, $\frac{1}{K}$, are positive and that $S_x = \frac{1}{K_x} + \frac{1}{K_{x+1}}$ does not equal zero; in other words, the $\frac{1}{K}$ - values are not zero for any two adjacent spans in a continuous beam. The nth approximation is expressed by Equation (5) of the paper and the $(n-1)$th is:

$$(M_x)_{n-1} = (M_x)_1 - \frac{1}{2\,S_x}\left[\frac{(M_{x-1})_{n-2}}{K_x} + \frac{(M_{x+1})_{n-2}}{K_{x+1}}\right] \qquad \text{........ (47)}$$

The difference between Equations (5) and (47) is:

$$(M_x)_n - (M_x)_{n-1} = -\frac{1}{2\,K_x\,S_x}\left[(M_{x-1})_{n-1} - (M_{x-1})_{n-2}\right]$$

$$-\frac{1}{2\,K_{x+1}\,S_x}\left[(M_{x+1})_{n-1} - (M_{x+1})_{n-2}\right] \qquad \text{................ (48)}$$

For $n = 2$, since $(M_{x-1})_0 = (M_{x+1})_0 = 0$, the difference is:

$$(M_x)_2 - (M_x)_1 = -\frac{1}{2\,K_x S_x}\,(M_{x-1})_1 - \frac{1}{2\,K_{x+1}\,S_x}\,(M_{x+1})_1 \qquad \text{....... (49)}$$

Let M be the largest absolute value among all the moments in the first approximations, including boundary values. Then, the difference, $(M_x)_2 - (M_x)_1$, lies between $+ 0.5\,M$ and $- 0.5\,M$. Writing the difference for $n = 3$:

$$(M_x)_3 - (M_x)_2 = -\frac{1}{2\,S_x\,K_x}\left[(M_{x-1})_2 - (M_{x-1})_1\right]$$

$$-\frac{1}{2\,S_x\,K_{x+1}}\left[(M_{x+1})_2 - (M_{x+1})_1\right] \qquad \text{................ (50)}$$

it is seen that this difference lies between $+ 0.25\,M$ and $- 0.25\,M$. In general, the difference expressed by Equation (48) lies between $\frac{+M}{2^{n-1}}$ and $\frac{-M}{2^{n-1}}$.

Hence, this difference approaches zero for increasing values of n. To show that $(M_x)_n$ approaches the solution, M_x, expressed by Equation (1), the difference is written in the form $\left(\text{remembering that } (M_x)_1 = \dfrac{U_x}{2\,S_x}\right)$:

$$(M_x)_n - (M_x)_{n-1} = -\frac{1}{2\,S_x}\left[\frac{(M_{x-1})_{n-1}}{K_x} + 2\,(M_x)_{n-1}\,S_x + \frac{(M_{x+1})_{n-1}}{K_{x+1}} - U_x\right] .(51)$$

Since $(M_x)_n - (M_x)_{n-1}$ approaches zero, the right-hand expression approaches zero; hence, $(M_x)_{n-1}$ satisfies the original Equation (1) for the condition that n becomes infinite.

Convergence is easily shown also for Equation (6) when $(M_{x-1})_n$ is used in computation instead of $(M_{x-1})_{n-1}$; thus:

$$(M_x)_n - (M_x)_{n-1} = -\frac{1}{2\,K_x\,S_x}\left[(M_{x-1})_n - (M_{x-1})_{n-1}\right]$$

$$-\frac{1}{2\,K_{x+1}\,S_x}\left[(M_{x+1})_{n-1} - (M_{x+1})_{n-2}\right] \ldots\ldots\ldots\ldots\ldots (52)$$

and, for $n = 2$:

$$(M_x)_2 - (M_x)_1 = -\frac{1}{2\,K_x\,S_x}\left[(M_{x-1})_2 - M_{x-1})_1\right] - \frac{1}{2\,K_{x+1}\,S_x}(M_{x+1})_1 .(53)$$

By making use of the upper and lower bounds, as stated for Equation (48) (that is, $(M_x)_2 - (M_x)_1$ is less than $+\,0.5\,M$ and greater than $-\,0.5\,M$), it is also true that $(M_{x-1})_2 - (M_{x-1})_1$ is less than $+\,M$ and greater than $-\,M$. Hence, for Equation (53), $(M_{x-1})_2 - (M_{x-1})_1$ is less than $+\,0.5\,M$ and greater than $-\,0.5\,M$; and, in general, $(M_x)_n - (M_x)_{n-1}$ is less than $\dfrac{+\,M}{2^{n-1}}$ and greater than $\dfrac{-\,M}{2^{n-1}}$, as before.

For the equation of five angles the proof of convergence is easily obtained by generalizing the proof as given for the equation of three moments; in the equation of five angles the value, $\Sigma\,K$, must not be equal to, or less than, zero. A proof of convergence based upon the minimum of a positive definite quadratic form associated with a set of simultaneous equations is given in the paper (4).

APPENDIX III

Notation

The following letter symbols, introduced in the paper, are arranged herein, for convenience of reference and for the guidance of discussers:

b = a subscript denoting "bending".

I = rectangular moment of inertia; I_x = moment of inertia in Span L_x, etc.

K = a stiffness ratio, $\frac{I}{L}$; ΣK = a sum of four stiffness ratios $= K_{x,y} + K_{x+1,y} + K_{y,x} + K_{y+1,x}$ at Joint (x, y).
k = number of floor-levels minus one.
L = length; L_x = span length between Supports $x - 1$ and x, etc.; as a subscript, L, denotes left and as a subscript to α, it indicates that the angle is to the left of a joint when the observer is to the right of a column.
M = moment of force; M_x = bending moment at Support x, etc.; M' = fixed-end moment; $\Delta M'_x$ = a local factor = a difference, $(M'_x)_L - (M'_x)_R$, between fixed-end moments at the left and right of Support x.
m = number of columns minus one.
n = a limiting number.
P = a horizontal force applied at any story; P_{yx} = horizontal force between floor levels, $y - 1$ and y.
Q = statical moments of area about a given axis; Q_{x-1} *and* Q_{x+1} are, respectively, the moments of the areas below the moment diagram in Spans L_x and L_{x+1} with respect to Supports $x - 1$ and $x + 1$.
R = a subscript denoting "right side".
S = a sum of two stiffness ratios; $S_x = \frac{1}{K_x} + \frac{1}{K_{x+1}}$.
s = a subscript denoting "side-sway".
U = a load factor in two adjacent spans.
α = angle of rotation of one end of one member; $(\alpha_{y,x})_L$ = angle of column rotation due to the horizontal displacement of the upper end, y, with respect to the lower end, $y - 1$, of the column, $L_{y,x}$; the subscript, L, applied to α indicates that the angle is to the left of a joint when the observer is to the right of a column.
Δ = a difference; $\Delta M'_x$ = a load factor = difference, $(M'_x)_L - (M'_x)_R$, between fixed-end moments.
θ = rotation of a joint; θ_b = the rotation due entirely to the bending action of horizontal loads on the columns; θ_s = the rotation due entirely to side-sway.
ω = an angle $= \theta - \alpha$.

DISCUSSION

Garrett B. Drummond,[4] Esq. (by letter).—A method of practical utility for the solution of simultaneous equations, is demonstrated in this paper. The steps for solving n simultaneous equations containing n unknown quantities, by the method of successive approximations, can be summarized as follows:

(1) Choose one equation in which the coefficient of one unknown is quite large in comparison with the coefficients of the other unknowns;

(2) Let all the unknowns, except that with the largest coefficient, assume the value zero;

(3) Solve for a first approximate value of this unknown;

(4) Choose another equation in which the coefficient of one of the unknowns, other than that chosen in Step (1) is quite large in comparison with the coefficients of the remaining unknowns;

(5) Substitute the first approximate value of the unknown already determined, allowing the remaining $n - 2$ unknowns to assume the value zero;

(6) Solve for a first approximate value of the second unknown;

(7) Continue in this manner, using first approximate values of each unknown, until first approximate values are determined for all unknowns; and,

(8) Repeat Steps (1) to (7) until the desired degree of approximation is reached, or until the difference between successive approximate values becomes negligible.

A very simple demonstration of this process can be given by solving the three-moment equations of the beam shown in Fig. 12. The equations are:

$$15\ M_2 + 54\ M_3 = -\ 132\,480 \qquad (54)$$

and,

$$50\ M_2 + 15\ M_3 = -\ 104\,820 \qquad (55)$$

From Equation (54): $54\ M_3 = -\ 132\,480$; and, $M_3 = -\ 2\,446$, which is the first approximate value of M_3. Substituting this value into Equa-

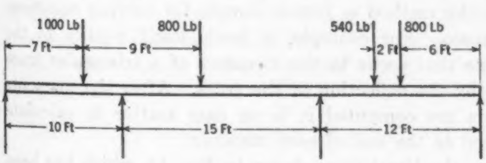

Fig. 12

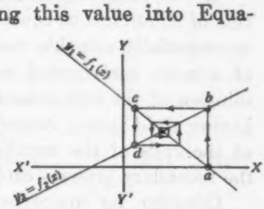

Fig. 13

tion (55): $50\ M_2 + (15)\ (-\ 2\,446) = -\ 104\,480$; or (simplifying and solving for M_2): $M_2 = -\ 1\,356$, which is the first approximate value of M_2.

Returning to Equation (54) with this value: $(15)\ (-\ 1\,356) + 54\ M_3 = -\ 132\,480$; and solving, $M_3 = -\ 2\,077$, which is the second approximate value of M_3.

[4] With U. S. Engr. Dept., Memphis, Tenn.

Continuing in this manner, the second approximate value of M_3 is found to be $-$ 1 473; the third approximate value of M_3 is found to be $-$ 2 041; and the third approximate value of M_2 is found to be $-$ 1 484. These third approximate values are identical with the exact values determined from the ordinary simultaneous solutions of the two equations.

This apparently trivial problem was selected because it is possible to show, graphically, the precise nature of the steps in the approximate solution of two equations. Consider the two functions, $y_1 = f_1(x)$ and $y_2 = f_2(x)$, as shown in Fig. 13. The process was to begin at Point a, where $y = 0$ in Equation (54). With the corresponding value of x, the next step is to find the value of y in Equation (55)—in other words, proceed to Point b, Fig. 13, with this value of y; the third step is to find the value of x in Equation (54)—that is, move to Point c, Fig. 13. Continuing in this manner, with the successive values found, from the graphical standpoint, one merely follows the path shown in Fig. 13, which approaches closer and closer each time to the intersection of the graphs of the two equations, or to the numerical values of the simultaneous solutions of the equations.

Of course, from its practical use, the purpose of this method of solution is to lighten the labor of solving a large number of simultaneous equations, such as are encountered in indeterminate structures. This raises the question of the desirability of "exact" solutions. Just what is meant by "exact" solutions?

Setting up the equations, say, for the solution of a frame by the method of slope deflection, is it not true that certain assumptions are made regarding the action of forces at joints, and is the assumption not also made that the moment of inertia of the various members are constant throughout their cross-section? Then, it appears to be stretching the point to insist that the equations resulting from these assumptions be solved for "exact" values. Approximate values are sufficient, and in arriving at such values the method explained by Professor Schwalbe is approximate and entirely applicable.

A. W. FISCHER,[5] ESQ. (by letter).—A rather unique method for the solution of simultaneous equations is presented in this paper. The simple examples are especially valuable, but the method is just as simple for solving equations of a more complicated nature. For example, it lends itself readily to the solution of the end moments that occur in the members of a triangular truss having rigid joints, caused by the deflection of the truss. After the moments at the ends of the members are computed it is an easy matter to calculate the secondary stresses caused at the end of each member.

Consider, for comparison, the Pratt truss shown in Fig. 14, which has been analyzed elsewhere[6] by Sophus Thompson, Assoc. M. Am. Soc. C. E., and Ralph W. Cutler, Jun. Am. Soc. C. E. Adding all the clockwise fixed-end moments and subtracting the counter-clockwise fixed-end moments at each joint and dividing them by $2 \Sigma K$ for all the members entering the joint the first approximation of $2 E \theta$ is determined for the various joints. For Joint 1,

[5] Care, Pennsylvania Sugar Co., Philadelphia, Pa.

[6] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), pp. 108–110.

the sum of all the clockwise fixed-end moments[6] $= 4\,768 + 2\,290 = 7\,058$, and $2 \Sigma K = 2\,(9.15 + 3.80) = 25.90$. From this, the first approximation of $2 E \theta$ at Joint 1 $= \dfrac{7\,058}{25.90} = 272.5$. For Joint 6 the sum of all the fixed-end clockwise moments minus all the counter-clockwise fixed-end moments $= 6\,440 - 6\,440 = 0$, and $2 \Sigma K = 2\,(12.43 + 0.774 + 12.43) = 51.268$. From this value the first approximation of $2 E \theta$ at Joint 6 $= 0$. All the first

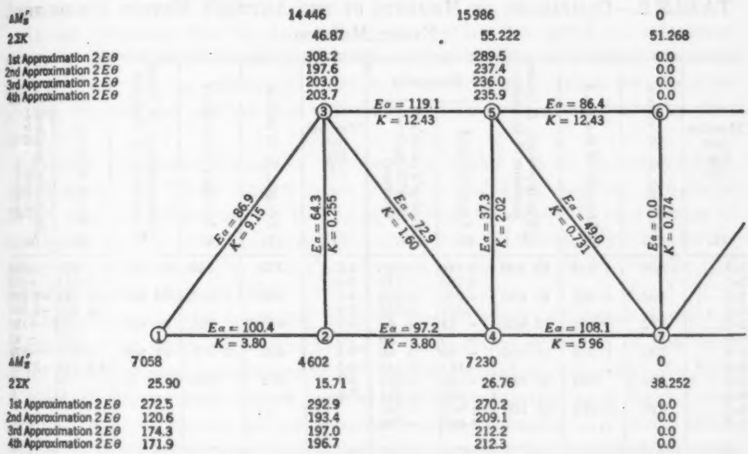

FIG. 14

approximate $2 E \theta$-values are shown in Fig. 14. The second approximate value of $2 E \theta$ for Joint 1 $= 272.5 - \dfrac{1}{25.90}\,(9.15 \times 308.2 + 3.80 \times 292.9) = 120.6$. The second approximate value of $2 E \theta$ for Joint 2 $= 292.9 - \dfrac{1}{15.71} \times (3.80 \times 120.6 + 0.255 \times 308.2 + 3.8 \times 270.2) = 193.4$. Proceeding in this manner from joint to joint, in the order numbered in Fig. 14, all the second approximate values of $2 E \theta$ are calculated and are shown in the diagram.

The third approximate value of $2 E \theta$ at Joint 1 $= 272.5 - \dfrac{1}{25.90}\,(9.15 \times 197.6 + 3.80 \times 193.4) = 174.3$. Thus, all the third approximate values of $2 E \theta$ are calculated (see Fig. 14). The fourth approximate values are then determined and as these values of $2 E \theta$ at all the joints agree fairly closely with the third approximate values, there is no need to continue the operations. Values of $E \alpha$ can be computed by drawing a Williot diagram, then, applying the well known slope-deflection formula:

$$M_{AB} = 2 E K_{AB}\,(2\,\theta_A + \theta_B - 3\,\alpha_{AB}) \ldots\ldots\ldots\ldots\ldots (56)$$

the moments at the end of all the members can be solved. Equation (56) will give the moment at End A for any member, A-B. In this case, the sign convention is the same as that recommended by W. M. Wilson, F. E. Richart, and Camillo Weiss, Members, Am. Soc. C. E.[7] The moments at the ends of all the members can also be solved by the formula:

$$M_{AB} = 2\ E\ K_{AB}\ (2\,w_A + w_B) \ldots\ldots\ldots\ldots\ldots\ldots (57)$$

TABLE 2.—COMPARISON OF MOMENTS BY THE AUTHOR'S METHOD AND BY THE EXACT METHOD

Member (see Fig. 14)	Length, L, in inches	Moment of inertia, I	Displacement, D, times modulus of elasticity	Moments		Member (see Fig. 14)	Length, L, in inches	Moment of inertia, I	Displacement, D, times modulus of elasticity	Moments	
				Exact method	Author's method (fourth approximation)					Exact method	Author's method (fourth approximation)
(1)	(2)	(3)	(4)	(5)	(6)	(1)	(2)	(3)	(4)	(5)	(6)
1-2.....	320	1 218	32 130	+230	−235	4-5....	372	750	13 870	−875	+882
2-1.....	......	......	....	+185	−141	5-4....	......	......	....	−924	+930
1-3.....	490.7	4 490	42 630	−230	+239	4-7....	320	1 907	34 600	+1 342	−1 335
3-1.....	......	......	....	−527	+530	7-4....	......	......	....	+2 602	−2 600
2-3.....	372	95	23 900	− 53	+ 54	5-7....	490.7	358	24 040	−130	+130
3-2.....	......	......	....	− 55	+ 56	7-5....	......	......	....	+42	− 42
2-4.....	320	1 218	31 100	− 80	+ 86	5-6....	320	3 978	27 650	+562	−579
4-2.....	......	......	....	−141	+145	6-5....	......	......	....	+3 544	−3 511
3-4.....	490.7	805	35 780[8]	−307	+292	6-7....	372	288	0	0	0
4-3.....	......	......	....	−320	+305	7-6....	......	......	....	0	0
3-5.....	320	3 978	38 100	+900	−886						
5-3.....	......	......	....	+495	−486						

From the values given in Fig. 14, all the moments at the end of each member can be calculated and the results are given in Table 2. (In their Williot diagram[8], Messrs. Thompson and Cutler give a value of the displacement of 38 470 for Member 3-4. For a fixed-end moment of 700 as shown[9] the correct value would be 35 780, which is the value used by the writer.)

For purposes of comparison the values of the end moments by an exact method[10] is also given in Table 2 and on comparing these values with those computed by Professor Schwalbe it is seen that the moments by the author's method agree very closely. The signs shown are different for each member for the two methods, due to a different sign convention assumed. Furthermore, it should be made clear that, in Column (4), Table 2, the values of D times E are displacements (at right angles to the axis of the member) of one end relative to the opposite end.

From the foregoing it seems that the author's method can be used to solve for the end moments of all the members in a triangular truss with rigid joints in a very short and simple manner. The analysis is such that the results with a 20-in. slide-rule are reliable.

M. B. GAMET,[11] JUN. AM. SOC. C. E. (by letter).—An interesting terminology to apply to methods of solution for, and types of, equations is developed in this paper. The writer wishes to commend highly the use of the term, "iteration", as a substitute for "successive approximation."

The writer wishes to make some very important additions to the author's "List of References" in Appendix I of the paper. These additions[12] represent the pioneer work done in the United States with this so-called "iteration" procedure in the solution of simultaneous equations of the type discussed by the author.

It will be noted that in Appendix I the author has listed no references to any of the numerous American developments in this field which occurred prior to 1930. All the references which he cites refer to German sources prior to 1930, whereas the method was well developed in the United States by that time.

Another important change in terminology is the use of the expressions, the "Equation of Three Angles", the "Equation of Five Angles: No Side-Sway", and the "Equation of Five Angles with Side-Sway", as a series of substitutes for the term, "slope-deflection" equations. Evidently, this terminology originates with the author's reference to the work of W. Gehler (3)[a] published in Germany in 1925.

There seems to be a continual need to remind recent students of the use of angular joint rotations as unknowns in rigid-frame problems, of the facts in the history of the development of this useful method of approach. As early as 1880, Manderla made use of angular rotations of joints in a rigid frame structure to determine the secondary-stress bending moments in a bridge truss. Soon after this (1893) Mohr used a similar approach which was identical with that which the slope-deflection method makes to the "general" problem of the rigid frame. Before 1915, only the isolated problem of secondary stresses had been approached in this manner.

In 1915, G. A. Maney, M. Am. Soc. C. E. published the first general statement of the slope-deflection method in this country[13]. In this treatment, not only are secondary stresses solved, but wind stresses and all types of frames with members transversely loaded as well. The idea of fixed-beam moments was there first developed, although at the time it was not called by that name. This work led immediately to the important publications originating at the University of Illinois.

In 1914, Professor Maney and W. M. Wilson, M. Am. Soc. C. E., developed, and in June, 1915, published[14] the solution of wind stresses in a twenty-story office building by the slope-deflection method. This solution was by the exact

simultaneous method. In 1918, Professor Wilson and F. E. Richart, and C. Weiss, Members, Am. Soc. C. E., published a bulletin[15] giving general formulas for a large number of types of structures by the slope-deflection method. These two publications, following Professor Maney's publication and using his methods, gave the "angular unknowns" approach to rigid frame and continuous beam solutions for bending moment distribution the great popularity it has had in the United States.

It should be emphasized that this is a typically American development and that the "general" use of the method of "angle unknowns" has lagged considerably in Europe. (This statement excepts only the problem of secondary stresses which was mentioned by Professor Maney[14].) The European approach to the general case of the rigid frame by the "unknown angles" method is outlined as follows: In May, 1914, Axel Bendixsen[16] published, in Denmark, a monograph which gives the first general statement of the slope-deflection relation for any type of loading. This publication appears to have been generally overlooked even in Europe until about 1923 when Professor A. Ostenfeld amplified it somewhat. In 1923, Professor Ostenfeld published[17] an amplification of Bendixsen's work, the presentation covering all cases for deformations rather than stresses.

An unusual development has followed Professor Maney's general statement of the use of angles as unknowns. Numerous ideas such as moment distribution, and the balancing of angle changes, have followed in its wake and they have all been strictly American variations of the "slope-deflection" theme.

Although this general idea of treating angles as unknowns was first presented in the United States by Professor Maney in 1915, it has since almost completely replaced the "least work" and "virtual work" approach to the problem. In Europe, these latter methods are still much used, in spite of their greater mathematically cumbersome nature.

In the following development some of the important equations and methods referred to by the author may be traced.

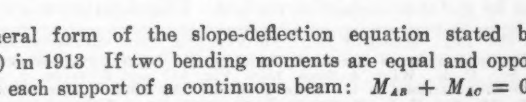

FIG. 15

Item (1).—In Fig. 15,

$$M_{AB} = \pm M_{F(AB)} + 2E\,K_{AB}\,(3\,R_{AB} - 2\,\theta_A - \theta_B) \quad \ldots\ldots\ldots(58)$$

is the general form of the slope-deflection equation stated by Professor Maney (13) in 1913 If two bending moments are equal and opposite in sign, as occur at each support of a continuous beam: $M_{AB} + M_{AC} = 0$; and, when

[15] "Analyses of Statically Indeterminate Structures by the Slope-Deflection Method", by William M. Wilson, F. E. Richart, and Camillo Weiss, *Bulletin No. 2*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill., 1918.

[16] "Die Methode der Alpha-Gleichungen zur Berechnung von Rahmenkonstructionen", von Axel Bendixsen, May, 1914.

[17] "Die Deformationsmethode", by A. Ostenfeld, *Der Bauingenieur*, January 31, 1923.

$R = 0$,

$$M_{AB} = \pm M_{F(AB)} - 2EK_{AB}(2\theta_A + \theta_B) \ldots\ldots\ldots\ldots (59)$$

and,

$$M_{AC} = \pm M_{F(AC)} - 2EK_{AC}(2\theta_A + \theta_C) \ldots\ldots\ldots\ldots (60)$$

Therefore,

$$K_{AB}\theta_B + 2(K_{AB} + K_{AC})\theta_A + 2K_{AC}\theta_C = \frac{\pm M_{F(AC)} \pm M_{F(AB)}}{2E} \ldots (61)$$

It will be seen that Equation (61) is identical with Equation (28) of the paper and is merely the slope-deflection "joint" equation for continuous beams. This is the equation which Gehler (3) called the "equation of three angles" in 1925, and has led to the author's use of this terminology. Similarly, the "equation of five angles" is merely a slope-deflection joint equation for the typical case of a rigid frame with four members framing into a rigid joint, instead of two, as in the preceding case of a continuous beam.

Item (2).—When the factor, $2E$, is cancelled and θ_B and θ_C are assumed to be zero temporarily, then Equation (61) becomes: $\theta_A = \frac{\pm M_{F(AC)} \pm M_{F(AB)}}{2(K_{AC} + K_{AB})}$; and, in general, $\theta_A = \frac{\Sigma M_{F(A)}}{2 \Sigma K_A}$ if there are two or more members at the joint, and $\Sigma M_{F(A)} =$ the algebraic sum of M_F-values at Joint A whereas $\Sigma K_A =$ the numerical sum of the K-values $\left(K = \frac{I}{L}\right)$ around Joint A.

Similarly, $\theta_B = \frac{\Sigma M_{F(B)}}{2 \Sigma K_B}$. If these expressions for θ_A and θ_B are substituted in Equation (61):

$$M_{AB} = \pm M_{F(AB)} - \frac{\Sigma M_{F(A)}}{\Sigma K_A} - \frac{1}{2}\left(\frac{\Sigma M_{F(B)}}{\Sigma K_B}\right) \ldots\ldots\ldots (62)$$

Equation (62) is simply the "moment distribution" equation in which $\frac{\Sigma M_{F(A)}}{\Sigma K_A}$ is the "distribution" factor and $\frac{1}{2}\left(\frac{\Sigma M_{F(B)}}{\Sigma K_B}\right)$ is the "carry-over" factor. By this variant of the slope-deflection method, the "iteration" method is applied through this "carry-over" factor until error is negligible.

Conclusion.—It is important to remember in connection with the entire general plan of solution by means of "angle unknowns", that the M_F-value, or the "fixed-beam" moment is the essential starting point, and that until the slope-deflection method was evolved in 1913, no one had previously used this approach. In connection with the problem of secondary stress, this conception was not involved.

Why do all equations of the type discussed by the author invariably converge when the so-called "iteration" process or "converging approximations" is used? The answer is found to be a purely physical reason which will only

be confounded by any mathematical approach. If Equation (59) is examined it reveals that the angle change, θ_A, at the joint in question, has twice as much influence on the final moment, M_{AB}, as the angle change, θ_B, at the far end from the joint in question. Furthermore, the last term of Equation (62), or the "carry-over" factor, reveals the same thing. When an error at any joint adjacent to the one for which the angle or moment is desired is always at least twice the error caused at the joint in question, rapid convergence by halving of the error at each iteration is assured.

The simple physical facts make convergence, or solution of equations by iteration, possible. If the quantitative importance of angle changes at each end of a member were nearly the same in affecting the moments at both ends, then "successive convergence" or "iteration" would have no place as a method of solution for moments in continuous-beam and rigid-frame members.

MARVIN A. GRAY,[18] JUN. AM. SOC. C. E. (by letter).—Equation (1) of this paper is a conception of the theorem of three moments which, in itself, requires additional explanation for teaching; in a typically popular book of applied mechanics the theorem of three moments is given nine times (probably many more times in other texts and reference books) as:

$$M_1 L_1 + 2 M_2 (L_1 + L_2) + M_3 L_2 = -\frac{1}{4} w_1 L^3_1 - \frac{1}{4} w_2 L^3_2 \quad \ldots\ldots(63)$$

The symbol, Q, is used in only one special problem, whereas there are forty to fifty problems in which the last mentioned form (Equation (63)) is used; and U_x is not mentioned in the entire book. It might be of interest to note that this particular problem of moments, in which Q was used, is not even mentioned in this paper. The development of the author's expression of the three-moment theorem comes from the following algebraic maneuvers:

$$M_1 L_1 + 2 M_2 (L_1 + L_2) + M_3 L_2 = -\frac{1}{4} w_1 L^3_1 - \frac{1}{4} w_2 L^3_2 \quad \ldots(64a)$$

and,

$$M_1 \frac{L_1}{I_1} + 2 M_2 \left(\frac{L_1}{I_1} + \frac{L_2}{I_2}\right) + M_3 \frac{L_2}{I_2} = -\frac{1}{4} w_1 \frac{L^3_1}{I_1} - \frac{1}{4} w_2 \frac{L^3_2}{I_2} \quad \ldots(64b)$$

Then,

$$\frac{M_1}{K_1} + 2 M_2 \left(\frac{1}{K_1} + \frac{1}{K_2}\right) + \frac{M^3}{K_2} = -\frac{1}{4} w_1 \frac{L^2_1}{K_1} - \frac{1}{4} w_2 \frac{L^2_2}{K_2} \quad \ldots(64c)$$

with the addition of symbols for symbols and changing from common notation to that suggested by the author, the reader will arrive at Equation (1)—and the student will be confused.

Equation (8) is also of interest because it too adds to the student's problem. In school before the theorem of three moments is taught, the problem is solved by the calculus. Then, because this does not seem to be sufficient

[18] Chicago, Ill.

explanation, it is again derived by the moment-area method; and again by several variations, or very slight modifications, of moment areas. However, there is a general formula for finding moments, rotations, and movement of beams; this equation (derived from a knowledge of moment areas) is known as the slope deflection equation: $M_{AB} = M_{F\text{-}AB} - \frac{2\,E\,I}{L}\,(2\,\theta_A + \theta_B)$, or,

$$M_{AB} = + M_{F-AB} - \frac{2\,E\,I}{L}\,(2\,\theta_A + \theta_B - 3\,R) \quad\text{.........}(65)$$

Using standard notation (as in the three-moment theorem), the writer obtains the two equations:

$$M_{2\text{-}1} = - M_{F\text{-}2\text{-}1} - K_1\,(2\,\theta_2 + \theta_1) \quad\text{..............}(66a)$$

and,

$$M_{2\text{-}3} = M_{F\text{-}2\text{-}3} - K_2\,(2\,\theta_2 + \theta_3) \quad\text{................}(66b)$$

but $- M_{2\text{-}1} = M_2 = M_{2\text{-}3}$; so that:

$$+ M_{F\text{-}2\text{-}1} + K_1\,(2\,\theta_2 + \theta_1) = M_{F\text{-}2\text{-}3} - K_2\,(2\,\theta_2 + \theta_3) \quad\text{.......}(67)$$

Solving Equation (67) by elementary algebra, the writer derives an equation for a given θ-value:

$$\theta_2 = \frac{M_{F\text{-}2\text{-}1} - M_{F\text{-}2\text{-}3} - (K_1\,\theta_1 + K_2\,\theta_3)}{2\,(K_1 + K_2)} \quad\text{...........}(68)$$

which is as exact as any elastic beam theory used. If it does nothing else, this method at least omits many new and varied symbols that are confusing not only to the student but to the practicing engineer.

The writer omits the author's applications of slope deflection as presented in his paper, and calls attention to Equations (22), (23), (24), and (25). By using the slope deflection equation,

$$M_{AB} = M_{F\text{-}AB} - K\,(2\,\theta_A + \theta_B) \quad\text{................}(69)$$

and correcting for the author's conception of signs from the simpler convention of slope deflection, the writer obtains from Fig. 7:

$$\theta_A = (\theta_A)_0 + \frac{M_A\,L}{3\,E\,I} + \frac{M_B\,L}{6\,E\,I} \quad\text{................}(70a)$$

$$\theta_B = -\,(\theta_B)_0 - \frac{M_B\,L}{3\,E\,I} - \frac{M_A\,L}{6\,E\,I} \quad\text{...............}(70b)$$

$$M_{AB} = M'_A + 2\,E\,K\,(2\,\theta_A + \theta_B) \quad\text{.................}(70c)$$

and,

$$M_{BA} = M'_B - 2\,E\,K\,(2\,\theta_B + \theta_A) \quad\text{................}(70d)$$

A little time spent in following the procedure (or algebra) necessary to arrive at the formulas mentioned, should convince the student or engineer that no "take off" on moment areas or variation of the slope deflection method could be as simple and practical as the slope deflection method itself. Certainly, the writer has proved his point that, fundamentally, this paper is an expression of slope deflection confused by new symbols; the same slope deflection, that is given in the paper (in general, Equation (65)), was originally presented[19] by G. A. Maney, M. Am. Soc. C. E.

The author would create a boon for students if he would take slope deflection and use it with its accepted convention in his teaching practice. The writer has shown that the background for slope deflection, and probably its derivation, is already taught; it seems that the use of Equation (65) with algebra or arithmetic (as is common in engineering) brings a widening of the structural field and applied mechanics in the accurate commercial solution of problems. In aeronautics alone slope deflection should find many uses because of its accuracy and speed; it also lends itself easily to rapidly converging approximations; and with the coming of aeronautical materials into the every-day structural field, the method is indispensable to the Engineering Profession. The author has started on the solution of a very important and useful problem, however, which should end in a symposium on the slope deflection method with its wider use in to-day's engineering, for students and for reference.

JOHN E. GOLDBERG,[20] JUN. AM. SOC. C. E. (by letter).—Discussion of Professor Schwalbe's paper affords an opportunity to emphasize several significant facts in the development of modern American slope-deflection practice:

(1) As early as 1913, Allston Dana, M. Am. Soc. C. E., used the method of iteration to obtain a slope deflection analysis of secondary stresses in the Kenova Bridge.

(2) In 1915, G. A. Maney, M. Am. Soc. C. E., proposed[21] the present general form of the slope deflection equation and demonstrated its application to a wide variety of rigid frame problems. Previous to this time, the slope deflection method existed solely as a means of analyzing secondary stresses in trusses. Professor Maney introduced the fixed-beam moment factor which makes possible the analysis of stresses in loaded frames and which forms the basis of the present simple and popular methods for the analysis of rigid or continuous frames. With the exception of the secondary stress problem, solution of the simultaneous equations was effected by algebraic methods.

Maney, *Engineering Studies No. 1*, Univ. of Minnesota, 1915; see, also, "Wind Stresses in the Steel Frames of Office Buildings", by W. M. Wilson and G. A. Maney, *Bulletin No. 80*, Eng. Experiment Station, Univ. of Illinois, 1915. (See footnote at bottom of page 1, *Bulletin No. 80*, on credit for the theory.)

(3) In 1931, the writer presented[22] a practicable method, based upon slope deflection and successive approximations, for the analysis of rigid building frames and similar structures under the action of gravity loads, largely developed by Professor Maney directly from the original slope deflection equations.

(4) In 1933, several years after its development, the writer presented[23] the method of wind-stress analysis of slope deflection and converging approximations which he developed directly from the basic theory.

A. FLORIS,[24] ESQ. (by letter).—This illuminating paper will undoubtedly bring to the attention of engineers in practice the great importance of iteration in the analysis of statically indeterminate structures. This method of solving simultaneous equations of statics can be applied equally well to other problems than those treated by the author.

The use of converging approximations for determining the values of the end moments of beams and columns in the moment distribution method is, in reality, an iteration process. Furthermore, the treatment, by this method, of problems involving side-sway yields simultaneous equations the number of which is equal to the number of stories. These equations can also be solved by iteration[25].

The author treats the problem of side-sway in rigid frames by applying the equations of five angles. In these equations the unknown angles are determined by iteration. The writer's practice[25] in using the moment distribution method in case of side-sway is, first, to determine the coefficients of proportionality in the equilibrium equations by iteration. The values of the moments are then found by multiplying the distributed moments by these coefficients. In every case of lateral forces or unsymmetrical loads there are obtained simultaneous equations in which the coefficients of the diagonal falling from left to right are considerably greater than the remaining coefficients. In this case, the calculated values approach the true values by repeated approximations. In other words, the equations converge. Contemporary contributions to this important criterion of convergence are: Runge, (2)[3], and Mises and Pollaczek-Geiringer (4) whose work has been cited by the author, and Helmut Wittmeyer[26].

W. L. SCHWALBE,[27] ESQ. (by letter).—The procedure for solving n simultaneous equations of a general nature by successive approximations has been outlined by Mr. Drummond. The iteration procedure in the paper is more useful for those special systems that can be expressed by means

of single equations, the single equation stating precisely what the iteration procedure must be for the solution of the n equations.

The example given by Mr. Fischer is a useful one for making a direct comparison of values computed by his exact method, by the procedure in the paper, and by the moment-distribution method according to Messrs. Thompson and Cutler.[6]

The development of "slope-deflection" methods in the United States proceeded essentially as pointed out by Messrs. Gamet and Goldberg. An additional reference may be cited, namely, the work of F. E. Richart, M. Am. Soc. C. E.[28]

In Germany, formulas of the type of Equations (22) and (23), Appendix II, were used by F. Lippich,[29] in the derivation of the three-moment equation. His equations included terms due to settlement of supports. F. Grashof[30] used formulas of the type of Equations (24) and (25) in deriving the three-moment equation for level supports. In his equations the load factor was not expressed in terms of fixed-end moments.

The writer would extend Mr. Gray's suggestion for a "symposium" to include not only "slope deflection," but all the theories of statically indeterminate analysis, with a glossary of symbols and terminology and a bibliography. In this connection the brief review and history, by H. M. Westergaard, M. Am. Soc. C. E.,[31] of the four general theories would serve as a basis.

The purpose of the paper (as stated in the "Synopsis") was not to present a new theory of statically indeterminate beams and frames, but to demonstrate the method of iteration in the solution of certain types of sets of simultaneous equations which occur in the application of theories already in existence. Consequently, the list of references is not a "who's who" in any particular theory.

It seemed desirable to extend the terminology which was begun by the introduction of the now well-established term, "three moment," to other equations of a similar character; hence, the use of the terms, "three angle" and "five angle" (3)[3]. To call equations of this type "slope deflection" equations, is a misnomer since "slope deflection" formulas are originally of the type of Equations (22) and (23). The latter are only a part of the story of statically indeterminate analysis. Virtual work or continuity and equilibrium conditions are also necessary to determine the final relationships.

The rapidly growing literature in the field of structural analysis gives one the impression of "schools of thought." Perhaps an increasing number of such esoteric sects is necessary for the growth of a subject but, surely, for a beginner the learning of fundamental principles underlying any later ritual is most important.

The importance of iteration in analysis has been emphasized by Mr. Floris. This procedure is especially useful when the statically indeterminate unknowns are selected in such a way that the set of simultaneous equations can be represented by a single equation in the form of a difference equation or recursion formula. Any unknown is thus expressed in terms of its neighbors. With known boundary conditions and convergence, the unknowns can then be computed by starting with any set of arbitrary values for the unknowns and correcting each value step by step by means of the recursion formula until all the values become fixed.

In the theory of elasticity, a differential equation can always be replaced by a difference equation which represents a set of algebraic equations. According to R. D. Carmichael[32]: "A differential equation, with or without boundary conditions, may be realized in an infinite number of ways as the limiting form of an algebraic system, so that there is always room for choice in setting up the system, and in fact need for care that it shall be done in a convenient way." The idea thus expressed may well serve as a guide for approximation methods in many problems for which integral solutions are impossible. The algebraic equations may be regarded as defining a statically indeterminate net or framework, the difference equation serving as a bridge from one field to the other.

Iteration as a method for the determination of roots of algebraic equations had its beginnings in 1674.[33] The earliest applications to the solution of problems in elasticity were probably those of C. Runge[34] and L. F. Richardson,[35] Since then the use of the method has been considerable.

SIMPLIFIED METHOD OF DETERMINING TRUE BEARINGS OF A LINE

By Philip L. Inch,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Earl F. Church, Paul E. Wylie, James B. Goodwin, C. H. Swick, Philip Kissam, George D. Whitmore, O. H. Chilton, Chalmers C. Schrontz, Frank M. Johnson, Walter H. Starkweather, C. I. Day, F. L. McRee, F. J. Duarte, Leonard C. Jordan, J. C. Pinney, R. L. Vaughn, John C. Penn, Robert H. Merrill, Crosby J. Wilkin, C. S. Jarvis, and Philip L. Inch.

Synopsis

A simplified method of computing a direct observation of the sun, for azimuth, is offered in this paper. It involves reference to a comprehensive table[1a] specially prepared for this purpose. The objects of the table are:

(1) To place the determination of a meridian within the attainment of engineers, unprepared, by reason of the pressure of their usual work;

(2) To obviate textbook reference, at the time a meridian is necessary;

(3) To displace the inaccuracy of compass meridians in field conditions where the compass is affected by local attraction;

(4) To reduce the time necessaary to compute a direct solar observation; and,

(5) To reduce trigonometric formulas to simple arithmetic.

Theory

Problems involving the determinations of true bearings may be solved by applying the formula,[2]

$$\cos Z = \frac{\sin \delta}{\cos h \cos \phi} - \tan h \tan \phi \qquad (1)$$

Note.—Published in September, 1936, *Proceedings*.

in which Z = the azimuth of the sun; δ = the sun's declination; h = its altitude; and ϕ = the latitude of the point of observation. Let $\frac{1}{\cos h \cos \phi} = A$; and, $\tan h \tan \phi = B$; then, Equation (1) becomes, simply,

$$\cos Z = A \sin \delta - B \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

The writer has developed a complete table[1a], of which Table 1 is a very condensed form, intended only for the solution of the illustrative example in the paper.

Field Procedure

The field party will need a transit with a full vertical circle, an ephemeris of the sun (obtainable from the Superintendent of Public Documents, United States Printing Office, or from most dealers in engineering instruments), a table of sines and cosines, and the latitude of the point of observation, as scaled from an accurate map.

Example 1.—To find the true bearing of Line XY (Fig. 1): (1) Set the transit firmly at Point X; (2) set the horizontal graduated plates at 0°; (3) level the instrument with extreme care; (4) sight on Point Y; (5) clamp the lower plate; and (6) loosen the upper plate. Using a solar prism or colored glass as a sunshade on the telescope, place the vertical and center horizontal cross-hairs, tangent, respectively, to the right and lower limbs of the sun as shown in Fig. 2(a). The observations are recorded as shown in Table 2, Item No. 1. Reverse the instrument, place the vertical and center horizontal cross-hairs tangent to the sun's left and upper limbs, respectively, and, as before, record the time, the vertical angle, and the horizontal angle, as shown in Table 2, Item No. 2. The mean of the recorded quantities (Item No. 3, Table 2) gives the time when the center of the of the sun has a certain elevation above the earth's horizon and is at a certain horizontal angular distance from Line XY.

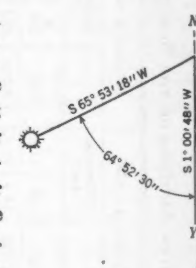

Fig. 1.

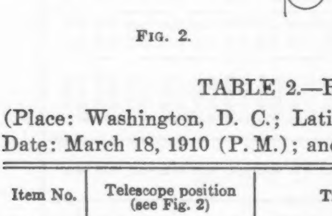

Fig. 2.

TABLE 2.—Record of Observations

(Place: Washington, D. C.; Latitude: 38° 53′ 40″ N; Eastern Time Belt; Date: March 18, 1910 (P. M.); and Point Y (Fig. 1) to the Left of the Sun.)

Item No.	Telescope position (see Fig. 2)	Time	Vertical angle	Horizontal angle
1.....	Direct	3 hr 53 min 05 sec	25° 20′ 00″	65° 00′ 00″
2.....	Reversed	3 hr 54 min 55 sec	25° 31′ 00″	64° 45′ 00″
3.....	Mean	3 hr 54 min 00 sec	25° 25′ 30″	64° 52′ 30″

Concisely, the computations may be arranged as follows:

Substitution Factors =	A	B
$h = 25°$; $\phi = 38°$ (see Table 1)	1.39989	0.36378
$+h =$ 0° 25′ 30″	495 = $25\frac{1}{2} \times 19.4$	712 = $25\frac{1}{2} \times 27.9$
$+\phi =$ 0° 53′ 40″	1750 = $53\frac{2}{3} \times 32.6$	1186 = $53\frac{2}{3} \times 22.1$
Total	1.42234	0.38276
$\sin \delta$ =	$\times$ 0.01811	......
$A \sin \delta$ =	0.025759	......
Natural cosine, bearing of the sun.................... =	0.38276 − 0.02576 =	0.40852
Bearing of the sun......... =	S 65° 53′ 18″ W	
Horizontal angle (see Table 2) =	64° 52′ 30″	
Bearing of Line XY (see Fig. 2).................. =	S 1° 00′ 48″ W	

The foregoing computations may be further explained as follows: From Table 1 select the values of A and B corresponding to the even degree of vertical angle and latitude, refining both for the additional minutes. Since the altitude used for computing Table 1 is obtained by applying the average refraction correction for the corresponding vertical angle, the computer is relieved of the necessity of applying the refraction correction and the parallax.

The ephemeris gives the declination of the sun, either north or south, at noon in Greenwich, England, and also gives an hourly change, which is either additive or subtractive. This declination at noon is the declination of the sun at:

7:00 A.M. within the Eastern Time Belt
6:00 A.M. within the Central Time Belt
5:00 A.M. within the Mountain Time Belt
4:00 A.M. within the Pacific Time Belt

Thus, in Example 1, the sun's declination, δ, is found to be 1° 02′ 16″ S; and the natural sine of δ = 0.01811. Multiply Factor A by $\sin \delta$ to obtain 0.02576, and this value, added to B = 0.38276, yields 0.40852, which is the natural cosine of the bearing of the sun. If the declination of the sun is north, subtract $A \sin \delta$ and B, the smaller from the larger. If $A \sin \delta$ is the larger, the bearing of the sun will be from the north (as, northeast and northwest); and, if B is the larger, the bearing of the sun is from the south (as, southeast and southwest). If the declination, δ, is south, add $A \sin \delta$ and B, and the bearing of the sun is from the south (as, southeast and southwest).

Finally, to the bearing of the sun, apply the horizontal angle to obtain the bearing of Line XY, S 1° 00′ 48″ W, allowing a probable error of 1′.

Conclusion

The writer disclaims all intention of introducing a "new method" to the Engineering Profession; his intention is simply to reduce to the commonest wording the intellectual niceties of an astronomical observation. The method of observation described herein is an old one; yet arranged more nearly in keeping with the elementary design of the paper. Any suggestions for the improvement of Table 1, compatible with its intent and purpose, will be appreciated.

DISCUSSION

Earl F. Church,[8] Assoc. M. Am. Soc. C. E. (by letter).—Modern revolutionary developments in the science of surveying, in instruments used, in methods followed, and in results required, are making heavy demands on the technical training of surveyors. Practical astronomy is one phase of the subject in which proficiency would seem imperative. Certainly every surveyor should understand thoroughly the astronomic triangle (sometimes called the *PZS*-triangle) and its applications; the full significance of its six elements; which of the six can be found in an ephemeris; which of them can be observed; the spherical trigonometry methods of calculating any missing elements when three are known; and the practical use of the six elements in geodetic astronomy. In fact, these very points, together with the various time transformations, actually constitute the basis for a working knowledge of practical astronomy, which should be one of the working tools of every surveyor. Any work, such as the preparation of Mr. Inch's paper, in so far as it assists engineers in fulfilling the demands of modern surveying practice, is to be highly commended.

Free use of astronomic methods for azimuth determination, is certainly to be encouraged. Doubtless, it is fitting that the author should recommend the altitude method of making the observation, for the computations are simpler than those for the hour-angle method. If the altitude method of observing is used, there are three methods of computation to be considered: (1) The method described by Mr. Inch, utilizing the special table (expanded Table 1); (2) logarithmic computation of the desired azimuth, using a different form of the astronomic triangle formula better adapted to logarithmic calculations than that shown in the paper; and (3) computation of the desired azimuth by means of the same formula shown in the paper, using a calculating machine, and without using Table 1. The writer proposes to discuss these three methods.

(*1*).—*Computation of Azimuth as Recommended by the Author.*—The surveyor would require a table of angular functions, a solar ephemeris, and the data presented by Table 1. The computation itself is shown in the paper and is not reproduced here.

(*2*).—*Computation of Azimuth by Logarithmic Calculation of the Astronomic Triangle.*—The surveyor would require a logarithmic table and a solar ephemeris, including a table of refraction and parallax corrections, but not the auxiliary table given in the paper. The formula used is:

$$\sin \frac{1}{2} Z = \sqrt{\frac{\sin \frac{1}{2} (z + \phi - \delta) \cos \frac{1}{2} (z + \phi + \delta)}{\cos \phi \sin z}} \quad \ldots\ldots\ldots(3)$$

[8] Associate Prof. of Photogrammetry, Coll. of Applied Science, Univ. of Syracuse, Syracuse, N. Y.

(in which, in addition to the notation of the paper, z = zenith distance), and the computation follows:

Observed h	=	25° 25′ 30″	$\log \sin \frac{1}{2}(z + \phi - \delta)$	=	9.89812
Refraction	=	−0° 2′ 01″	$\log \cos \frac{1}{2}(z + \phi + \delta)$	=	9.79670
Parallax	=	+0° 0′ 08″	colog $\cos \phi$	=	0.10885
			colog $\sin z$	=	0.04413
h	=	25° 23′ 37″			
z	=	64° 36′ 23″		2)	9.84780
ϕ	=	38° 53′ 40″			
			$\log \sin \frac{1}{2} Z$	=	9.92390
$z + \phi$	=	103° 30′ 03″	$\frac{1}{2} Z$ =		57° 03′ 45″
δ	=	−1° 02′ 16″	Z =		114° 07′ 30″
					S 65° 52′ 30″W
$z + \phi - \delta$	=	104° 32′ 19″			64° 52′ 30″
$z + \phi + \delta$	=	102° 27′ 47″			
$\frac{1}{2}(z + \phi - \delta)$	=	52° 16′ 10″			
$\frac{1}{2}(z + \phi + \delta)$	=	51° 13′ 54″			S 1° 00′ 00″W

(*3*).—*Computation of Azimuth by Solving the Astronomic Triangle by Natural Functions and a Calculating Machine.*—The surveyor would require a table of natural functions of angles, a solar ephemeris, and a calculating machine, but not the special table (expanded Table 1).[14]

Equation (1) is used for this case and the entire computation is as follows:

Observed h	=	25° 25′ 30″	ϕ	=	38° 53′ 40″
Refraction	=	−0° 2′ 01″	δ	=	−1° 02′ 16″
Parallax	=	+0° 0′ 08″			
h	=	25° 23′ 37″			

$\sin \delta$	=	−0.01811	$\dfrac{\sin \delta}{\cos h \cos \phi}$	=	−0.02576
$\cos h$	=	0.90341	$\tan h \tan \phi$	=	0.38296
$\cos \phi$	=	0.77830			
$\tan h$	=	0.47470	$\cos Z$	=	−0.40872
$\tan \phi$	=	−0.80674	Z	=	65° 52′ 32″
					64° 52′ 30″
					S 1° 00′ 02″W

It will be noted that by far the simplest calculation is the third, by means of natural functions with a calculating machine, but without the special table given in the paper. It will also be noted that the logarithmic calculation without Table 1 is really no longer or more difficult than the computation shown in the paper by means of the special auxiliary table.

The conclusions, therefore, are obvious: (1) The altitude method of determining azimuths by solar observations is simple, and its use is to be encouraged; (2) the field procedure described by the author is entirely adequate; (3) the quickest and most convenient method of computation, however, is by means of the formula, Equation (1), using natural functions and a calculating machine, but without the special table; and (4) further development of Table 1 for the purpose of facilitating the computation is scarcely worth while, because the calculating machine method, without an auxiliary table, is more accurate, and is easier.

PAUL E. WYLIE,[4] M. AM. SOC. C. E. (by letter).—A valuable short method of solving the astronomical triangle for azimuth is presented in this paper. It would be interesting if Mr. Inch would add data concerning the effect upon the accuracy of the result due to his assumption that A and B each vary in direct proportion throughout 1° of altitude.

Modern methods of navigation are based upon the solution of this same astronomical triangle, and much ingenuity has been expended upon labor-saving tabulations for the purpose. The navigator needs the azimuth of the sun (or other heavenly body) not only for the determination of compass error, but also in order to lay down upon the chart, in the proper direction, the line of position on which his ship is located. He does not, however, require azimuth within an error which is less than the error of plotting; consequently, most navigators' tables are not adapted to the use of the engineer.

To this rule there is at least one exception. A table[5] compiled by Lieut. Arthur A. Ageton, U. S. N., involves no knowledge more complicated than the addition or subtraction of two numbers. There is no interpolation and no multiplication. One addition and one subtraction of tabular values suffice to determine the azimuth, with a maximum error of less than a half minute of arc.

In the writer's opinion, Lieut. Ageton's method is as rapid in use as that of the author, and it probably presents even less opportunity for error. Moreover, it is already available at any agency of the Hydrographic Office at (to quote the statute) "the cost of printing and paper." An example, adapted from "Problem III", in Lieut. Ageton's 50-page book, follows: On December 17, 1934, at Latitude 20° 10′ N.; Longitude 163° 33′ W., the altitude of the sun (corrected) was observed to be 43° 36.0′ at G. C. T. 21 hr. 45 min. 26 sec. Find the sun's azimuth.

From the almanac, determine the local hour angle and the declination of the sun in the usual manner. Opposite each half minute of arc in the tables, two columns are found, marked A and B. Using the tables as noted:

Local hour angle =	(arc) 16° 13.4′ E.	A 55 376	(using nearest tabular value)
Declination =	23° 21.9′ S.	B 3 716	
		59 092	
Altitude =	43° 36.0′	B 14 076	
Azimuth = 159° 13.5′, corresponding to		A 45 016	

The simple underlying theory is given in the publication, and need not be repeated herein. The Ageton method involves an accurate knowledge of the time, and a working familiarity with the co-ordinates of the celestial sphere. In this respect, it is inferior to the author's method, and is disqualified for ordinary or occasional use, but its virtues make it well worth the attention of surveyors who must determine astronomical azimuths habitually.

[5] "Dead Reckoning Altitude and Azimuth Table", by Lt. Arthur A. Ageton, U. S. N., Hydrographic Office, *Publication No. 211*, U. S. Navy Dept., Washington, D. C.

JAMES B. GOODWIN,[6] M. AM. SOC. C. E. (by letter).—Suggestions have been solicited for making Table 1 serve its purpose more efficiently, and the only criticism that the writer would think applicable is that, perhaps, it might be more convenient if the sines of the angles of the sun's declination were embodied in an additional column, together with an accompanying column of differences for each minute. The column of altitudes (Column (1)) would then be combined to include the declinations. It would then be necessary to refer to only one source for altitude, latitude, and declination factors.

Equation (1) may be written in another form, namely:

$$\cos Z = \frac{1}{\cos h \cos \phi} (\sin \delta - \sin h \sin \phi) \ldots\ldots\ldots\ldots (4)$$

where $\frac{1}{\cos h \cos \phi}$ is as defined in the paper and $\sin h \sin \phi$ replaces $\tan h \tan \phi$. However, it is questionable whether this is any improvement on the author's procedure.

It would appear that, in the selection of the declination, standard time has been used for the 75th Meridian. In some possible conditions the use of standard time might lead to appreciable errors in establishing azimuths, especially at or near the limits of standard time belts. As an illustration, assume two traverse lines on either side of the boundary between two standard time belts or zones, run generally northerly and relatively close to the division line. One would have azimuths derived from a time 1 hr different from the other, whereas the same declination for the sun should practically apply, if close to the boundary.

Since the sine of the sun's declination is multiplied by $\frac{1}{\cos h \cos \phi}$, the effect on the resulting azimuth is apparent. It would seem more nearly precise to consider the longitude of the place of observation in determining the time for the sun's declination referred to Greenwich.

In the illustration as given, there would be a difference in time corresponding to 2° of longitude, assuming Washington to be on the 77th Meridian. It would be of interest to know why, in determining azimuths, preference appears to be given to the method outlined as against observations on Polaris.

C. H. SWICK,[7] ESQ. (by letter).—Simplification of engineering methods and computations is always desirable, but this is especially true when astronomical measurements are involved. Ordinarily, an engineer has little need to start or check his surveys by the use of astronomical determinations and, therefore, is likely to lack familiarity with astronomical methods and computations. The method proposed by Mr. Inch is quite simple to apply and, therefore, will probably prove useful in certain types of surveys. The factors which he proposes to obtain from the table are rather easily computed for the indi-

[6] Toronto, Ont., Canada.

[7] Chf., Section of Gravity and Astronomy, U. S. Coast and Geodetic Survey, Washington, D. C.

vidual observations, and it is questionable whether the double interpolations can be made from the table any more readily and quickly than the factors could be computed directly. The table has the advantage, however, that gross errors in the computations are probably less likely to occur when it is used.

The form of table proposed by Mr. Inch is compact and easily followed. As published, the interpolation interval is large, and this results in some inaccuracy especially in those parts of the table where the tabulated differences change rapidly, but the table would become rather unwieldy to compute and publish if the interval were decreased to 10 min or even to 30 min.

PHILIP KISSAM,[8] Assoc. M. Am. Soc. C. E. (by letter).—There are many advantages inherent in the determination of azimuth by sun observations. The method is chiefly applicable to route surveys or traverses of this type where neither established azimuth control is available nor high precision necessary. Under average conditions an azimuth determined by this method will be within 0° 2′ of the correct value, depending on the latitude and time of year. The observations require 10 min, or less, time in the field and about 20 or 30 min for computation. They can be made during the regular program of observations and should be made once every clear day. Polaris observations usually are made more successfully at night than in the late afternoon when Polaris is visible during working hours, and the preparation necessary for night observations, including the transportation of the field party to the site, usually requires an hour or more, is inconvenient, and often interferes with the progress of the next day's traverse work.

Since the sun method is so useful and can be made so frequently, it is important that the computations should be made with least difficulty. The value of the paper by Mr. Inch is the saving of time for computation. It will be interesting to compare the two usual methods of computation with that of the paper: Method (*a*) involves a formula for use with a computing machine, as follows:

$$\cos Z = \frac{\sin \delta - \sin \phi \sin h}{\cos \phi \cos h} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(5)$$

and Method (*b*) involves a formula for use with a table of logarithms, as follows:

$$\cot^2 \frac{Z}{2} = \frac{\sin (s - \phi) \sin (s - h)}{\cos s - \cos [s - (90 - \delta)]} \quad \ldots\ldots\ldots\ldots(6)$$

in which, in addition to the notation of the paper.

$$s = \frac{\phi + h + (90 - \delta)}{2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(7)$$

The steps required for computation are shown in Table 3. It will be noted that Method (*b*) requires several additions and subtractions of angles (9) which require time and may cause blunders. The Inch method requires fewer operations, and the references to the table are more convenient.

[8] Associate Prof. of Civ. Eng., Princeton Univ., Princeton, N. J.

The author mentions the necessity of a solar ephemeris for computation of the sun's declination. It might be well to note that the best type of ephemeris to use is one that gives the declination at civil time (as in the Nautical Almanac). It is necessary to have an ephemeris for the proper year. If a permanent declination table is desired, the reader is referred to the report entitled "Azimuth Determination", by E. F. Coddington, M. Am. Soc. C. E.[9] Tables in this *Bulletin* extend through the year 2000, but the necessary computation is slightly more laborious.

TABLE 3.—COMPARISON OF METHODS OF COMPUTATION

Steps required	Method (a)	Method (b)	Inch method
References to a table	6	5	4
Interpolations	6	5	6
Multiplications or divisions	3	0	1
Other minor steps	0	9	3

The "Field Procedure" suggested by Mr. Inch is not the only practical one available. An excellent method is described under the title, "Topographic Instruction of the U. S. Geological Survey."[10] The chief feature of this method is in bisecting the sun's disk rather than in bringing the cross-hairs tangent to the disk. Ten pointings are recommended instead of two. The field time necessary for the ten pointings is about 6 min so that the average of the ten pointings can be used without danger of errors due to the curved path of the sun. Both the aforementioned *Bulletins* recommend using a white card behind the eye-piece on which the sun's image appears with the cross-hairs visible across the image. This method is rapid, as the observer does not have to place his eye at the eye-piece, and easy to use as no special equipment is necessary. The eye-piece must be focussed for this method, but this is balanced by the time required to attach a colored glass or prism.

(There is a difference of opinion as to the relative accuracy of pointing the instrument at the edge of the sun's disk rather than bisecting it. One of the faults of a sun observation is the difficulty of pointing a moving object. Although the sun's disk is large, the writer believes that bisection is more accurate. It is very difficult indeed to bring the cross-hairs to the edge of the disk without bringing them into the disk. Any effort to bring a cross-hair to the edge of a target is fraught with difficulties, whereas the eye can bisect with surprising accuracy as long as the entire image is visible without shifting the eyeball. An experimental determination of the comparative accuracies might well be made. It is also noted that special cross-hair arrangements are available from many instrument makers in which intersecting wires form a square slightly smaller than the sun's disk and for which claims are made of greater accuracy of pointing.)

In connection with the field procedure described in the paper, Step (3), namely, "level the instrument with extreme care", it might be well to recom-

[9] *Bulletin No. 79*, Eng. Experiment Station, Ohio State Univ., Columbus, Ohio, September, 1930.

[10] *Bulletin 788-C*, U. S. Geological Survey.

mend leveling with the bubble tube attached to the telescope if such a bubble is available. No amount of reversals will eliminate the errors caused by the vertical axis not being exactly vertical.

GEORGE D. WHITMORE,[11] M. AM. SOC. C. E. (by letter).—Unquestionably, the method presented by Mr. Inch for computing solar azimuth observations is a time-saver. Actual tests indicate that by his method the sun's azimuth can be found in about one-half the time required for solving the formula by use of trigonometric functions. It must be realized, however, and prospective users should be so warned in the explanatory text, that the azimuth found by this short-cut method may be incorrect by as much as 1′ in azimuth, solely because the interpolated values for Factors A and B may be incorrect. This is because the tables give the A and B factors only for each degree of altitude and each degree of latitude. For practical reasons, the intermediate values must be based on straight-line interpolation, whereas actual intermediate values would follow a curved line.

Taking the author's example for illustration, the azimuth obtained by solving the spherical trigonometry formula gives a result about 30″ lower than the one he secures by using the A and B tables. Other experiments showed that, under certain conditions and combinations, the azimuth secured by using the tables of this form could be in error by as much as 60″.

In Example 1, Factor B is taken for 38° of latitude, the actual latitude being 38° 50′ 40″. The author finds the value for Factor B by interpolating between 38° and 39°, taking the tabulated difference of 22.1 for 38° of latitude, multiplying this value by 53′ 40″, and adding the result to Factor B for Latitude 38°. (A closer result would have been secured, incidentally, had he found B by interpolating "downward" from 39°, the actual latitude being only 6′ 40″ less than 39°, compared with 53′ 30″ plus from 38°.) The point, however, is that the difference in the fifth place of logarithms for Factor B for 1′ at 38° is 22.1, and for 1′ at 39° is 22.7. It is apparent that this difference of 0.6 will create rather sizable differences in the values for Factors A and B, when the latitude is about midway between the even degrees.

Readers should be warned also that Factor B is perhaps a more critical value than Factor A. They will both be subject to some error, but whatever the error might have been in Factor A, as taken from the tables, its effect is considerably reduced when A is multiplied by sin δ, which may be any quantity between 0.0 and 0.4. Factor B is used in the formula, however, just as it is taken from the tables, and is not reduced in any manner. The explanation should include a warning also that the computed result will vary in accuracy with the seasons, since the greater the declination and the larger its sine, the less the error in Factor A is reduced. It also appears that a south declination is likely to give a greater error than a north declination, since the two factors, A and B, are always added when the declination is south.

Inexperienced computers should be warned as to the declination tables to be used. Some of the solar ephemeris tables published by instrument manufacturers, supposedly to be used in connection with solar attachments, give

[11] Chf. of Surveys, Maps and Surveys Div., T.V.A., Chattanooga, Tenn.

the declination as including refraction corrections. The author's table gives the values for A and B already corrected for refraction; hence declination tables used in connection with this method should never include refraction corrections.

The tables might be more conveniently arranged by using one full page for each degree of latitude, and giving A and B values for altitudes from about 10 to 49°. Under this arrangement, the page might be divided into four columns, each column covering a range of 10° of altitude. This arrangement might also prove to be of advantage to a survey party wishing to compute solar azimuths in the field, as only one or two pages of the tables would be required for any one locality, thus eliminating the need for carrying a full set of tables for all latitudes. For the benefit of inexperienced computers, it might be well to explain that the "Differences for 1′" are in units of the fifth decimal place.

Except for the questions raised herein, it is believed that the five objects stated in the "Synopsis" will be accomplished, except possibly Item (2), which is to "obviate textbook reference." The tables and the necessary explanations suggested by the author will in themselves constitute a textbook, and will have to be present always when solar azimuth observations are to be computed. It is suggested also that the principal uses of the method may be by computers who are engaged in calculating many solar observations as a routine operation, rather than by the engineer making an occasional solar observation and computation. Such an engineer may not be aware of the existence of these tables, or may not have them in his library, and the few extra minutes required to develop the regular formula is not so important where only an occasional observation is required. On the other hand, the saving in time for a computer calculating many observations, day after day, may be important. If this is to be the principal use, then it might be well to expand the table, showing the factors for, say, every 10′ or 20′ of altitude, and similarly for latitude. Such expansion of the tables would eliminate also the previous comments on inaccuracy in the interpolated values for the A and B factors.

O. H. Chilton,[12] Esq. (by letter).—Many engineers, to whom the intricacies of field astronomy are a mystery, will welcome this paper and the simplification of the work of finding the azimuth of a line which it enables. For the very reason that it is addressed to those who are not fully acquainted with the subject, it seems all the more desirable to draw attention to some points which, as they stand at present, are likely to cause confusion.

Consideration of the formulas of the paper shows that the exact time of observation does not enter into the computations. The only purpose for which the time is observed is that of obtaining the correct declination of the sun from the ephemeris.

The limitations of Table 1 in its present form with somewhat wide intervals of 1°, will result in no great accuracy in the azimuth obtained.

[12] Asst., Dept. of Civ. Eng., Imperial Coll. of Science and Technology, London Univ., London, England.

The author suggests a probable error of 1′. Accepting some such degree of accuracy, it can be easily shown that even at the more unfavorable seasons of the year, when the sun's declination is changing most rapidly, if the time of observation is known to the nearest 10 min, the present purpose will be adequately served. Thus, it would be quite sufficient for the observer to look at his watch at the beginning and at the end of the observations, and to take the mean of the times, or even to record merely one time, to the nearest minute, when reversing the instrument between pointings at the sun. The recording and averaging of times to the nearest 5 sec in Table 2 is not necessary and is misleading.

In the instructions for the field work there should be a clear statement that observations for azimuth should not be made on the sun except when it is favorably situated in the heavens. It can be shown that the effects, on the azimuth obtained, of errors in the assumed values of the latitude and the declination, are least when the sun is on the prime vertical—that is, due east and west. However, for the present purpose, it would suffice to limit observations to those periods when the sun is more than 3 hr off the meridian, that is, to mornings before 9:00 A. M., and afternoons after 3:00 P. M.—always having regard to the possible incidence of summer (daylight saving) time and any large variation between the local civil time and the true sun time at the place of observation.

The engineer will require some indication of the accuracy requisite in the value of the latitude of the place of observation, which he is instructed to obtain from "an accurate map." A map may be accurate, but the scale may be too small for some purposes. By differentiation of the fundamental equation relating the azimuth to the observed and assumed quantities it can be shown that:

$$\delta Z'' = -\delta c'' \frac{\cot t}{\sin c} \qquad \text{(8)}$$

in which Z = azimuth; $c = 90° - \phi$; and t = hour angle.

Assuming that azimuth observations will be made by this method only when the sun is more than 3 hr off the meridian, and that the paper is addressed to engineers working in the United States between limits of latitude of, say, 49° and 30° N, it can easily be computed that for $\delta Z = 60''$, δc has a mean value of about 45″. There will be other sources of error in the computation, although possibly operating to balance each other. However, allowing, say, one-third of the error to this source (say, 15″ in the latitude, which is about 1 500 ft on the ground) a map of not less than 0.5 in. to 1 mile is indicated.

It is unfortunate that the author has chosen an example solved as long ago as 1910, and has included in the text a statement which was true for that year, and indeed until 1924. The American Ephemeris, in common with the ephemerides of other countries such as the British "Nautical Almanac", now gives the elements of the sun's position, such as the declination, for each day "for 0 hours Greenwich Civil Time which is 12 hours before Greenwich Mean Noon of same date." A mean hourly variation of declination is

no longer tabulated, but finite differences between each of the daily values are given. As it stands at present the text would cause much confusion to an engineer, uninstructed in these matters, who was attempting to apply the method.

With regard to a possible extension of Table 1 the proposed range of values of the vertical angle and of the latitude, is not stated. In Table 1 as printed, an altitude as low as 21° is given. This might be open to question on account of the magnitude of the refraction correction involved. A lower limit of 25° is suggested. If it is intended to compute the table for latitudes north of the United States, the unsuitability of the method to very high latitudes will doubtless be borne in mind.

Until the limits of latitude for which the table is to be computed are known, it is not possible to comment finally on its form, but even for the part of the table printed, there is doubt as to its suitability. The writer has compared the methods of computation of the worked example, and the azimuth so obtained appears to differ by 45″ from that given by Table 1. Taking the author's standard of accuracy, "a probable error of 1′", a discrepancy of 45″ arising solely from the method of interpolation from the table is too great to be acceptable when there are other sources of error all operating to effect the final accuracy of the determination, such as errors in the assumed latitude of the place, sun's declination, and the observed angles.

Examination of the part of the table available shows that the method of linear interpolation by first differences becomes still more inadequate as the values of altitude and latitude increase. The worked example is taken from the most favorable part of the table. As it stands it could, of course, be made to serve its purpose if interpolation by second differences is resorted to; but that is scarcely likely to appeal to the engineer in the field, and indeed a direct computation by formula adapted to logarithmic working would be almost as rapid. If the form of the table is to be retained with interpolation direct by first differences, then it does appear that the intervals of 1° in both altitude and latitude may have to be broken down to 30′, or perhaps 20′, for the higher values.

CHALMERS C. SCHRONTZ,[13] M. AM. SOC. C. E. (by letter).—Equation (1) of this paper can be solved mechanically by the solar compass or by a solar attachment to the transit when the apparent altitude and declination of the sun are employed instead of their true values, as used in the method by direct observation. There are no means by which the correction for direct refraction in altitude can be made in the use of the solar attachment. A compensating correction must be made which can be applied to the declination arc of the solar attachment.

The declination correction is applied to an angle normal to the plane of the equator, whereas the direct refraction is applied to an angle normal to the horizon at the place of observation. Consequently, the declination correction for refraction is an increment of an angle in a system of polar co-ordi-

[13] Associate Engr., U. S. A. Engrs., Jacksonville, Fla.

nates corresponding to an increment of an angle in another system of polar co-ordinates, the two systems of which are coincident in the vertical plane passing through the pole of one, and the zenith of the other, system at the place of observation. Therefore, the refraction correction for declination is mathematically comparable with the direct refraction for altitude.

This relation of polar co-ordinates has made it possible to solve this problem mechanically by the use of the solar attachment and the same solution may be made mathematically from a direct observation of the sun.

The table for corrections to be applied to the true declination in order to determine the apparent declination of the sun for the hour and latitude of the place always accompanies the solar ephemeris. In either case, whether the solution of the spherical triangle is to be made from the true or from the apparent altitude of the sun, the declination as given in the ephemeris for noon at Greenwich must be corrected for the hourly change from Greenwich noon to the time of observation. The apparent declination is then obtained by the addition or subtraction of the refraction correction for declination corresponding to the time and latitude of the place of observation. When the apparent declination is used, these two corrections for hourly change and refraction are the only ones required, no correction being necessary for the observed altitude of the sun.

In the writer's experience this problem can be solved most satisfactorily by the use of a table of logarithmic and natural trigonometric functions, together with a solar ephemeris (furnished gratis by the instrument manufacturers), and a map from which the longitude and latitude of the place can be determined. In the tables of logarithmic functions the cosines and tangents of the latitudes occur on the same page and on the same line and also the same functions, for the vertical angles, which greatly facilitates the selection of the values of functions. Examples of the solution of the formula based upon the true and apparent altitude and declination follow.

Example 2.—Solution based upon apparent altitude and declination of the sun:

Date: April 30, 1936.
Place: Latitude, 40° North; longitude, 105° West.
Declination sun, Greenwich, noon, N 14° 48.3′.
Hourly change, + 0.76′ (declination increasing).
Time of observation: 9:00 A. M. (local mean time).
Altitude of sun's center, 43° 31′ 30″. (No correction to be applied to observed altitude.)

Apparent declination of sun at time of observation:

Longitude, 105° West, at 15° per hr is 7 hr from Greenwich, noon, to place of observation, noon.
Time of observation, 9:00 A. M., is 3 hr before noon at place of observation.
∴ Time of observation is 7 − 3 = 4 hr after noon at Greenwich.

Declination, Greenwich, noon............	N. 14° 48′ 18″
Hourly change, 4 × 0.76′..................	0° 3′ 2″
Declination at time of observation........	N. 14° 51′ 20″
Refraction for third hour (from noon), Latitude 40° N........................	+ 0° 0′ 40″
Apparent declination for time and place...	N. 14° 52′ 00″

Solution:

$$\phi = 40°;\ h = 43°\ 31'\ 30'';\ \text{and},\ \delta = +\ 14°\ 52'\ 00''$$

Logarithms:

cos ϕ..........	9.884254	tan ϕ..........	9.923713
cos h..........	9.860382	tan h..........	9.977630
log.............	9.744636	log.............	9.901443
Co-log............	10.255364		
sin δ...........	9.409207		
log.............	9.664571		

Natural functions (corresponding to foregoing logarithms):

	(+) 0.461924	(−) 0.796971
	(−) 0.796971	
cos Z =	(−) 0.335047; and, $Z = 70°\ 25'\ 49''$	

Example 3.—Computation based upon true altitude and declination of the sun:

Observed altitude, sun's center..............	43° 31′ 30″
Correction for refraction and earth's parallax, 0.9′	− 0° 0′ 54″
True altitude	43° 30′ 26″
Sun's true declination for time of observation (as in Example 2)......................	14° 51′ 20″

Solution:

$$\phi = 40°;\ h = 43°\ 30'\ 26'';\ \text{and},\ \delta = 14°\ 51'\ 20''$$

Logarithms:

cos ϕ..........	9.884254	tan ϕ..........	9.923813
cos h..........	9.860510	tan h..........	9.977360
log.............	9.744764	log.............	9.901173
Co-log............	10.255236		
sin δ...........	9.408890		
log.............	9.664126		

Natural functions (corresponding to foregoing logarithms):

$$\begin{aligned} & (+)\ 0.461451 \\ & (-)\ 0.796475 \\ \cos Z = & (-)\ 0.335024;\ \text{and, } Z = 70^\circ\ 25'\ 35'' \end{aligned}$$

The difference in the two results, of 14" of arc, is deemed negligible in view of the interpolation of the values in the tables of functions for seconds of arc and the tabulated difference in refraction for the two systems of polar co-ordinates.

The signs of the declination (+ for north and − for south) become important when the direction of the sun is close to the east or west point from the point of observation. If the result, cos Z, is +, the direction of the sun is to be referred to the north point, and when it is −, as in this case, the direction is to be referred to the south point.

It is to be noted that the cos ϕ, tan ϕ, and sin δ can be taken as constants for several observations taken within 15 or 20 min without appreciable error in the results. This provides ample time to make several observations in which only the altitude and azimuth of the sun will change materially. The arrangement of the solution lends itself to several computations simply by supplying the changed values of cos h and tan h. Consequently, the solution is thus expedited.

Field Operations.—The travel of the sun's disk when viewed through the telescope of the solar attachment is parallel with the two horizontal cross-hairs and when the sun's disk is brought between these parallel cross-hairs by the lower tangent screw of the transit, the transit telescope points to the true north or south, provided, of course, that the proper latitude and apparent declination have been used. In this position it will be some time before the sun's disk can be detected to move above or below the horizontal cross-hairs of the solar telescope, which is due only to the sun's change in declination. This allows plenty of time to make a precise setting of the cross-hairs of the solar telescope on the limbs of the sun, and, hence, a precise pointing of the transit telescope on the true meridian. When the proper declination is once set off for the time and latitude of the place, one single observation is sufficient to determine the meridian.

In a direct solar observation the sun does not travel parallel with either the horizontal or the vertical cross-hairs of the telescope, but in a diagonal direction across the field of vision. In the usual method of pointing the telescope for forenoon observations, the vertical and horizontal cross-hairs are brought simultaneously in contact with the right and upper limbs of the sun, recording the vertical and azimuth angles; then reversing the telescope and setting the cross-hairs in contact with the left and lower limbs of the sun and recording the vertical and azimuth angles. For afternoon observations, the lower and right, and upper and left, limbs are observed and recorded in the same way. The means of the vertical and azimuth angles for each pair of observations are taken as the apparent altitude and true azimuth of the sun's center for the mean time of the two observations.

It is evident that such observations cannot be made with the ease and precision attained in the setting with the solar attachment. The results obtained in a direct observation are never so uniform, satisfactory, or trustworthy as those obtained with the solar attachment, unless in the case of two or more direct solar observations. One single determination from direct observation is scarcely trustworthy.

The results of a direct observation are easier, quicker, more uniform, and more satisfactory when the observation is made upon the center and tangent to the lower limb of the sun by bisecting, with the vertical cross-hair, a small segment of the sun just before contact of the horizontal cross-hair with the lower limb of the sun. To the vertical angle thus obtained the sun's mean semi-diameter is added, 16′ of arc, to obtain the altitude of the sun's center. The greatest variation of the sun's mean semi-diameter is 18″ of arc, and may be neglected unless greater precision is required. The horizontal angle is the azimuth of the sun, and no correction to it is necessary. Five observations are usually taken alternatively in direct and reverse positions of the transit. Each observation is treated independently. At least two observations are used to determine the azimuth. When these agree within less than 1′ of arc the mean of the two results is accepted. If not, one or more of the remaining observations are used for azimuth determinations. Seldom more than two or three determinations are necessary to obtain the desired result. The apparent declination is determined for the mean time of all the observations and is used as a constant for all the observations, so that for each independent determination of azimuth of the sun there are three constant values that must be taken once only from the tables of trigonometric functions, namely, cos ϕ, tan ϕ, and sin δ.

In this procedure one erratic result occasionally may be obtained in the azimuth determination which will evidence an error either in the solution or in the observation and may be corrected or discarded. The error thus discovered is confined to one single observation, whereas in the use of the mean of two observations, the error is reduced one-half and usually is not discoverable.

By the use of these expedients and the arrangement for the solution of the formula for azimuth, a set of observationes and computations may be made in the field with little delay, and the only tables required are the regular trigonometric tables which are familiar to all engineers and surveyors. Additional tables seem scarcely necessary and do not materially simplify the solution of the formula for azimuth.

The factor, A, is the natural number corresponding to the co-logarithm of cos ϕ cos h; or if natural functions are used, it is the reciprocal of cos ϕ cos h in which, for either case, the correction for refraction and parallax has been applied to h.

The factor B, is the natural number corresponding to tan ϕ tan h, also in which the correction for refraction and parallax has been applied to h; but if the apparent altitude of the sun is used there is no correction to be applied to h and all the correction for refraction and parallax is applied only once to

one value of the declination, which may be used for several azimuth determinations, provided not more than 10 to 20 min are consumed in making the observations.

It is not the writer's purpose to criticize or to discourage any such worthy purpose or effort to simplify the solution of the azimuth formula. It is only to call attention to the fact that the apparent altitude of the sun may be used in solving the azimuth formula, and by so doing the refraction correction is referred and applied to the declination, once and for all, for a single set of several observations, and that the solution of the formula is made easily and quickly by a simple arrangement and use of a logarithmic function already familiar to the engineer and the surveyor.

The writer is unaware of the use of the apparent altitude and declination having been suggested heretofore, or used, in the determination of the true meridian by direct solar observation. It has only been suggested to him by the fact that in the use of a solar transit the solution of this formula is accomplished mechanically. It would seem that the mathematical solution has been overlooked.

It has always been somewhat of a mystery why the solar attachment has not come into more general use. The attitude seems to be that its use is derogatory to the dignity of the engineer, or an admission of a lack of scientific technique and ability, and that the transit and its use is the acme of perfection. Except for those who are continuously employed in public land surveys, the expense of the solar attachment seems a burden. Its occasional use does not justify the expense. Many are not fully convinced of its accuracy and dependability. Its adjustments are thought to be difficult and can be made satisfactorily only by the instrument makers. Furthermore, it adds weight and makes the transit unbalanced, or otherwise interferes with the routine work of the transit. All these objections are largely imaginary, and a very little experience in its use will dissipate such objections.

FRANK M. JOHNSON,[14] M. AM. SOC. C. E. (by letter).—The method proposed in this paper has been studied carefully to ascertain whether it does, in fact, afford a saving in the number of steps ordinarily required in the use of trigonometric tables. The saving, if any, is not as great as it is made to appear by the author.

It seems better to state frankly that there are no so-called "short-cuts" in making direct observations on the sun for azimuth, or in the reduction of steps by the trigonometric process, if reliable results are to be secured. By "reliable" is meant the ascertainment of results that can be verified within the limits of the accuracy of the instrument used for the observation; this should be less than 1′, and with care may be kept within 15″. Observations and results should be such as may be verified by others if occasion arises, thus removing elements of doubt or approximation.

This paper is not a satisfactory substitute for the explanations on the subject which may be found in textbooks on surveying, and several official

[14] U. S. Superv. of Surveys, Dept. of the Interior, Denver, Colo.

publications. It is unfortunate to create the impression that the textbook treatment of the subject has been made difficult; the method has been brought into general use, and the number of examples offered are designed to clear all questions of doubt if the engineer will make a fair attempt to grasp the several steps and make a few practice observations.

The use of the tabulations in the paper does not dispense with the need for tables of natural sines and cosines, and it is not believed that their use materially lessens the time required to resolve the formula in the usual way. On the other hand, it is felt that the method adds materially to the uncertainties of the results in case of one or more errors in making the observations, or other discrepancies.

* Values of Factor A for a vertical angle, $h = 35°$, in Table 1. † Values of Factor B for a vertical angle, $h = 35°$, in Table 1.

On examination, it is believed that the interval of Table 1 is altogether too great, as demonstrated by Tables 4 and 5. Assuming that all these values have been carefully verified and are available as indicated, with an interval of 1° in latitude and 1° in vertical angle, it will be noted that a considerable number of pages similar to Table 4 will be required in order to provide for latitudes ranging from about 25 to 65°, and similar to Table 5 for vertical angles ranging from about 15 to 60 degrees. The third variable, that of the sun's declination, as well as the final result in azimuth angle, are provided for by the use of tables of natural sines and cosines.

The method of direct observation on the sun for azimuth is regarded in high favor by engineers, and has been used extensively for many years. Reliance upon compass meridians for all classes of public land surveys was discontinued in 1890. Federal surveying and mapping agencies have stressed the importance of exact methods so long that it seems out of place to suggest a practice that has the value of an approximation only.

An obvious improvement for the tabulation of values of Factors A and B, if the method is to be favored, is to make the intervals of the latitude and vertical angles not greater than 0° 10′, but this extends the tables to such a length that it is doubtful whether it would be worth while to go to that much trouble. The tabular differences will increase more rapidly in the higher latitudes, and as the vertical angles become greater, the results then become correspondingly more uncertain.

The example given by the author does not derive the value to the nearest even 1′, as the bearing of the line by trigonometric reduction is S 1° 00′ 02″ W (not S 1° 00′ 48″ W, as ascertained by the use of the factors, A and B).

The trigonometric steps are not many, as will be seen from the following:

Observed vertical angle................			25° 25′ 30″
Refraction			− 0° 2′ 00″
Parallax			+ 0° 0′ 08″

Walter H. Starkweather,[15] M. Am. Soc. C. E. (by letter).—As arranged by Mr. Inch, with double increments for 1′ of altitude and 1′ of latitude, Table 1 is quite ingenious and should prove welcome to field engineers who have occasion to determine azimuths of lines, since it shortens the necessary computation considerably. One operation is also eliminated completely by having the factors in the table corrected for refraction in altitude.

There are several points which might prove to be confusing, however, to any one who had not used this formula or one evolved from it. For many years Equation (1) and formulas evolved from it have been used by field engineers and in the technical press with all the variables represented by letters of the English alphabet; but in most textbooks and handbooks, with a few exceptions, Greek letters have been used for some of the variables. The formula appears less formidable if stated as follows:

$$\cos Z = \frac{\sin d}{\cos h \cos L} - \tan h \tan L \quad \text{.............. (9)}$$

in which Z = the angle between the sun and the local meridian; d = the true declination of the sun; h = the altitude of the sun corrected for refraction; and L = the latitude of the observer.

TABLE 6.—Notes for Computing the Bearings of a Line

d	-1° 02.5′	......
h	25° 25.5′	......
L	38° 53.5′	......
Factor A	For 25° h and 38° L	1.3999
Correction h'	25.5′ × 1.9	48
Correction L'	53.5′ × 3.3	177
A	$\frac{1}{\cos h \cos L}$	1.4226
Factor B	For 25° h and 38° h	0.3638
Correction h'	25.5′ × 2.8	71
Correction L'	53.5′ × 2.2	118
B	tan h tan L	-0.3827
sin d	....	-0.0182
A sin d	....	-0.0259
cos Z	A sin d − B	-0.4086
Z	65° 53′.1	
Horizontal angle	64° 52′.5	......
Azimuth	1° 01′	......
Bearing	S 1° 01′ W	......

The writer wishes to present a plea for using d for declination and L for latitude, believing that some confusion will thereby be eliminated. As d and L are the initials of the words, declination and latitude, they would not be likely to cause the uncertainty as to what they represent as would the Greek letters, δ, ϕ, θ, and λ.

As the readings of the vertical angles usually cannot be taken closer than the nearest minute of arc with an ordinary transit, refining any of the computations to a point closer than 0.5′ of arc, or farther than four decimal places in the computations, is not justified, as the results within the required

[15] Civ. Engr.; Technical Asst. Engr. to Chf. Civ. Engr., U. S. Coast Guard, Washington, D. C.

limits will be obtained without these refinements. For the same reason, the time is not needed to seconds, as the nearest 15′ to 20′ of the correct time will define the declination of the sun sufficiently close.

In Table 6 the computation is made from the values used for Example 1 of the paper, arranged for convenient placing on the page of a standard field notebook, and is carried only to the limits suggested herein. The results are within less than 0.5′ of arc of the values calculated to seconds of arc with five-place computations. This is believed to be sufficiently close, as authorities are apparently agreed that the accuracy of the results by this method is limited to one-half the least reading on the horizontal or vertical arc, in making the observation, and the author writes "allowing a probable error of 1′," but the azimuth has been computed to seconds.

C. I. DAY,[16] ASSOC. M. AM. SOC. C. E. (by letter).—The avowed purpose of this method is to improve the accuracy of true bearing determinations, now largely dependent upon the compass needle. Many county surveyors and others who have not been fortunate enough to receive the necssary mathematical training avoid direct readings on the sun because of the complicated appearance of the formulas. This has been somewhat remedied by the various solar attachments that can be added to the transit, but which are too expensive for only occasional use.

The formula (Equation (1)) from which the author's tables (illustrated in part by Table 1) have been derived does not lend itself to rapid mathematical solution, particularly when logarithms are used. Therefore, the tables are faster to use and can be used by any surveyor who is not familiar with logarithms. The $\tan^2 \frac{1}{2} A$ formula lends itself to solution by use of logarithms in about the same time as the tables, unless a computing machine is used in making the cumbersome multiplications.

Some surveyors are always somewhat uncertain as to how to apply the refraction correction to altitude observations and for them the tables suggested by the author are a boon.

In comparing the tables against the formulas, the accuracy seems to be within that claimed and certainly is considerably better than can be gained with a compass. Mr. Inch is to be commended highly for his efforts.

F. L. MCREE,[17] ESQ. (by letter).—Some mention should be made of the accuracy of the values obtained from the table prepared by Mr. Inch. In working with Table 1 the writer was surprised to discover how little error is introduced by the use of an average parallax and refraction correction. The principal error seems to be due to straight-line interpolation being used between tabular values. This error, fortunately, is partly compensating for values of Z (measured from the north) greater than 90 degrees. An examination of the following examples will show that when $A \sin \delta$ is negative and is added to B, although the individual values of $A \sin \delta$ and B, as computed from Table 1, differ from the exact values, the result does not differ materially

[16] Pres., W. & L. E. Gurley, Troy, N. Y.

[17] Associate Prof. of Civ. Eng., Texas Technological Coll., Lubbock, Tex.

from the exact value for cos Z. However, when Z is less than 90° (when $A \sin \delta$ is positive), this compensation does not exist, and larger errors may appear. Unfortunately, the range of Table 1 does not allow investigations for smaller values of Z. The writer would like to raise this question with the author: Do larger errors occur for interpolated values from the tables when Z (measured from the north) becomes small?

To illustrate the writer's viewpoint with respect to the accuracy of the results obtained from the tables the following examples are given.

Example 4.—Latitude = 35° 32.0′ (North); observed h = 35° 36.1′; declination = N 23° 24.0′; and, temperature = 50° C.

By the exact formula:

$$\begin{aligned} \text{Observed } h &= 35°\ 36.1' \\ \text{Parallax and refraction correction} &= \underline{\ 0°\ \ 1.1'} \\ h &= 35°\ 35.0' \end{aligned}$$

$$\cos Z = \frac{\sin 23°\ 24.0'}{\cos 35°\ 35.0' \ \cos 37°\ 32.0'} - \tan 35°\ 35.0' \tan 37°\ 32.0'$$

$$\cos Z = \frac{0.39715}{0.81327 \times 0.79300} - 0.71549 \times 0.76825$$

$$\cos Z = 0.61581 - 0.54968 = 0.06613$$

$$Z = 86°\ 12.5'$$

By the author's tables:

	Factor A		Factor B
h = 35°; ϕ = 37°	1.52811		0.52723
36.1 × 32.0	= 0.01155	36.1 × 33.1	= 0.01195
32.0 × 34.3	= 0.01098	32.0 × 32.4	= 0.01037
	1.55064		0.54955
sin δ	= 0.39715		
A sin δ	= 0.61584		

$$\cos Z = 0.61586 - 0.54955 = 0.06629$$
$$Z = 86°\ 11.9'$$

Example 5.—Latitude = 40° 30.0′ (North); observed h = 21° 32.4′; declination = S 22° 30.0′; and, temperature = 0° C.

By the exact formula:

$$\begin{aligned} \text{Observed } h &= 21°\ 32.4' \\ \text{Parallax and refraction correction} &= \underline{\ 0°\ \ 2.4'} \\ h &= 21°\ 30.0' \end{aligned}$$

$$\cos Z = \frac{\sin(-22°\ 30.0')}{\cos 21°\ 30.0'\ \ \cos 40°\ 30.0'} - \tan 21°\ 30.0' \tan 40°\ 30.0'$$

$$\cos Z = \frac{-0.38268}{0.93042 \times 0.76041} - 0.39391 \times 0.85408$$

$$\cos Z = -0.54089 - 0.33643 = -0.87732$$

$$Z = 151°\ 19.2' \text{ (measured from the north)}$$

By the author's tables:

	Factor A		Factor B
$h = 21°;\ \phi = 40°$	1.39790		0.32143
32.4×16.1	= 0.00522	32.4×28.3	= 0.00917
30.0×35.0	= 0.01050	30.0×19.3	= 0.00579
A	= 1.41362		B = 0.33639

$$\sin \delta = -0.38268$$

$$A \sin \delta = -0.54096$$

$$\cos Z = -0.54096 - 0.33639 = -0.87735$$

$$Z = 151°\ 19.4'$$

Example 4 gives a variation from the exact value as obtained from the formula of 0.6′. If Table 1 had been based on exact values of h, and if corrections had been made for parallax and refraction, the values of Z for this particular example would still be 86° 11.9′.

In both examples, it is noted that, from Table 1, that $A \sin \delta$ is larger and B smaller than the like expression in the exact formula. When $A \sin \delta$ is negative and is added to B the discrepancies compensate partly so that $\cos Z$ is not materially in error.

Examples 4 and 5 show that the proposed tables cannot be used where extreme accuracy is desired, in which case a more precise instrument than the transit should be used. It has been the writer's experience that the ordinary observer does well to obtain results accurate to the nearest minute with a transit. There are many instances in which azimuths or bearings to the nearest minute are sufficiently accurate and Table 1 seems to be well within this limit of accuracy.

The writer would like to see the complete table published. Due to his own labors in that direction he realizes the enormous amount of labor involved in its preparation, and that the author deserves considerable credit for his work.

F. J. Duarte,[18] Esq. (by letter).—A more complete table than Table 1 could be computed if the corrections for mean refraction and parallax were omitted. It would then be sufficient to compute another subsidiary table,

[18] Director del Observatorio de Caracas, Caracas, Venezuela.

for every degree of altitude of the mean refraction less the altitude parallax. With this auxiliary table the observed altitude angle would be corrected before entering Table 1.

The differences for 1′, both for altitude and latitude, have been computed on Table 1, dividing the first differences by 60 (chord interpolation). It would perhaps be more convenient to compute the derivatives (tangent interpolation), as follows:

$$f'(x) = \text{unit variation} = \frac{\Delta_1 - \frac{1}{2}\,\Delta_2 + \frac{1}{3}\,\Delta_3}{60}$$

The method described is easy to apply and precise enough for the orientation of a topographic map. The novelty of the method consists in Table 1 designed to facilitate the solution of the formula. This work, however, could be accomplished more rapidly by the use of a table of natural circular functions and a calculating machine, than with Table 1.

LEONARD C. JORDAN,[19] M. AM. SOC. C. E. (by letter).—For his effort to simplify and reduce the labor of field computations, Mr. Inch is to be commended. A transitman cannot always wait until evening to compute his bearings by candlelight in the office tent, but, sometimes, must take a solar observation, compute the results (perhaps on a windswept mountain side), and proceed to run lines in accordance with predetermined bearings. Any method that aids in making quick and accurate field computations will be welcomed by those men who find it suitable to their needs.

Attention should be called to the particular necessity for frequent correction of bearings on surveys that extend over considerable east and west distances. On such surveys, bearings very soon become incorrect, the errors increasing with the latitude of the location.

A base line, run in a straight line, 90° from any meridian, and from any latitude, will cross the equator when it is one-fourth of the distance around the world. Obviously, for a line north of the equator, the true bearing will be slightly southward, within the course of a few miles.

In sighting the sun, the writer has found it most convenient to focus the instrument on a distant object and, with his back to the sun, direct the telescope by means of its own shadow until it is nearly in the correct position. Then, the standard method of focusing the sun's image upon a page of field notebook held at the eye-piece (with the bisecting cross-hairs plainly visible) gives accurate results. Five independent observations, computed individually, generally are found to be in agreement. The most convenient transits for these observations are those which have additional hairs at 45° and at equal distances from the intersection of cross-hairs. These diagonal hairs are placed so that they cut thin segments from the sun's image. The slightest error in direction will cause one segment to be conspicuously longer than the opposite one. Looking through the instrument, no matter how shielded,

[19] Cons. and Designing Engr., New Rochelle, N. Y.

should be avoided since the observer is almost certain to look past the telescope and directly into the sun. His work during the succeeding few minutes would be unreliable.

J. C. PINNEY,[30] M. AM. SOC. C. E. (by letter).—The determination of the true meridian by direct solar observation is a practical necessity in ordinary surveying work, and any method which will reduce the time necessary for computing the field observations without sacrificing accuracy is worthy of consideration. Several formulas have been developed for computing the azimuth, Z, of the sun from the spherical triangle. The four which the writer recalls give the solution in terms of cos Z, vers Z, cot $\frac{Z}{2}$, and sin $\frac{Z}{2}$, and from these terms an equation can be developed for other trigonometric functions. With the ordinary instruments and methods used by the land surveyor, about 1′ in azimuth is the limit in accuracy, and computations carried beyond 0.1′ are futile.

Mr. Inch has presented a method for solving the cosine formula arithmetically in a much shorter time than a regular arithmetic solution would take without the use of a computing machine. This is accomplished by presenting the major computations pre-worked in the form of Table 1. The writer's main criticism of this table is that a straight-line interpolation is used for determining the constants, A and B, between whole degrees. For certain values of the altitude and latitude, this may lead to appreciable errors.

The cosine formula, Equation (1), is usually assumed as being adaptable to natural functions rather than to logarithms. The writer, however, believes that when properly arranged it is very susceptible to logarithms, and he presents herewith the solution of Example 1 by logarithmic computations of both the cosine and versine formulas, comparing the number of operations involved in these formulas and in Mr. Inch's solution. For convenience of reference the versine formula is given:

$$\text{vers } Z = \left\{ \sin \left[90 - (h + \phi) \right] + \sin \delta \right\} \sec h \sec \phi \ldots\ldots (10)$$

Example 6.—Using Equation (1), with north as the zero azimuth, and correcting the observed h for refraction and parallax:

colog cos 0.044128	... h =	$25^\circ\ 23.'6$	... log tan 9.676408
colog cos 0.108851	... ϕ =	$38^\circ\ 53.'7$	... log tan 9.906741
log sin 8.258190n	... δ =	$-1^\circ\ 02.'3$	
log A 8.411169n	A =	-0.02578	
	B =	0.38296	9.583149
	$A-B$ =	-0.40874	
	=	cos $245^\circ\ 52.'5$ = S $65^\circ\ 52.'5$ W	

[30] Asst. Cadastral Engr., U. S. Biological Survey, Des Moines, Iowa.

Example 7.—Using Equation (10) with south as zero azimuth, and correcting h as in Example 6:[20]

$$
\begin{array}{lllll}

\end{array}
$$

Although the most rapid method for obtaining the final result depends largely upon the computer and the method of procedure with which he is best acquainted, it may be worth while, nevertheless, to compare these three solutions in respect to the number and kind of operations required in each. These operations may be classified as: Arithmetic multiplication and division, arithmetic addition and subtraction, and references to tables. Of these, multiplication and division are to be particularly avoided as tedious and, therefore, subject to errors.

TABLE 7.—COMPARISON OF WORK INVOLVED IN SOLUTIONS

Method	Example 6	Example 7	Inch method
Addition and subtraction	0	0	5
Multiplication and division	4	5	3
Table reference	7	7	2

The comparison (adding one more addition and one more table reference to the cosine and versine methods than is shown in Examples 6 and 7 because Table 1 includes refraction correction) is shown in Table 7. It is assumed for the cosine formula (Example 6) that the cosine and tangent combined will constitute only one table reference as the logarithmic sines, cosines, tangents, and cotangents are contained in a single table.

As compared with the method given by Mr. Inch the writer believes either of the other two methods are preferable, because of the five arithmetic multiplication and division operations alone. The cosine method seems to have a very slight advantage over the versine method only if the computer is able to write down the colog cosine directly from his reading of the log cosine. Even in this case there is a fertile field for error. This same objection is also true for the versine method in case the computer has no table of log secants (= colog cosines). If the computer is equipped with a handbook[21] containing consecutive, five-place tables of log secants, natural sines, logarithms of numbers, and log versines, the versine method is considerably shorter.

The foregoing discussion applies primarily to conditions where the computations are to be made in the field, or under circumstances where a computing machine is not available.

[20] This solution is taken from "Azimuth" by the late George L. Hosmer, M. Am. Soc. C. E., and the arrangement is taken from Form Bi-1096 of the U. S. Biological Survey.

R. L. VAUGHN,[23] M. AM. SOC. C. E. (by letter).—Of all methods of obtaining a true bearing that by observation of Polaris at elongation is the most simple. It has several disadvantages, among which may be mentioned: (1) In high latitudes it is difficult to observe, and even more difficult to obtain, a desirable degree of accuracy; and (2) in low latitudes, even on clear nights, the star is likely to be obscured by atmospheric haze, the necessary arrangements for illuminating the cross-hairs, the verniers, and the station sighted on entail more or less bother. A fairly accurate determination of the latitude is essential. Lastly, the time of elongation is more than likely to be at a most inconvenient hour. Accurate local time is not indispensable.

The "any hour method" of observation on Polaris is subject to all but one of the foregoing objections, and furthermore requires accurate local time (not standard time). It does possess the advantage that the observation may be made at any time when Polaris is visible.

Methods of obtaining true azimuths or bearings by observation on the sun, of course, are by no means new. To an engineer not particularly versed in field astronomy and who has only occasional need for making an azimuth determination, the method may appear involved and laborious. Such, however, is not the case. Whenever a determination accurate to the nearest minute will suffice, sun observations will be found to be greatly superior to observations on Polaris both as regards speed and as regards convenience.

A number of formulas are available, one of which is given by the author in Equation (1). This formula is well adapted to computations where natural functions and a calculating machine are used. For computations using logarithmic functions a somewhat more convenient formula is:

$$\cot \tfrac{1}{2} A = \sqrt{\sec S, \sec (S - P), \sin (S - h), \sin (S - \phi)} \ldots\ldots (11)$$

in which A is the angle between the true south and the sun, measured clockwise if the observation was made in the afternoon; counter-clockwise, if the observation was in the morning; P is the north polar distance of the sun (90° plus a south declination, or minus a north declination); h is the altitude, of the sun, corrected for parallax and refraction; ϕ is the latitude of the station from which the observation is taken; and,

$$S = \tfrac{1}{2} (P + h + \phi) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

Whenever S is less than P or h or ϕ, merely subtract the smaller angle from the larger and proceed without regard to the negative algebraic sign.

During the early years of its existence, regulations of the Bureau of Public Lands of the Insular Government of the Philippine Islands required that an astronomical determination of azimuth should be made as a part of each land survey. The solar method was preferred on account of reliability and convenience. The standard observation consisted of eight pointings on the sun, as shown in Table 8, Sets I and IV being made with the telescope erect and Sets II and III with the telescope reversed, and the A vernier being

[23] Cons. Engr., San Francisco, Calif.

read in all cases. A fairly rapid instrumentman could set up an instrument and take the entire observation in a period of 20 min, or less; a fairly proficient computer could perform all the calculations in an additional 20 min. It cannot be said that the determination of a true bearing was an unduly burdensome task.

The true purpose of the time of observation seems to be misunderstood by some surveyors. Accurate local time is not required for a solar observation. The only purpose for which time is used is to obtain the sun's declination at the time of observation, which requires that the Greenwich time of the observation be known within an accuracy of about 5 min. Within the area of the United States the observer's watch will almost certainly be keeping standard time, and in order to obtain Greenwich mean time it is merely necessary to add 5, 6, 7, or 8 hr to the observed time, depending on which standard time is carried. If the observation is made in some other part of the world, it will be necessary to ascertain in some manner the relation between watch time and Greenwich time, but in no case is the longitude of the place of observation needed. In some cases it will be found that the particular Ephemeris which happens to be available gives the sun's declination for Greenwich mean noon. In this case the calculation of the declination for the time of observation is simple and obvious. It may be found that the declination is given for Greenwich apparent noon, in which case the apparent time of observation may be found by adding or subtracting the equation of time (also given in the Ephemeris) to the mean time.

Solar attachments, and sextant telescopes, contain special arrangements of wires by the use of which the sun may be centered. Ordinary transits are not so equipped and it is necessary to make observations in pairs and use averages, as is indicated in Table 8. This method assumes that the path of the sun is a straight line between the two positions in each set. Such is not the case, but no appreciable error is introduced providing the observations are taken with reasonable speed. However, the telescope should not be reversed between the two pointings which constitute any one "set."

Two methods are available by means of which the necessary readings may be taken. In one method the sun's image and the pattern of the cross-hairs are cast upon a card held about 6 in. from the eye-piece. There will be no difficulty in focusing so as to obtain a sharp image of the sun, but the eye-piece must be especially set to obtain a sharp image of the cross-hairs. With some transits there will be no difficulty about focusing the eye-piece. With other instruments, however, it will be found impossible to obtain a sharp image of the cross-hairs within the limit of motion of the eye-piece. In such instances, the small screw which limits the motion of the eye-piece may be removed, after which the latter may be drawn outward a sufficient distance to give the required sharp image of the wires. Fairly good results may be obtained by this method in the hands of an experienced observer. However, at the exact instant of tangency of any wire with the edge of the sun, the image of that wire is not visible on the card and in order to get really accurate results the observer must be a good guesser.

TABLE 8.—AZIMUTH COMPUTATION FROM SOLAR
(Latitude, 37° 21′ 00″ N; Longitude, 122° 54′

position near the edge of the sun. It will be found necessary to remove the attachment each time the instrument is transited.

Observed altitudes of the sun must be corrected for refraction. The correction is always subtractive, and is usually obtained from a table of average refraction values. Theoretically, there should be a correction for parallax because the point of observation is on the surface of the earth, not at its center. Parallax is not of great importance in a solar observation, although it is a serious factor in lunar observations. However, both refraction and parallax are a function of the altitude and may be combined quite simply. Many standard texts give tables of combined refraction and parallax, and the correction should be taken from such a table rather than from one giving refraction only. In this connection it is well to emphasize the fact that

the author has incorporated the parallax and refraction correction in his table and when using it the observed altitudes should not be corrected. In fact, attention should be invited to this circumstance in the heading to the tables.

Properly used, the solar method is capable of excellent results. The writer does not approve of reversing the instrument between the two observations constituting a pair, as indicated by the author in Fig. 2; nor should reliance be placed on a single pair of observations. The method used by the Bureau of Lands was found to be quite satisfactory. The results of Sets I and IV, Table 8, should agree within 1 min, as should the results of Sets II and III. The discrepancy between the former and the latter may be considerably wider, reflecting the effect of lack of instrumental adjustment. Taking the average of all four sets will eliminate the effect of such instrumental errors and, of course, will minimize accidental errors of observation.

One instrumental error that cannot be eliminated by the method of reversal, is the effect of error in leveling the horizontal plates. Any error in the determination of the latitude will be reflected to an appreciable extent in the results. However, error from this source may be eliminated by taking one complete series of observations in the morning and another in the afternoon.

The method of dealing with horizontal angles shown by the author in Fig. 1 is correct; but with the sun in a different relative position, it might cause confusion because of the necessity of measuring angles in a counterclockwise direction. Adherence to the following rule will avoid all difficulty: Set the horizontal plates so that they read 0° 00′ when pointing along the line the direction of which is to be determined. Read all horizontal angles to the sun in a clockwise direction, from 0° to 360°. Compute the azimuth of the sun (not its bearing). Subtract the observed horizontal angle from the computed azimuth of the sun, adding 360° to the latter if necessary. The remainder is the desired azimuth of the line.

Table 1 of the paper certainly represents an impressive mass of labor, and the publication of the complete table would be a service to the profession which should be encouraged. It entails double interpolation: One to reach the values for the actual latitude, and another to reach the actual altitude. Interpolation by second differences must be resorted to in order to achieve an accuracy in the computations commensurate with the precision of the method. Experience has shown that it is almost impossible to publish such a table for the first time without some errors. The possibility of such errors should be guarded against when using the table.

The formulas given in this discussion apply equally well to any other heavenly body. The Nautical Almanac gives the necessary data concerning the planets and a selected list of fixed stars. The only difficulty is to identify the particular body under observation. Star charts are available by means of which the fixed stars may be identified. Planets are most easily identified by computing the approximate elevation and time of transit across the local meridian. In some locations and under some atmospheric conditions, it may be desirable to determine azimuth by observation on some object other than the sun or Polaris. In case a planet is observed, which is closer to the

earth than the sun, the parallax correction should be given due consideration. Observations on the moon are not likely to give very good results, and this body is best avoided.

John C. Penn,[28] M. Am. Soc. C. E. (by letter).—The most favorable time for observations on the sun is when it is on or near the prime vertical; that is, when it is east or west, or nearly so. The azimuth of the sun is then $\pm$ 90° (0° is assumed to be north). Any formula that solves the azimuth by means of its "cosine" necessitates entering a logarithmic table or tables of natural functions where the interpolation is most difficult and most inaccurate. In the United States, most work will be done in the field when the sun's declination is north (that is, in the time between March 21 and September 21), and with a lower limit for altitude of 25° (because of uncertainty in refraction correction below that figure), azimuth will fall between 80° and 100°, and slide-rules, tables, and any other arrangements for using $\cos Z$ will not be accurate.

Any astronomical method for finding azimuth requires the nautical almanac, an ephemeris, or a similar table. The choice of the year 1910 in the example in Mr. Inch's paper is unfortunate. The astronomical day, like the civil day, has begun at midnight ever since 1925. The American Nautical Almanac now (1937) contains tables for refraction, parallax, etc.

The solar ephemerides, as published by instrument companies for use with solar attachments, contain tables for refractions, but care must be taken in not using these refraction corrections for the setting of the attachment. Refraction corrections involve the latitude of the place and cannot be applied as corrections for an observed altitude.

There are several other formulas available, and surveyors are not necessarily limited to observations on the sun for the determination of meridian. Navigators use,

$$\cos \frac{Z}{2} = \sqrt{\cos S \cos (S - P) \sec \phi \sec h} \quad \text{.............(13)}$$

in which Z = the azimuth of a heavenly body (star, planet or sun); $S = \frac{1}{2}(h + \phi + P)$ in which h = corrected altitude; ϕ = latitude; and P = polar distance (90° $\pm$ declination). For those not familiar with "secants," this formula may be written:

$$\cos \frac{Z}{2} = \sqrt{\frac{\cos S \cos (S - P)}{\cos \phi \cos h}} \quad \text{.................(14)}$$

Equation (14) solves for azimuth in terms of $\frac{Z}{2}$ and involves logarithmic tables in the vicinity of 45° where the values for cosine mean something.

It is a pity that the present American Nautical Almanac gives the azimuth of Polaris for various hour angles of Polaris only to the nearest tenth of a degree. Older almanacs and the American Ephemeris give azimuths of

[28] Director of Civ. Eng., Armour Inst. of Technology, Chicago, Ill.

Polaris to 0.1′. If the American Nautical Almanac gave the same consideration to surveyors as it now does to aviators, the necessity for tables and slide-rules would be entirely obviated and, incidentally, there would be no need for an accurate map for the determination of latitude, as both azimuth and latitude can be determined by an observation on Polaris with very little arithmetic.

If the table suggested by Mr. Inch is to be of any value to a surveyor it must be well understood that the surveyor goes into the field with the following equipment:

(*A*) The table itself, extended to allow for better interpolation;

(*B*) Instructions for use of this table to include: (1) A bold statement that altitudes need not be corrected for parallax and refraction; (2) a similarly strong statement that if the declination of the sun is north, $A \sin a$ and B are subtracted (the smaller from the larger); (3) if $A \sin a$ is the larger, the bearing of the sun will be from the north, and if B is the larger, the bearing is from the south; and (4) if the declination is negative, the bearing is from the south;

(*C*) A table of natural sines;

(*D*) An almanac for the year;

(*E*) A watch correct within a few minutes; and,

(*F*) A quadrangle sheet of the U. S. Geological Survey, or a similar map for the determination of latitude. (Perhaps this map could be left in the office.

Some of these items are facetious, of course. A little knowledge of trigonometry will eliminate Items *B* (2), *B* (3), and *B* (4), but to one who is not "on his toes" in the mathematics of surveying and the bearing should prove to be 90° ± 20′, these very rules will save many an anxious moment.

The writer would rather carry an almanac, a log table, with the value of cos 0.5 Z neatly printed inside the cover, and a small pad of paper, for meridian determinations during the day. The solution of Example 1 of the paper, by Equation (13) is as follows: Refraction plus parallax correction is 0° 1′ 54″; corrected altitude equals 25° 23′ 36″.

$$
\begin{array}{rll}
P = & 91^\circ\ 02'\ 16'' & \\
h = & 25^\circ\ 23'\ 36'' \text{ log sec} & 0.04413 \\
\phi = & 38^\circ\ 53'\ 40'' \text{ log sec} & 0.10885 \\
2\ | & \underline{155^\circ\ 19'\ 32''} & \\
S = & 77^\circ\ 39'\ 46'' \text{ log cos} & 9.32974 \\
S - P = & 13^\circ\ 22'\ 30'' \text{ log cos} & \underline{9.98835} \text{ (always positive)} \\
 & & 2\ |\ 19.47107
\end{array}
$$

log cos 0.5 Z = 9.73554 = 57° 3′ 4″; and Z = 114° 6′ 8″.

Bearing of line = 180° − (114° 6′ 8″) = S 65° 53′ 52″ W

Given	=	S 64° 52′ 30″ W
		1° 1′ 22″
By table	=	1° 0′ 48″
Difference	=	0° 0′ 34″

In the determination of azimuth by a time-altitude of the sun, regardless of the method that may be used, some knowledge of astronomy is absolutely necessary. Without a calculating machine, and in the field, logarithms must take preference over natural functions. All methods so far proposed require either one or the other. A table so involved and so limited as all tables must be, can never take the place of the foregoing simple computation.

Robert H. Merrill,[24] M. Am. Soc. C. E. (by letter).—By way of revising "tables in their most convenient form, as an Appendix", with due allowance for second differences, Fig. 3 shows (in the four margins) the four rates per minute of arc that are involved. In plotting the two columns under each degree of latitude from Table 1, many points fail to fall precisely on line. To secure uniformly spreading curves, these columns (to be eliminated by a graph) should be recalculated accurately to an additional decimal place.

For comparison the rates used in the typical example given in the paper are tabulated in Column (2) of the following example; the rates at the terminal values, $h = 25° 25' 30''$ and $\phi = 38° 53' 40''$ in Column (3) are also not necessary. Only at the mid-points of the interpolation (namely, at $h = 25° 13'$ and $\phi = 38° 27'$ are the true values found which are listed in Column (4).

Rate of:	In: (1)	From: (2)	To: (3)	Mean: (4)	Minutes added to $h=25°$ and $\phi=38°$ (5)	A 1.39989 (6)	B 0.36378 (7)
A	h	19.4	20.2	19.8 ×	25.5 =	505	...
A	ϕ	32.6	34.3	33.5 ×	53.7 =	1 798	...
B	h	27.9	29.1	28.5 ×	25.5 =	...	726
B	ϕ	22.1	23.2	22.6 ×	53.7 =	...	1 212
						1.42292	0.38316

$d = -\ 1° 02' 16''$ nat sin $= \times$ 0.01811 = 0.02580

$Z = 65° 51' 38''$ nat cos = 0.40896

Instead of $Z = 65° 53' 18''$ (of the paper) = 0.40852

and since $Z = 65° 52' 30''$ by more precise calculation, the range in using Table 1 is + or − more than $30''$.

The late James B. Davis, M. Am. Soc. C. E., explained forty years ago "the mystery as to why the solar attachment has not come into more general use" by emphasizing the delicacy of adjustments, the extra weight, and the cost, which is quite out of proportion to its infrequent use. About twenty-three years ago a "mechanical navigator"[25], costing $2 400 was placed on the market. It solved, mechanically, the general spherical triangles, but was heavy and bulky, with seven axes measuring altitude, latitude, hour angle, azimuth, declination, and 90° on 6-in. disks with verniers that were precise to $\frac{1}{1200}$ in. Obviously, great mechanical skill was attained in adjusting all parts so perfectly that the last setting gave results accurate to 1′ or 2′ of arc. With a relatively cheap 10-in. straight slide-rule, or a 7-in. circular slide-rule, one may attain similar accuracy in solving the same problems.

[24] Cons. Engr. (Spooner & Merrill), Grand Rapids, Mich.

[25] *Engineering News*, Vol. 71, p. 180.

For greater precision it is easy to recompute by the rather clumsy but adequate formula, using both naturals and logarithms of standard field tables thus, to solve the formula, $\cos Z = \dfrac{\sin d - \sin h \sin \phi}{\cos h \cos \phi}$:

Quantity	Angle	nat sin	log sin	log cos
d (−)	1° 02′ 16″	−0.01811	....	....
h	25° 23′ 37″	....	9.632290	9.955872
ϕ	38° 53′ 40″	....	9.797882	9.891149
$\sin h \sin \phi$	....	0.26926	9.430172	....
$\cos h \cos \phi$	....	....	....	9.847021
Numerator	....	−0.28737	....	9.458441
Z	65° 52′ 32″	....	....	9.611420

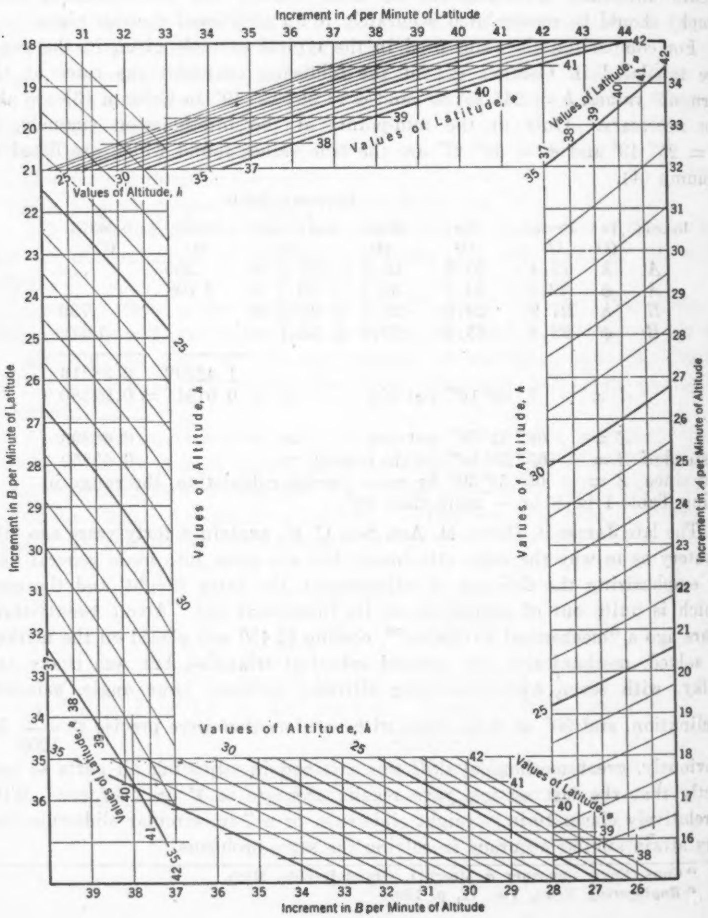

FIG. 3.

The writer favors the sun-disk bisections for observations on the sun as the easiest and the one developing all the accuracy of which an ordinary 1′ transit is capable. In the absence of colored-glass shades and a prismatic eye-piece, it is often handy to use a carpenter's 24-in. folding rule to hold the focusing card. With a spring clip near the 9-in. mark, clamp the 6-in. to 12-in. leg of the rule to the left front standard of the transit. Flex the rule at the 12-in. and the 18-in. joints so that the 21-in. mark falls on the line with the telescope about 3 in. below the eye-piece, and clip on the card at that point.

Although it is not necessary to use the uniform time intervals it is easy to check as the observations progress, according to the following schedule:

Watch Time: Hours	Minutes	Seconds	Z	dZ	h	dh
4	03	00	276° 03′		31° 10′	
				0° 04′		0° 13′
4	04	00	276° 07′		30° 57′	
				0° 05′		0° 14′
4	05	00	276° 12′		30° 43′	
				0° 04′		0° 13′
4	06	00	276° 16′		30° 30′	
				0° 04′		0° 15′
4	07	00	276° 20′		30° 15′	

The uniformity of the increments per unit of time, shows at a glance that the middle pointing of the five was a fair mean value in spite of the erratic intervals. It is customary, however, to require the series of pointings to be continued until five consecutive ones show equal increments to the nearest 1′. Note also that, if well chosen, the more rapid motion in *dh* lessens the probable error in computed azimuth.

CROSBY J. WILKIN,[26] ASSOC. M. AM. SOC. C. E. (by letter).—Textbooks, slide-rules, tables, etc., are of little avail in obtaining the correct true bearings of a line if the data used in the formula are not right. The writer has yet to see a typical problem fully solved by the use of commonplace data. In his work, he would prefer to use true azimuths in all property surveys but he is somewhat hesitant to do so without considerably more experience to gain complete confidence in his computations; and he can imagine that surveyors with less education would be more non-plussed. This is probably the main reason why most surveys are based on a magnetic north, which is unreliable for re-running surveys, large or small, particularly in the absence of sufficient monuments.

The following solution was made on a survey in the summer of 1936. An engineer's transit was used in the field work and the writer obtained the data without assistance. The sun's image was focused on a white card wired to the telescope and the cross-hairs were made tangent to the image.

For the calculations, the Ephemeris of the Sun and Polaris, obtained from the U. S. Government Printing Office, was used, together with a calculating machine. The method is a composite of various other methods none of which was complete in itself for the tables at hand.

---

[26] Land Surv., Gardiner, N. Y.

Field Work: Date, July 22, 1936; long., W 74°-08.4′; lat., 41°-38.1′; watch slow 9 sec.; temperature, 75° F:

Difference for difference in time, 0.50 × 1.892 =		− 0.95
Declination for place of observation		20° -15.15′

$$\cos Z = \frac{\sin d - \sin h \sin l}{\cos h \cos l} = \frac{-0.13127}{0.51976} = 0.25276, \text{ or } Z = -75° \text{-}22'$$

from south point, in which:

$d = 20°$ -15.15′ $\qquad h = 45°$ -56.3′ $\qquad l = 41°$ -38.1′

Horizontal angle based on magnetic needle	116° -23′
True azimuth of sun 180° − 75° 22′	104° -38′
Declination of needle	11° -45′ W.

The writer has no criticism to offer of the method proposed by Mr. Inch, for he gladly adopts simplification of any process in solving a problem which is as accurate as the usual method. However, the addition of a set of tables to the Ephemeris of the Sun and Polaris might only confuse the computer further. It seems to the writer that engineers had better continue using the customary method, eliminating any steps in the solution compatible with the precision required in the answer.

The difficulty with the usual solution is that, apparently, no one has endeavored to publish a method using the ephemeris only. The formula introduced in the foregoing example is easy to use with any calculating device, or even by long hand.

C. S. Jarvis,[27] M. Am. Soc. C. E. (by letter).—A simplified method of determining azimuth by direct observation of the sun has been ably presented by the author, but simpler methods of determining true bearings of a line deserve consideration and extended use.

It is possible to determine the true meridian within an error of 1′ or 2′ consistently day after day, by using methods similar to the one described by the author, differing only in details, with or without the solar attachment for the ordinary engineer's transit; but it happens too often that the uncertainties or errors of bearing from such methods are considerably larger. No doubt this fact guided the standard practice of the General Land Office in requiring that the bearings of land-subdivisional lines be checked occasionally by observations on Polaris, and that the records of such tests and results be incorporated in the official field notes of public land surveys.

In view of the accessibility of correct standard time to within a second or two, through telegraphy and radio broadcasts, it appears that the transit of the sun's center across the meridian at apparent noon should be included. True solar time, derived from standard time by corrections for longitude and for the equation of time as published in a solar ephemeris, might be as much as 45 min slower or faster than standard time. An error of 4 sec in time would account for an error of 1′ of arc.

As the sun's semi-diameter varies from 15′ 45″ on July 1 to 16′ 18″ on January 1, and the time of its passing the meridian varies from 64 sec to 71 sec, as obtained from a solar ephemeris, it is quite feasible to observe the western limb of the sun at the corresponding time before apparent noon, and the eastern limb at the same interval after noon, but with the telescope reversed. These two lines should coincide on the meridian, except as affected by instrumental errors. A bisector of the small angle between them, therefore, should be the true meridian, obtained by the simplest method available, but susceptible to considerable errors if the time is not known accurately. However, by observing the sun's passage over the highest point of its orbit, together with its position a few minutes before and after noon (that is, at equal altitudes) both the apparent solar time and the meridian may be determined approximately, perhaps within 5′ as to bearing of the line.

[27] Hydr. Engr., SCS, Washington, D. C.

Caution should be exercised to avoid injury to the observer's eyes through exposure to direct rays of the sun. Colored glasses of suitable density, or a colored translucent shield to be placed over the object glass of the telescope, may afford the required protection. However, after using such expedients and having to devise other methods when necessary, the writer has abandoned the telescopic sighting except for the purpose of bringing the sun's image into the field of the telescope. Thereafter, the observer's eyes are directed away from the sun in order to adjust the cross-wires, through movement of the tangent screws, to the edge of the solar disk as projected on a sheet of white paper, held perpendicular to the telescopic line of sight, and a few inches from the eye-piece. The cross-wires appear in magnified dimensions if the eye-piece is moved sufficiently from its normal position; that is, if thrown out of focus, and the paper is held far enough from the telescope. With such a magnified image of the sun and the cross-wires, either the bisecting or the tangential position may be readily attained by slow motion, vertically and horizontally.

Of all methods used by the writer for determining a meridian, the hour-angle observation of Polaris proved to be the most satisfactory. Utilizing twilight for illuminating the cross-hairs of the telescope, morning or evening, or both, the direct and reversed readings on the star and on the traverse line may be completed with very little time devoted to instrumental work and final calculations. Moreover, by occupying a station on the traverse line and sighting to one of the flags or marks, the observer is enabled to obtain the data for determining the bearings without the use of a flagman or rodman. As compared with observations at either culmination or elongation of Polaris, often involving tedious hours of waiting during the night, the hour-angle method has many advantages.

At the time of the vernal equinox (about March 21) the right ascension or time of meridian passage of Polaris at upper culmination is 1 hr 38 min by both sidereal and solar time, and the former gains nearly 4 min per day on the latter so as to accommodate one more day each year. It is evident, therefore, that on April 21 the upper culmination will occur 2 hr earlier, or at 11:38 A. M., and the lower culmination at 5:36 P. M., so that a twilight observation at about an hour later (assuming the latitude as 40° N), would define a line bearing 21′ east of north, and the altitude of the star would be about 39 degrees. An error in time amounting to 3 min would account for an error of 1′ in azimuth at or near culmination; or for the entire hour extending equally before and after elongation, the change of bearing would not exceed 1′, the actual azimuths at 30-min intervals being 80′.1, 80′.7, and 79′.8, beginning with 5 hr 30 min as the hour angle.

When the atmosphere is exceptionally clear and free from haze, dust, and smoke, it is quite possible to locate Polaris through a transit telescope a few minutes before sunset or after sunrise, and thus to complete the observation and calculations within daylight. In order to bring the star within the field of the telescope, it is necessary to set off an angle on the vertical circle to elevate the telescope equal to the latitude of the station plus or minus the correction for position of Polaris above or below the pole; or the cosine

of the hour angle times 62′. Then, by setting the horizontal circle at approximately the correct position for the star, and using the tangent screw to search back and forth, the image should be made to streak part way across the field; and after centering it, the observation is soon completed.

PHILIP L. INCH,[28] ASSOC. M. AM. SOC. C. E. (by letter).—The intent and purpose of Table 1 was to enable an engineer to obtain a meridian, within a limit of 1′ of accuracy in azimuth, with the least inconvenience or preparatory study, ever bearing in mind that thousands of surveyors are not equipped educationally to cope with trigonometric formulas, logarithms, etc.; nor are computing machines generally available. Although the discussion has revealed little on the subject of the form of the table, the writer believes that the methods discussed have enriched the general knowledge of the subject.

The writer approves the suggestion to eliminate the use of Greek symbols, however familiar they may be; he agrees that less confusion will result.

As to star observations: To observe the upper or lower culmination of Polaris, or to determine a meridian by an hour-angle observation requires accuracies in time readings that are too great for those who are working to an accuracy of 1′. Furthermore, both these methods and elongation require night work unless an instrument is specially equipped for daylight observations.

The determination of a meridian by the equal altitude method is orthodox; but, again, the necessary preparation and the time consumed fits it inadequately to the needs of the field engineer.

The computation of the fifth decimal place of the table has received some comment. It will be noted that, in the tables of natural sines and cosines, a 1′ variation in either appears as from 1 to 3 in the fourth decimal place. In the determination of the fifth place, an even number for a 5 in the sixth place was maintained.

The discussion has included the advisability of computing the table of 1′ differences in A and B upon the arc, instead of one-sixtieth of the difference between two arc-determined, even degrees. Intensive investigation has demonstrated that such a refinement would add little or no increase in the general accuracy of the table. Before any one of the basic calculations was accepted, from two to six observations on the arc were computed and comparisons made. An experimental table was also constructed and comparisons were made of solar observations in latitudes as high as 60° north; the declinations used ranged from the highest to the lowest. The computation by table was found to be well within the required limits. For reference, the entire table has been included herein as Table 9. This form includes values of A and B for vertical angles, h, from 15° to 54°, inclusive; and latitude, ϕ, from 31° N to 48° N.

[28] U. S. Cadastral Engr., Public Survey Office, Reno. Nev.

In the use of Table 9, the slide-rule is commended. The necessary multiplications are made quickly, with an advantage both in the assurance of accuracy and in the time consumed.

The solar attachment has been introduced into the discussion. The writer is of the opinion that the initial cost is not so prohibitive as the continuing cost of adjustment and maintaining the adjustment.

The suggestion that sun altitudes between 10° and 49° be used has its inconsistencies. The writer agrees that 49° is high enough, considering the factor of safety. When it is at an altitude of 10° the sun is moving vertically at too rapid a rate to insure a good observation. Moreover, the refraction is large and variable. Above 49°, although the refraction element is nearing its minimum, the sun is moving horizontally at a comparative rate as great as it is moving vertically at minimum altitudes. Furthermore, the least error in the horizontal reading appears directly in the bearing that is sought.

The ideal time for sun observations is about three hours either before or after apparent noon. Experiments, however, have demonstrated that everything depends upon the accuracy with which the observation is taken and how nearly the personal equation can be eliminated. At certain seasons of the year excellent observations can be obtained as early or as late as five hours before or after apparent noon. The freedom from personal inaccuracies is the paramount issue, not the time nor the computation by any particular accepted method.

A suggestion for solar observation is as follows: Reduce the use of the tangent screws to a minimum. Hold a limb of the sun tangent to one hair of the telescope with the tangent screw and allow the sun to drift into tangency with the other selected hair. Personally, the writer holds the faster moving limb of the sun tangent with the tangent screw. A little practice and one's judgment of the sun's movement can be placed within a 2-sec interim. In an observation in which all four quadrants are used, the perfect co-ordination of two hands and an eye at eight different times is rare.

In the discussion, reference is made to the additional hairs that can be placed in a telescope to facilitate a solar observation. They enable the sun to be centered approximately at the intersection of the horizontal and vertical hairs. This arrangement gives excellent results; but few instruments are equipped with this accessory.

From the viewpoint of a field engineer, the most needed addition to the field procedure is some check on the accuracy of a solar observation in the field, and at the time of observation. Fig 4 will suggest a method of observation that will afford an excellent check upon the accuracy of each complete observation, by comparison with the others in any group. Observe the sun in this manner, recording the time, the horizontal angle, and the vertical angle. Combine the observations, respectively; thus: $\frac{1+8}{2}$, $\frac{2+7}{2}$, $\frac{3+6}{2}$, and $\frac{4+5}{2}$.

In theory, and in theory alone, the mean time, the mean horizontal angle, and the mean vertical angle of each complete set will be equal; one's judgment, together with the degree of accuracy required, should be one's best guide as to the rejection or acceptance of any set. One good observation is better than the mean of one good one and three poor ones. Observations taken 1 min apart, with 2 min between the series of direct and reversed readings, give very satisfactory results.

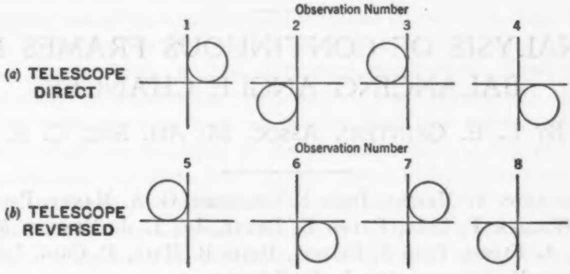

FIG. 4.

The ease of computing a solar observation by means of simple formulas, logarithms, and computing machines is apparent. The writer approves of their use, but only in skilled hands. The selection of a solar observation taken in 1910, as an example, has been commented upon; it was taken from the Manual of Instructions for the Survey of Public Lands of the United States, 1930 (page 112); it represents a criterion.

ANALYSIS OF CONTINUOUS FRAMES BY BALANCING ANGLE CHANGES

By L. E. Grinter[1], Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. John E. Goldberg, G. A. Maney, Paul Andersen, William F. Luce, Ralph E. Byrne, Jr., L. J. Mensch, Marvin A. Gray, A. Floris, Fred J. Benson, David B. Hall, P. Craig Livesay and William M. Simpson, and L. E. Grinter.

Synopsis

The interest that has been shown by the profession in the method of balancing fixed-end moments (introduced by Hardy Cross, M. Am. Soc. C. E.[2]) as an alternative to the classic methods of analyzing continuous frames, has suggested the publication of a second alternative process based upon the conception of balancing angle changes to obtain joint rotations. The procedure of balancing angle changes is shown to parallel the procedure used in balancing and distributing fixed-end moments. No claim is made that the suggested method surpasses the method of moment distribution either in simplicity or in a reduction of time consumed by the analysis. In fact, it will take somewhat longer to arrive at the final end moments. However, the additional time consumed may be far more than equally repaid by the fact that the method is practically self-checking. Furthermore, upon completion of the analysis, one has at hand all necessary data for sketching, rapidly and accurately, the deflected structure, a procedure that experience has proved to be a most valuable tool both in analysis and in design. The method of balancing angle changes is particularly useful for studying secondary stresses in trusses and for investigating the effect of elastic distortion or of slip in the riveted or welded connections of a continuous steel frame. Approximate influence lines for live load studies can be obtained very rapidly thereby. The pro-

Note.—Published in September, 1936, *Proceedings*.

cedure of balancing angle changes is susceptible to expression in many forms. It is thought, however, that discussion will be used primarily for presenting evidence tending to test the theory proposed herein.

Introduction

Slope and Deflection.—The method of balancing angle changes should appeal to engineers who are most familiar with the slope-deflection equations because it makes use of the same physical variables of end slope, joint rotation, and relative deflection, at the same time possessing the other advantages which are so apparent in the method of moment distribution. There are other published methods[3] in which joint rotations have been obtained by series convergence, but these methods seem to involve relatively tedious procedures. The present method was developed by the writer in 1927. A few of the many special applications that have been found useful will be presented herein, but the basic method is essentially in its original form.

The well-known slope-deflection equations make it possible for one to compute the end moments in any unloaded member of a continuous frame from known values of end slopes and relative end deflections. If the member is loaded, the slope-deflection moments become the changes in the end moments from an originally fixed-end condition. Hence, the analysis of a continuous frame can be made upon the basis of a treatment in which joint rotations and relative deflections are chosen as the redundants. Many advantages have been claimed for the use of these functions as the redundants, most of which have not been justified by experience, but there is one which can not be disputed. Joint rotations and deflections are the equivalents of the physical action of the structure and the emphasis of these factors lends a desirable pictorial clearness to the method, provided this picture is not obscured by the mechanical details of the procedure.

Successive Rotation.—The method of balancing fixed-end moments starts with all members restrained against end rotation. The alternative procedure to be developed will start with all horizontal members acting as simply supported beams and all columns as pin-ended. Then, by successively balancing the angle changes at the joints until continuity is fully restored, one will obtain values of the true joint rotations from which the deflected structure can be sketched and the joint moments determined. Naturally, joint translation will complicate the analysis somewhat. The discussion that follows will present the method for use in continuous-beam analyses, after which its application to frames in which the joints translate will be considered briefly. A thorough understanding of a previous paper by the writer[4], will assist the reader in his interpretation of this paper.

Definition of Terms

A few new terms will be needed and for clearness they will be defined at once:

(1) By "angle change" (ϕ-value) will be meant the change in slope produced at the end of a member either by the loads or by an applied end moment; for example, certain easily determinable "angle changes", ϕ, occur at the ends of a simple beam when it is loaded.

(2) By "joint rotation" (θ-value) is meant the angular twist of a joint in a loaded frame when absolute continuity exists between all members meeting at the joint.

(3) By "joint rotation factor" is meant the ratio between the joint rotation and the angle change existing at the end of a connecting member when the angular discontinuity between that member and the joint is removed by applied moments. It is assumed that the far ends of all members are pin-connected when the joint rotation factor is computed. Evidently, there is a joint rotation factor associated with each member meeting at a joint.

(4) By "carry-over factor" is meant the angle change at the far end of a simply supported or pin-ended member when the near end is rotated through an angle change of unity.

Procedure of Balancing Angle Changes

The condensed statement of the procedure of balancing angle changes that follows will be helpful to the reader and much clarified, if it is used for continual reference while the illustrative examples are being studied.

Angle Change and Joint Rotation.—With all joints of the frame held fixed against all possible translations and with the ends of all members either simply supported or pin-connected, one "permits" the members to deflect under the loads and computes the values of the end angle changes. Any joint is selected and the end angle change existing at that joint in one of its members is eliminated by twisting that particular member and the joint in opposite directions until continuity is restored. The recorded value of the joint rotation is the angle change that existed at the end of the member selected, after being multiplied by the joint rotation factor for that member.

Carry-Over Angles.—All members meeting at this joint have now been rotated through determinable end angles. The end angular rotation is the joint rotation for all members other than the one operated upon. For that particular member, the end angular rotation is the difference between the joint rotation and the end angle change caused by the loads. Since all these members were considered to be simply supported at their far ends, one must record an angle change (not a joint rotation) at the far end of each member equal to the angular rotation at the near end, when multiplied by the carry-over factor. Then, one proceeds from member to member and from joint to joint balancing the angles at each joint as many times as necessary, which means to continue the procedure until the carry-over angles are negligibly small. Continuity has then been established. Under normal conditions, it will be necessary to balance each joint from three to four times.

Simple Beam Angle Changes

The starting point in the analysis is to obtain the angle changes or the slopes at the ends of the loaded spans. This problem is solved in all text-books on the strength of materials. For rapid calculation one should use the conjugate-beam method[6]. It scarcely seems necessary to present this treatment and instead the angle changes are given for a few simple cases in Fig. 1.

$$\phi_A = -\phi_B = \frac{w\,L^3}{24\,E\,I}$$

$$\phi_A = -\phi_B = \frac{P\,L^2}{16\,E\,I}$$

$$\phi_A = +\frac{P\,a\,b}{2\,E\,I\,L}\left(\frac{2\,b}{3} + \frac{a}{3}\right)$$

$$\phi_B = -\frac{P\,a\,b}{2\,E\,I\,L}\left(\frac{2\,a}{3} + \frac{b}{3}\right)$$

$$\phi_A = +\frac{M\,L}{3\,E\,I}$$

$$\phi_B = -\frac{M\,L}{6\,E\,I}$$

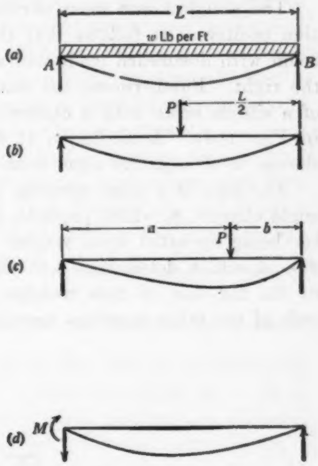

Fig. 1.—End Angle Changes for Simple Beams.

Joint Rotation and Carry-Over Factors

Stiffness of Joint and Member.—The stiffness of a beam may be defined as the end moment necessary to produce a unit end rotation and, therefore, it is proportional to the ratio, $\frac{I}{L}$, which is commonly designated as K. If an angle change, ϕ_1, occurring at the end of a member which frames into a joint, is to be eliminated and continuity is to be restored by twisting the member and the joint in opposite directions (by equal end moments), it is apparent from the definition of stiffness that the joint must be rotated through an angle, θ_1, equal to the angle, ϕ_1, times the stiffness ratio, $\frac{K_1}{\Sigma K}$. Here, as elsewhere, K_1 is the stiffness factor for the member having the end slope, ϕ_1, and ΣK is the sum of the stiffness factors for all members meeting at the joint. Hence, $\frac{K_1}{\Sigma K}$ is the "joint rotation factor" for Member No. 1 at the joint under consideration. In this paper, the far ends of all members are considered to be pin-connected or simply supported.

[6] *Transactions*, Am. Soc. C. E., Vol. 98 (1927), p. 1.

Usual Carry-Over Factor.—From Fig. 1 it is observed that the end angle changes in a simple beam loaded with a single end moment are in the ratio of 2 to 1. This represents the condition of a member when one end is being rotated into continuity. Hence, the carry-over factor for angle change is 0.5 whenever the member is prismatic or of uniform section.

Sign Convention

The simplest and most obvious sign convention is to call clockwise rotation positive. It follows that the end angle changes in a simply supported beam with downward loads will always be positive at the left and negative at the right. Furthermore, the same signs of angle changes apply for the case of a simple beam with a clockwise moment applied to the left end, as shown in Fig. 1(*d*). Accordingly, it follows that the carry-over factor for angle change is of negative sign, namely, − 0.5.

The sign of a joint rotation, θ, necessarily is the same as that of the end angle change, ϕ, which produces it. Note, however, that the end of the member being operated upon rotates in the opposite direction through an angle, $\theta - \phi$, which determines both the value and the sign of the carry-over angle to the far end of this member. All of the carry-over angles to the far ends of the other members meeting at the joint are simply $-0.5\ \theta$.

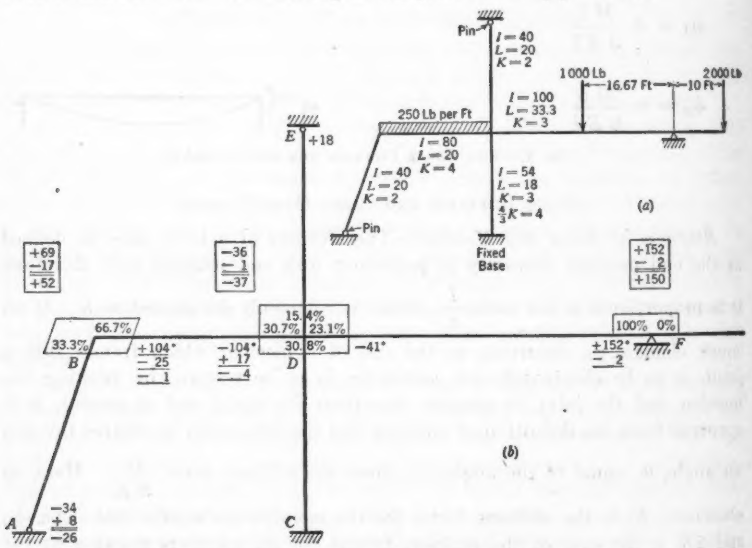

FIG. 2.—BALANCING ANGLE CHANGES FOR A CONTINUOUS FRAME. (* = RELATIVE SIMPLE BEAM ANGLE CHANGES IN LOADED SPANS; ϕ - VALUES.)

Illustrative Example

The Frame.—Fig. 2 shows the application of the method of balancing angle changes to a continuous frame with prismatic members when all joints are fixed against translation. This academic example was chosen to illustrate, quite simply, the general procedure. Fig. 2(*a*) shows the loaded frame and

gives the properties of the members. The end angle changes of the loaded spans, when the joints are pin-connected, are marked with an asterisk in Fig. 2(*b*) which further illustrates the balancing of these angle changes to obtain the joint rotations. The end angle changes in Span *BD* are those of a simple beam carrying a uniform vertical load. The angle changes in the span, *DF*, are the resultant end slopes of the simple beam with a concentrated center load of 1 000 lb and an applied moment at the right-hand end of 20 000 ft-lb. From these joint rotations, the deflected structure can be sketched and the end moments calculated by use of the standard slope-deflection equations. Only the balancing of angle changes to obtain joint rotations will be discussed, since the remainder of the procedure should be clear to any one who is familiar with the ordinary theories of indeterminate structures.

Balancing the Angle Changes.—The balancing procedure was started (Fig. 2(*b*)) at Joint *B*, although any other unbalanced joint might have been selected. The angle change of + 104 at End *B* of Member *BD* produced a joint rotation of 66.7% of + 104 or + 69. This is simply the angle change times the joint rotation factor, or $\phi\left(\frac{K_1}{\Sigma K}\right)$. Joint rotation factors $\left(\frac{K}{\Sigma K}\text{-values}\right)$ are expressed as percentage factors and enclosed in boxes at the joints for convenient reference. End *B* of Member *BA* has been rotated through an angle of + 69 which gives rise to a carry-over angle of − 34 to Joint *A*. The carry-over factor is − 0.5 and only whole numbers are recorded in this example. End *B* of Member *BD* has been rotated backward from + 104 to + 69, or through an angle of − 35. The carry-over angle is + 17 to End *D*.

Two angle changes occur at Joint *D* which was selected as the second joint to be balanced; that is, − 41 in Member *DF* and − 87 in Member *DB* obtained as the algebraic sum of − 104 and + 17. The joint rotation is 23.1% of − 41 plus 30.7% of − 87, or a total of − 36. The carry-over angle to *E*, therefore, is + 18. End *D* of Member *DF* has rotated positively from − 41 to − 36, or through an angle of + 5 which produces a carry-over angle of − 2 to End *F*. End *D* of Member *DB* has rotated positively from − 87 to − 36, or through an angle of + 51. The carry-over angle to *B* is − 25. There is no carry-over angle to End *C* of Member *DC* which is a fixed end. To allow for the added resistance of this member to end rotation at *D*, its *K*-value or stiffness factor was increased $33\frac{1}{3}\%$ when joint rotation factors were being determined. One will observe this relationship from Fig. 3.

The Cantilever End.—The third joint selected for balancing was *F*, where the entire resistance to rotation occurs in Member *FD* which has a joint rotation factor of 100 per cent. Hence, each value of ϕ is simply recorded as a joint rotation, θ, and there is no carry-over angle to Joint *D*. In other words, there is no external resistance to rotation at Joint *F* which

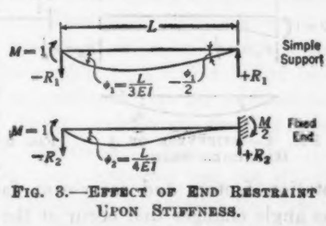

FIG. 3.—EFFECT OF END RESTRAINT UPON STIFFNESS.

means that it can be treated like Joints A and E where there is no distinction made between values of ϕ and θ. The fourth and fifth joints balanced were B and D which involved merely a repetition of the procedure that has already been described. The repetition was necessary in order to balance out the carry-over angles mentioned previously.

Accuracy in Balancing Angles

In Fig. 2 the balancing process was stopped when the carry-over angles became less than unity. This is the proper procedure. Greater accuracy could be obtained if desired by introducing an extra significant figure into the original angle changes or ϕ-values. A device frequently found useful is to double or triple the first three significant figures of the original ϕ-values and then balance joints until the carry-over angles are less than unity. This device can be used to improve the accuracy of the analysis without adding a fourth significant figure to the original ϕ-values. Of course, the final joint rotations must be reduced in the same ratio that the original angle changes were increased. Accuracy was sacrificed for clearness in Fig. 2.

Checking the Final Moments

The simplest procedure for checking the analysis is to apply the equation $\Sigma M = 0$ to each joint after final moments are determined from the θ-values by use of the slope-deflection equations. Since the balancing is performed on angles rather than moments and since fixed-end moments are introduced through the slope-deflection equations, any error in the computation of an original angle change, in the balancing procedure, or in the application of the slope-deflection equations, will be detected by this simple check. Of course, compensating errors might occur, but this slight possibility for error exists in all methods. A sketch of the deflected structure will help to locate such unusual errors.

Haunched Beams and Curved Members

Basic Terms Redefined.—A variation of cross-section or a curved axis affects the resistance of a member to end rotation and makes necessary a careful calculation of end angle changes, joint rotation factors, and carry-over factors. End angle changes can be computed conveniently by use of the conjugate-beam method. Since the possible variations of loading are infinite, it would be unreasonable to attempt to formularize this procedure. Joint

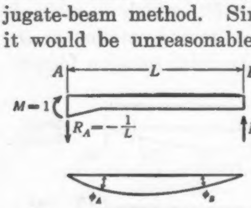

Fig. 4.—Stiffness of a Haunched Beam.

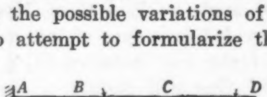

Fig. 5.—Settlement of a Support.

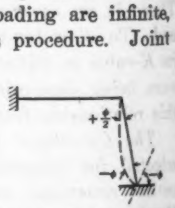

Fig. 6.—Rotation of a Footing.

rotation factors and carry-over factors can be obtained quite simply from the angle changes that occur at the ends of the simply supported beam loaded with a unit moment at one end (see Fig. 4). The carry-over factor for angle

change from Point A to Point B is $\frac{\phi_B}{\phi_A}$ and has a negative sign as in a prismatic beam. Stiffness is defined rigorously as the moment necessary to produce a unit end rotation, and evidently is $\frac{1}{\phi_A}$. The factor, K, has been used for prismatic beams to define relative stiffness. Hence, since $\phi_A = \frac{L}{3\,E\,I} = \frac{1}{3\,E\,K}$, or since $\frac{1}{\phi_A} = 3\,E\,K$ for such a beam, it is permissible and possibly desirable to omit the factor, $3\,E$, in making calculations for a haunched beam. Accordingly, one can define K as $\frac{1}{3\,E\,\phi_A}$ for the haunched beam and then the definition for the joint rotation factor remains unchanged as $\frac{K}{\Sigma\,K}$. Curved members can be handled by this procedure without re-defining any terms. The carry-over factor for angle change may reverse its sign for an arched member.

Settlement of Supports and Other Impressed Distortions

The effect of a settling support is readily introduced into the calculations. Fig. 5 makes it apparent that a settlement of Δ at Support C is represented by angle changes of $\phi_1 = + \frac{\Delta}{L_1}$ at the two ends of Span BC and $\phi_2 = - \frac{\Delta}{L_2}$ at each end of Span CD. One balances these angle changes and computes the moments in exactly the same manner as for angle changes produced by loads. There are no fixed-end moments to be considered when applying the slope-deflection equations. Temperature change of a continuous frame gives rise to linear distortions represented by end angle changes in a similar manner. The unplanned rotation of a footing could be represented by two angle changes, as shown in Fig. 6.

Influence Lines for Continuous Beams

The Deflected Load Line.—The process of balancing angle changes offers a highly pictorial method of determining influence lines for continuous beams. It is well known that the influence line for any function, such as moment or shear, can be obtained as the deflected load line produced by an impressed unit distortion in the nature of the stress function; that is, a unit rotation must be impressed upon the structure to obtain an influence line for moment and a unit shearing distortion must be used to obtain an influence line for shear. The corresponding end angle changes are illustrated in Fig. 7. Fig. 7(a) shows the angle changes that will give rise to an influence line for M_c, the moment over Support C. In balancing angles, one maintains the discontinuity, $\phi = 1$, at Joint C by balancing only carry-over angles at Joint C.

An influence line for moment between supports of a continuous beam would be obtained as illustrated by Fig. 7(*b*). In this case the end angle changes, $\phi_1 = -\dfrac{b}{a+b}$ and $\phi_2 = +\dfrac{a}{a+b}$, must be balanced out and the

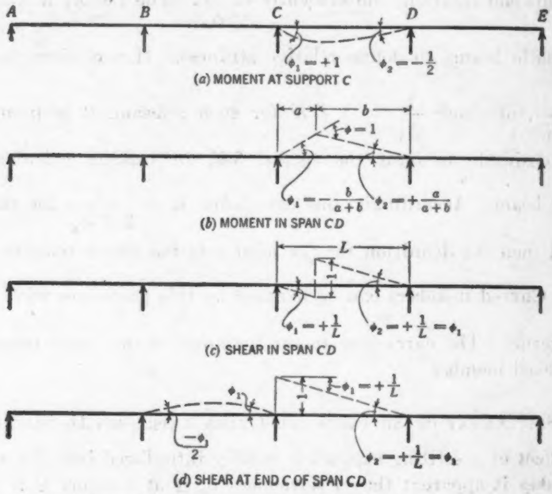

FIG. 7.—ANGLE CHANGES FOR PRODUCING INFLUENCE LINES FOR A CONTINUOUS BEAM

internal, unit, angular discontinuity will be maintained automatically by the standard procedure of balancing angles. Similar configurations for obtaining influence lines for shear between supports and at a support, are illustrated by Fig. 7(*c*) and Fig. 7(*d*). Observe that there are no angular discontinuities to be removed at the sections of vertical displacement.

Approximate Influence Lines.—The procedure, as described for continuous beams, is quite as applicable to all types of continuous frames in which joints do not translate. Hence, the method may be particularly useful as a tool for sketching an influence line rapidly and for obtaining the approximate load divides; that is, balance the angle changes shown in Fig. 7 without making any attempt at great accuracy, and then, from the approximate values of the joint rotations, sketch the shape of the deflected structure, which is the influence line desired. Approximate influence lines are frequently quite as useful as exact ones. However, the exact influence lines can also be obtained rapidly by this method.

THE PROBLEM OF JOINT TRANSLATION

Known or Estimated Deflections.—Rigid frame structures usually have certain joints that are free to translate as permitted by the elastic distortions of the structure. Evidently, the analysis of such a structure would be simplified by a previous knowledge of the deflections. From the known deflections,

it would be possible to write a corresponding set of angle changes, balance these angle changes to obtain the joint rotations, and then compute the corresponding end moments. When exact deflections cannot be known beforehand, it usually is possible to estimate the deflections approximately and to base the analysis upon them, later introducing correction factors if necessary. The procedure of basing an analysis upon estimated deflections has been presented by the writer in a paper on wind stress analysis.[4]

Successive Distortion.—If deflections cannot be estimated with sufficient accuracy, one can always revert to the device of obtaining the shears in all stories or panels from an applied distortion (represented by equal end angle changes) produced, successively, in each story or panel. Then, by combining these configurations to produce the desired shears, one has obtained the true deflected structure and the corresponding moments are precise. This process is more exact and consumes more time than is justified in wind stress analysis, but it is useful in the study of open web trusses where it furnishes the data required for a study of partial live loadings.

Secondary Stress Analysis

Bar Rotations.—The analysis of secondary stresses in bridge trusses forms a perfect illustration of the use of predetermined deflections for computing indeterminate moments. Since the deflections are produced primarily by the changes in lengths of the truss members and only to a slight extent by the secondary moments, they are readily calculable. However, only the bar rotations are needed to start the balancing process and these can be obtained without the formality of drawing a Williot-Mohr diagram. The angle changes of the triangles of a truss can be expressed by the following relations which were derived by the late Milo S. Ketchum, Hon. M. Am. Soc. C. E., in his book entitled "Steel Mill Buildings":

$$E\,(\Delta\,A) = (s_{bc} - s_{ab}) \cot B - (s_{ca} - s_{bc}) \cot C \,.........(1)$$

$$E\,(\Delta\,B) = (s_{ca} - s_{bc}) \cot C - (s_{ab} - s_{ca}) \cot A \,.........(2)$$

and,

$$E\,(\Delta\,C) = (s_{ab} - s_{ca}) \cot A - (s_{bc} - s_{ab}) \cot B \,........(3)$$

In Equations (1), (2), and (3), ΔA represents the change in Angle A caused by the stresses, s_{ab}, s_{ca}, and s_{bc}, in the correspondingly lettered bars of the truss of Fig. 8. Accordingly, if it is assumed that Bar *a-c* remains horizontal, ΔA becomes the rotation of Bar *a-b*. Similarly, Bar *b-c* rotates through an angle, $\Delta A + \Delta B$, Bar *b-d* rotates through an angle, $\Delta A + \Delta B - \Delta D$, etc. These bar rotations are relative to a zero rotation for Bar *a-c*. The true rotations relative to a line through the supports, or *a-i*, are obtained by subtracting from each bar rotation relative to Bar *a-c* the true rotation of Bar *a-c*, which,

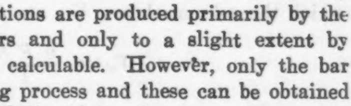

Fig. 8.—Bar Rotations for Secondary Stress Analysis.

for Fig. 8, can be shown to be the average relative bar rotation for all lower chord members.

Secondary Moments.—Bar rotations are treated as end angle changes and balanced by the usual procedure to obtain joint rotations. Then, the secondary moments follow from the slope-deflection equation,

$$M_{AB} = 2EK\,(2\,\theta_A + \theta_B - 3\,\rho)\ldots\ldots\ldots\ldots\ldots\ldots(4)$$

in which θ represents a joint rotation and ρ is the bar rotation.

Bent Analysis

Shear Adjustment by Proportion.—A simple bent will be used to illustrate the general method of adjusting shears by proportion. Such a bent is characterized by having a single degree of lateral freedom—its side lurch. Hence, if moments and shears are known for any given side-sway, those corresponding to any other side-sway can be obtained by multiplying the known moments and shears by the ratio of lateral deflections. It follows that the balancing procedure can be started by imposing upon the bent an unresisted side lurch represented by equal angle changes at the top and bottom of each column. Then, by balancing angle changes, one obtains the joint rotations from which the column shears, V_H, are determined by the relation:

$$V_H = \frac{6\,E\,K}{h}\,(\theta_A + \theta_B - 2\,\rho)\ldots\ldots\ldots\ldots\ldots\ldots(5)$$

The ratio of actual horizontal shear to total calculated horizontal shear is then to be used as a multiplication factor for adjusting lateral deflection, joint rotations, and column and girder moments. The "actual" horizontal shear may be caused by lateral loads or by an artificial restraint introduced through the balancing process when one is studying the effect of dissymmetry.

Analysis Involving Joint Slip

Riveted connections undergo elastic distortion and slip, both of which permit angular discontinuities to occur at the joints. For the purpose of outlining a method of analysis, it is unnecessary to distinguish between elastic and plastic joint deformation, although it is evident that these effects would have to be isolated and studied separately to investigate the action of moving loads.

Balancing Moments and Angles.—Test data on joint slip are available in a paper[6] by J. Charles Rathbun, M. Am. Soc. C. E. The cases to be discussed will be chosen so that these data are applicable. The method of analysis given herein will involve the double conception of balancing moments and balancing angle changes. The procedure can be developed entirely in terms of balancing moments, but the combination suggested herein has the advantage of permitting the use of standard stiffness factors and the unchanged carry-over factor of 0.5 for a prismatic member. The method

[6] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 524.

of balancing angle changes can also be used without the aid of balancing moments but less advantageously.

Continuous Beams with One Elastic Connection.—The first example presented (Fig. 9) is one solved by Professor Rathbun[7]. Joint B is assumed to

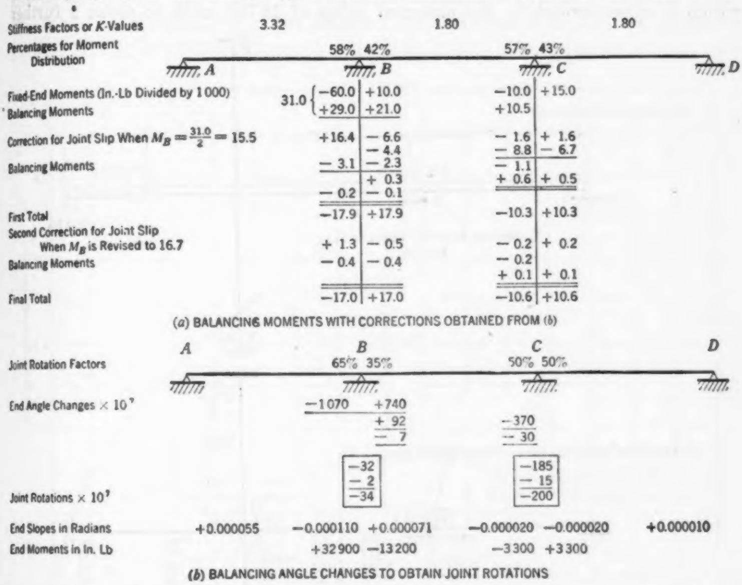

FIG. 9.—ANALYSIS OF CONTINUOUS BEAM WITH ELASTIC CONNECTION AT JOINT B.

be an elastic connection having a modulus of rotation of 4.2×10^8 in-lb per unit (radian) rotation in Span BC and 2.9×10^8 in-lb per unit rotation in Span BA.

Fixed-end moments are computed and the moments at Joint B are balanced once to obtain the first approximation of 31 000 in-lb for M_B. This moment will be reduced considerably by joint deformation and as a starting point it was assumed that the final moment at Joint B would be reduced 50%, to 15 500 in-lb. The moment at Joint B gives rise to angle changes from joint deformation of $\phi_{BA} = \dfrac{31\,000}{290\,000\,000} = 0.000107$; and, $\phi_{BC} = \dfrac{31\,000}{420\,000\,000}$ $= 0.000074$. These angle changes must be maintained as angular discontinuities and, accordingly, they are not balanced. Nevertheless, there is a carry-over angle of $-0.5\ \phi_{BC}$ to Joint C which is to be balanced as in previous examples. (See Fig. 9(*b*).)

End moments are calculated from end rotations by the slope-deflection equations and are introduced as fixed-end moments. Joint moments are then completely balanced, and the joint moment at B is found to be 17 900 in-lb

[7] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 561, Fig. 33.

as compared to the estimated moment of 15 500 in-lb. The true moment lies between these values and was then estimated at 16 700 in-lb. Correction moments can be obtained in this simple example by proportion since there is only one elastic joint in the structure. The revised value of M_B is 17 000 in-lb, which is close enough to the assumed value of 16 700 in-lb to make a further

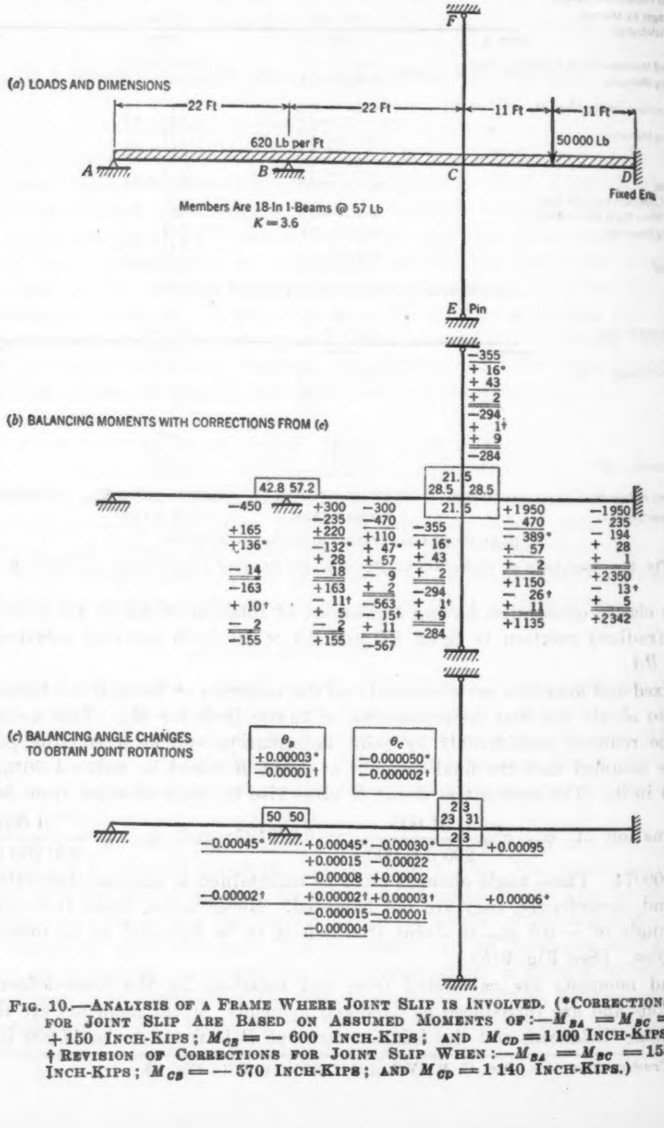

FIG. 10.—ANALYSIS OF A FRAME WHERE JOINT SLIP IS INVOLVED. (*CORRECTIONS FOR JOINT SLIP ARE BASED ON ASSUMED MOMENTS OF: $-M_{BA} = M_{BC} = +150$ INCH-KIPS; $M_{CB} = -600$ INCH-KIPS; AND $M_{CD} = 1\,100$ INCH-KIPS. † REVISION OF CORRECTIONS FOR JOINT SLIP WHEN: $-M_{BA} = M_{BC} = 155$ INCH-KIPS; $M_{CB} = -570$ INCH-KIPS; AND $M_{CD} = 1\,140$ INCH-KIPS.)

correction unnecessary. These final moments check the values computed by the writer by Professor Rathbun's procedure.

Continuous Frame with Two Deformable Connections.—The second example, shown in Fig. 10, represents a more complicated analysis of a frame having two joints where both elastic deformation and plastic joint slip occur. The modulus of rotation for the connections at Joints B and C are as shown by Fig. 11. It is of importance to note that it is not permissible in this case

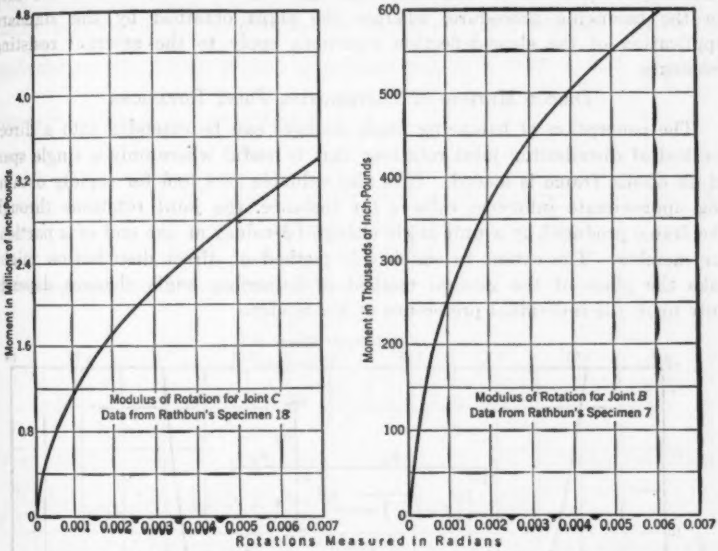

FIG. 11.—MODULI OF ROTATION FOR RIVETED JOINTS OF FRAME OF FIG. 10.

to simplify the analysis by the assumption of a straight-line relationship between joint slip and end moment.

The procedure is started in Fig. 10(b) by a single balance of fixed-end moments at Joints C and B. From these approximate moments, an estimate of final moments is made. Care should be taken in making this estimate because a close approximation of the final moments will remove the need for making additional corrections. From the estimated moments and the data of Fig. 11, one obtains approximate values for joint slip. These angular discontinuities give rise to carry-over angles which are balanced in Fig. 10(c). From the computed values of end rotation, one obtains end moments which are shown followed by an asterisk in Fig. 10(b). When these moments had been balanced out, the end moments were compared with the estimated values and found to be in reasonable agreement. However, to illustrate the procedure of introducing corrections, an improved estimate of final moments was made, and the changes in these moments were used to obtain correction angles from Fig. 11, which also are balanced in Fig. 10(c). The correc-

tion moments obtained from these correction angles are introduced into Fig. 10(b) and balanced to obtain final moments. Second corrections to moments and angles are marked with a dagger in Fig. 10(b) and Fig. 10(c).

Sign Reversal.—The foregoing procedure will not be found easy to understand until one is quite familiar with the methods of balancing moments and balancing angle changes. Possibly a confusing point is the reversal of signs of the moments as obtained by the slope-deflection equations. This is necessary because of the fact that the signs of internal moments are used in the balancing procedure, whereas the signs obtained by the standard application of the slope-deflection equations apply to the external resisting moments.

Direct Method of Distributing Joint Rotations

The conception of balancing angle changes can be extended into a direct method of distributing joint rotations that is useful where only a single span of an elastic frame is loaded. It is also valuable as a tool for rapidly obtaining approximate influence values; for instance, the joint rotations through the frame produced by a unit angle change (ϕ-value) at one end of a particular member. The extent to which this method of direct distribution might take the place of the general method of balancing angle changes depends only upon the individual preference of the reader.

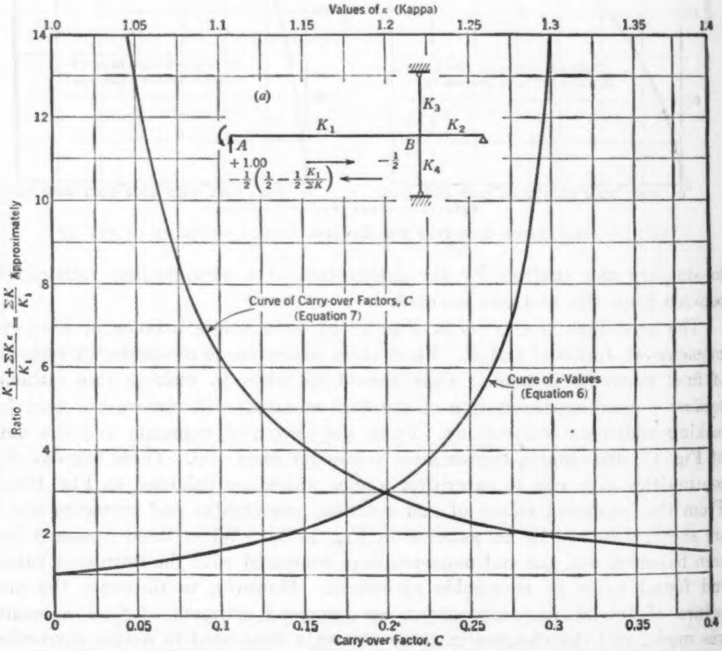

Fig. 12.—Carry-Over Factors and K-Values for Direct Distribution of Joint Rotations.

Stiffness Dependent Upon End Restraint.—Fig. 12(*a*) shows the resultant θ-values as produced by a unit ϕ-value at End A of Member AB which is restrained but not fixed at Joint B. Since stiffness is defined as resistance to rotation, the stiffness of the member in terms of rotation at End A is increased by the restraint at Joint B. The stiffness at a joint usually is expressed as $\Sigma K = K_1 + K_2 + K_3 + K_4$. If κ is defined as the ratio of the stiffness of the restrained member to its stiffness when the far end, B, is simply supported, then $K \kappa$ becomes the stiffness factor for a restrained member exactly comparable to the K-value for an unrestrained member. From the small sketch, Fig. 12(*a*), it will be evident that $\theta_A = 0.75 + 0.25 \dfrac{K_1}{\Sigma K}$ and that $\theta_B = -0.5 \dfrac{K_1}{\Sigma K}$. Accordingly,

$$\kappa = -\frac{1}{\theta_A} = \frac{1}{0.75 + 0.25 \dfrac{K_1}{\Sigma K}} = \frac{4}{3 + \dfrac{K_1}{\Sigma K}} \quad \ldots\ldots\ldots(6)$$

The carry-over factor for joint rotation is,

$$C = -\frac{\theta_B}{\theta_A} = -\frac{0.5 \dfrac{K_1}{\Sigma K}}{0.75 + 0.25 \dfrac{K_1}{\Sigma K}} = -\frac{2}{1 + 3 \dfrac{\Sigma K}{K_1}} = -\frac{\kappa}{2} \frac{K_1}{\Sigma K} \;.(7)$$

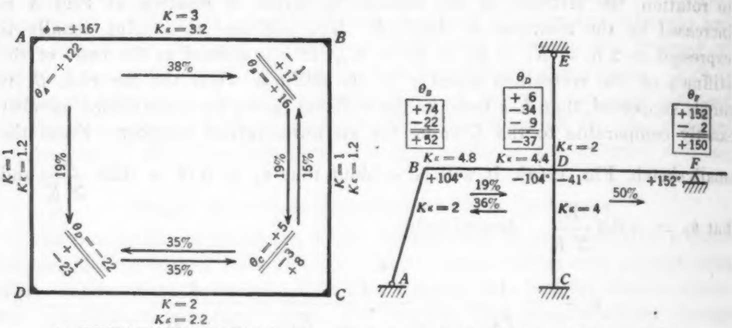
When the far ends are restrained, substitute in the foregoing equations, $\dfrac{K_1}{\Sigma K \kappa}$ for $\dfrac{K_1}{\Sigma K}$, in which $\Sigma K \kappa = K_2 \kappa_2 + K_3 \kappa_3 + K_4 \kappa_4$.

The curves of Fig. 12 show the plotted values of κ and C for a wide variation of the ratios, $\dfrac{\Sigma K}{K_1}$. Actually, when the far ends of the restraining members are not simply supported, one should substitute $\dfrac{K_1 + \Sigma K \kappa}{K_1}$ for $\dfrac{\Sigma K}{K_1}$, but this refinement is unnecessary when approximate θ-values are satisfactory.

Examples of Direct Distribution.—The use of the curves of Fig. 12 is illustrated by the two examples of Fig. 13. The elastic frame in Fig. 13(*b*) was analyzed previously in Fig. 2. The ϕ-value of + 104 at End B gives rise to the joint rotation of + 74 which, in turn, produces the joint rotation of + 6 at Joint D. The remainder of the θ-values are produced by balancing Joint D and carrying over the proper rotations to Joint B and Joint F.

A box culvert is analyzed in Fig. 13(*a*) for the effect of a single ϕ-value of + 167 at Corner A. The joint rotations become influence values from which the effect of any symmetrical loading could be obtained. The calculations are self-explanatory except perhaps for the use of a single κ-value for each vertical member. Actually, there are slightly different κ-values for the two ends of the vertical member, but this difference is small enough to be

neglected. The corresponding effect upon the carry-over factor was of greater importance, and, accordingly, two carry-over factors were recorded for the vertical member.



(a) INFLUENCE VALUES FOR CLOSED FRAME (b) ANALYSIS OF CONTINUOUS FRAME IN FIG. 2

FIG. 13.—DIRECT DISTRIBUTION OF JOINT ROTATIONS. (*RELATIVE ϕ-VALUES.)

CONCLUSION

The procedure of balancing angle changes has been found to offer a parallel method to that of balancing moments. Either tool can be used to analyze continuous beams, rigid frames, open-web trusses, tall building frames, continuous arches on elastic piers, and other continuous framed structures. In certain cases they can be used to advantage to supplement each other, as in the analysis of a frame undergoing joint slip. The procedure of balancing angle changes possesses the inherent disadvantage that final moments are computed from the differences between angular rotations. Hence, angular rotations must be computed with greater accuracy than joint moments by the method of moment distribution. However, the method of balancing angle changes possesses two important advantages of its own: (1) It is essentially self-checking; and (2) it offers one the clearest possible picture of the physical action of the structure. These attributes seem sufficient to justify its use by those designers who are accustomed to thinking in terms of joint rotations and deflections.

DISCUSSION

John E. Goldberg,[8] Jun. Am. Soc. C. E. (by letter).—The method of analyzing continuous frames by balancing end rotations presented by Professor Grinter is similar in many respects to the simple slope-deflection method largely developed by G. A. Maney, M. Am. Soc. C. E., from his basic slope-deflection equations and presented[9] by the writer in 1931. Both methods consist, essentially, of determining the angular positions at which the various joints of the continuous structure are in equilibrium, or balanced, and then substituting these values of the angular rotations in the basic slope-deflection equation to obtain the final or actual moments at the ends of the various members. Both methods may be extended, by the application of well-known and well-understood principles, to the solution of a wide variety of rigid-frame problems. The advantages which Professor Grinter cites for his method are at least as applicable to the earlier slope-deflection method.

The slope-deflection method seems, to the writer, to have certain additional inherent advantages; for example, the starting point of the slope-deflection method is the fixed-beam moments which are again used to obtain the final or actual moments after the various rotations have been determined. This itself may be construed as a twofold advantage: First, a complete series of calculations (the simple beam end-angles) is avoided; and, second, the fixed-beam moments are themselves better known and more easily remembered for the various standard loadings than the simple beam end-angles. Another advantage lies in the fact that, throughout the entire slope-deflection analysis, the concept of continuity is firmly maintained, a fact that adds greatly to the clarity and physical significance of the method, besides being inherently more direct. In Professor Grinter's analysis, on the other hand, this continuity is first completely destroyed and then successive parts of it are re-established. Another inherent advantage of slope-deflection methods lies in the fact that there are frames the analysis of which by methods based upon successive approximations, corrections, or balancing, may be inadvisable, impractical, or even impossible.

Various types of simple frames, for example, may be analyzed by slope deflection by the solution of a limited number of equations, in many cases by only one equation. Simple bridges, culverts, and many other similar frames fall into this category of frames which may be analyzed with actually less effort and greater reliability by direct methods. The frame shown in Fig. 2, although chosen by the author for its classical values, is nevertheless an illustration of a structure that could be solved very neatly by these direct slope-deflection methods. One who is adept and familiar with the slope-deflec-

[8] Chicago, Ill.

[9] "Vertical Load Analysis of Rigid Building Frames", by John E. Goldberg, *Engineering News-Record*, November, 12, 1931; see, also, "Simplified Methods for the Analysis of Multiple Joint Rigid Frames", by George A. Maney and John E. Goldberg, *Northwestern Univ. Bulletin*, Vol. XXXIII, No. 7, October 17, 1932.

tion theory could very easily set up the two equations which would solve the frame. Solution of these equations would give, with absolute certainty, the joint rotations from which the final or actual moments may be calculated. There are also frames which, by their very proportions, can not be solved successfully by methods based upon successive approximations or corrections. For the analysis of these frames there always remains the alternative method of solving the slope-deflection equations by algebra.

Professor Grinter, it seems, has touched upon the matter of bent analysis too lightly. He implies that if the shear for any assumed side-sway at a particular story is known, the actual shear in the various members may be calculated by a single, simple, proportionate adjustment. Unfortunately, the analysis is not so simple, except in a very few mathematically perfect cases, chief among which is the single-story bent, itself not a very complex problem. Equations (4) and (5), the slope-deflection equations, show that the shear in a member is as much a function of the joint rotations at the ends of the member as of the relative joint translation. These rotations, in turn, are affected just as much by the shears above and below the story under consideration as they are by the shears in that particular story, etc. Consequently, except in these few perfect cases, this simple adjustment is itself only an approximation.

Professor Grinter has referred to the method of analyzing wind stresses by slope-deflection and converging approximations, which the writer developed from basic slope-deflection theory and presented[10] in 1933, as being based upon series convergence. Actually, the method consists simply of obtaining, successively, closer or more nearly correct values of the various rotations in accordance with simple and easily understood principles, and thus to label the method with an abstract mathematical term is confusing to the student and to the reader. Furthermore, he has referred to the method as being "relatively tedious" without, however, stating to what it is relative. Nevertheless, after an exhaustive survey of methods of wind stress analysis, the results of which are contained in its latest report[11], Sub-Committee No. 31, Committee on Steel of the Structural Division of the Society, on Wind-Bracing in Steel Buildings points out that among the desirable characteristics of the writer's method are speed, accuracy, simplicity, and the clarity of the physical concept maintained throughout the analysis. Professor Grinter's present appreciation of the slope-deflection equation and of the importance and significance of the physical concept of joint rotations is definitely complimentary to the slope-deflection method and to those who have consistently sponsored and developed its use.

The frame of Fig. 2 is analyzed herein by slope deflection to illustrate the general methods of attack. One familiar with the slope-deflection theory can set up, practically by inspection, the joint equations which express the simple

[10] "Wind Stresses by Slope-Deflection and Converging Approximations", by John E. Goldberg, *Transactions*, Am. Soc. C. E., Vol. 99 (1934), pp. 962–975.

[11] *Proceedings*, Am. Soc. C. E., March, 1936, p. 397.

physical fact that ΣM (in terms of fixed-beam moments and joint rotations) equals zero. For the frame of Fig 2:

$$\text{Joint } B\text{: } 11.0\ \theta_B + 4.0\ \theta_D = 8.333$$

and,

$$\text{Joint } D\text{: } 4.0\ \theta_B + 21.5\ \theta_D = -\ 12.0833$$

From which, by simple algebra:

$$\theta_D = \frac{11.0\ (-\ 12.0833)\ -\ 4.0\ (8.333)}{11.0\ (21.5)\ -\ 4.0\ (4.0)} = -\ 0.754$$

and,

$$\theta_B = 0.758 + 0.274 = 1.032$$

Substitution of these values in the basic slope-deflection equation,

$$M_{AB} = M_{F\text{-}AB} - K\ (2\ \theta_A + \theta_B) \qquad (8)$$

gives the final end moments; that is, $M_{DB} = -\ 8.333\ \ -\ 4.0\ (-\ 1.508 + 1.032) = 6.429$; and, similarly, for the other end moments. The moments are in kip-feet; and, K-values are used in only a relative sense. As a result of these facts, the joint rotations in the foregoing analysis are approximately one-fiftieth of the rotations indicated by Professor Grinter.

When direct analysis of a frame is so simple, there is scant justification for the use of methods based on successive balancings or corrections, or even for the use of methods based on semi-empirical formulas. However, as an illustration of an alternative slope-deflection method, particularly applicable to frames in which the number of joints precludes the use of algebraic methods, the analysis of the frame of Fig. 2 by converging approximations is also given: The respective joint equations are, for simplicity, reduced and solved for the respective values of θ:

$$\text{Joint } D\text{: } \theta_D = -\ 0.562 - 0.186\ \theta_B$$

and,

$$\text{Joint } B\text{: } \theta_B = 0.758\ -\ 0.364\ \theta_D$$

For the purpose of obtaining a first approximation, θ_B is taken to be equal to the constant term in its own equation; that is, 0.758. Then, $\theta_D = -\ 0.562 - 0.186\ (0.758) = -\ 0.703$. From which, $\theta_B = 0.758 - 0.364\ (-\ 0.703) = 1.014$.

For a second approximation: $\theta_D = -\ 0.562\ -\ 0.186\ (1.104) = -\ 0.751$; and, $\theta_B = 0.758\ -\ 0.364\ (-0.751) = 1.031$. For all practical purposes, this second approximation is sufficiently accurate. However, a third approximation gives: $\theta_D = -\ 0.562\ -\ 0.186\ ((1.031) = -\ 0.754$; and, $\theta_B = 0.758 - 0.364\ (-\ 0.754) = 1.032$.

By comparison of these results it is clear that convergence is now complete. Substitution of these final θ-values in the respective basic slope-deflection equations gives the final end moments for the various members. It is clear that no appreciable inaccuracy would have resulted if the θ-values obtained as a second approximation were used to calculate the final end moments.

G. A. MANEY,[12] M. AM. SOC. C. E. (by letter).—In comparing the method used in his paper with the moment distribution method, the author comes to two conclusions as follows: (1) It is essentially self-checking; and (2) it

offers the clearest possible picture of the physical action of the structure. The writer agrees heartily with these conclusions and submits four short solutions in tabular form, which are made by using the slope-deflection method first proposed by him in the United States in 1915. These solutions (which explain themselves because of the tabular forms used), together with the past

[12] Prof. of Structural Eng., School of Eng., Northwestern Univ., Evanston, Ill.

history of slope-deflection and of converging approximate solutions, lead to the following comments:

(1) "Balancing angles changes" is merely a new group of words to describe what has been done for years in the solution of slope-deflection equations by converging approximations of the θ-values.[18]

(2) In the problems of Tables 1 and 2 values of $2E\theta$ were determined by the usual method of "balancing angles" or "converging slope values", instead of the θ-values themselves. This has always been done merely as a convenience in calculation, since the quantities resulting are easier to handle. In all slope-deflection solutions made in recent years in which the number of unknowns is large, this method of "balancing angles" or "converging end slope values" has been used, but the convergence or balancing has started from the zero end angle case in which M_F is the fixed-end bending moment.

(3) In Table 1(b) a solution is given for the case of elastic angle slip at the joints, which has the advantage of making a trial solution unnecessary. Note the close check on values of final moments. In another problem checked by the writer (see Table 2), the case of both elastic and plastic joints is

[18] For an example, see "Statically Indeterminate Stresses", by John I. Parcel and G. A. Maney, Members, Am. Soc. C. E., Fig. 142, opposite p. 276, John Wiley and Sons, 1936.

treated. The "corrections due to yielding angle" (see Table 2(*b*) where this correction is -127) herein used can only be,

$$\Delta M_{BC} = -2\,E\,K_{BC}\,[2\,\phi_{BC} + \phi_{CB}] \quad \ldots\ldots\ldots\ldots\ldots (9)$$

using the slope-deflection formula in which ϕ-values are angular discontinuities. When they are elastic, ϕ_{BC} becomes $\frac{M_{BC}}{R_{BC}}$ and $\phi_{CB} = \frac{M_{CB}}{R_{CB}}$ (in which the R-values are the moduli of rotation) which are ratios of bending moment to corresponding angular rotation of the end of the member, in radians. In Table 2(*b*), this correction becomes $-2\,E\,K\left(\frac{2\,M_{BC}}{R_{BC}}\right)$ for M_{BC}, or $-0.498\,M_{BC}$.

(4) Particular attention is called to the case of "plastic" discontinuity of end angles as included in the author's problem in Fig. 10 and in the writer's corresponding solution in Table 2(*b*). The percentage change in end moments due to lack of joint rigidity is listed in Column (9), Table 2(*b*). This percentage varies from a decrease of 41% to an increase of 7%, and emphasizes the need for a solution as given in Table 1(*b*) which eliminates guesswork regarding the final moment values.

(5) If there is a "plastic" feature of the angular discontinuity, why should not all end moments closely approach zero finally? A plastic condition *per se* means "give" under continued load with a corresponding steady increase of ϕ-values with time. If this simple beam condition is approached, why indulge in rigid-frame analysis for frames with "flowing" or "plastic" joints?

Tables 1 and 2 may be clarified by examining Table 1(*a*), as follows:

(*a*) Line 2 indicates that $-8\,\theta_B - 4\,\theta_D + 8.33 = M_{BD}$, which is a specific statement of the general equation applicable to this case. The general form would be stated:

$$M_{BD} = \pm M_{FBD} - K_{BD}\,(2\,\theta_B + \theta_D) \quad \ldots\ldots\ldots\ldots (10)$$

in which, $\pm M_{FBD} = +8.33$ ft-kips; $2\,K_{BD} = 8$; $K_{BD} = 4$; and θ_B and θ_D are multiples of the angular rotation of Joints B and D when equilibrium is reached.

(*b*) Line 8 shows that $\Sigma\,M_B = 0$; or that the net rotational tendency of all moments acting on Joint B is zero when equilibrium is reached. The expressions for M_{BA} in Line 1 and for M_{BD} in Line 2 are added to obtain the joint equation of Line 8, which is: $11\,\theta_B + 4\,\theta_D = +8.33$. Likewise, equations of Lines 3, 4, 5, and 6, are added to obtain the equation (Line 9) for Joint D.

(*c*) Lines 10, 11, and 12, indicate that $1.000\,\theta_B + 0.364\,\theta_D = 0.758$ and that $0.186\,\theta_B + 1.000\,\theta_D = -0.566$. Lines 13, 14, 15, and 16 are the balancing steps for the angle values ($0.364\,\theta_D$ for θ_B, and $0.186\,\theta_B$ for θ_D) at the far end, converging until the corrections approach zero.

(*d*) Line 17 represents final values of $2\,E\,\theta$, or additions of five preceding quantities, which are substituted in the original moment expressions (Lines 1 to 7, inclusive) and values such as $-$ 3.00 ft-kips are obtained for all member ends, such as End *B* of Member *BA* (M_{BA}). It will be noted that the sum of all moments around a joint must be equal to zero, a desirable check on the numerical accuracy of the work.

PAUL ANDERSEN,[34] ASSOC. M. AM. SOC. C. E. (by letter).—In many respects Professor Grinter's method will prove a more flexible tool to the designing engineer than the Cross method. It is true that the latter has the advantage over the former in that it makes use of moments throughout its procedure and leads directly to the actual bending moments; but this disadvantage of the Grinter method is more than compensated for by the facts that it is self-checking and that the actual work involved in establishing continuity has been reduced materially. Thus, in using the Cross method, it is necessary to balance the moments at each end of a member, whereas by balancing angle changes, only one set of values is needed at each joint.

The procedure used in solving the example in Fig. 2 seems incorrect; Joint *B* is balanced and the carry-over angle from *B* is added to the angle changes of Joint *D* and included in the first process of balancing Joint *D*. The proper procedure is to balance all joints first and then to carry over the angle changes, and repeat.

Side-Sway.—Instead of obtaining the corrections for side-sway by imposing equal angle changes at the top and bottom of each column, the writer suggests applying, at the column tops, any set of angle changes inversely proportional to the column heights, and distributing these changes throughout the structure. It is readily seen that, by equating horizontal deflections before and after balancing the angle changes, the moment at the top of a column is:

$$M = \frac{Vh}{2} \times \frac{\phi - \theta}{\phi - \frac{3}{4}\theta} \quad ..(11)$$

in which ϕ = an arbitrary angle change of the top of the column; θ = the resulting joint rotation; V = column shear, proportional to $\frac{K}{h^2}$; and h = column height.

This procedure is applied to the two-legged bent

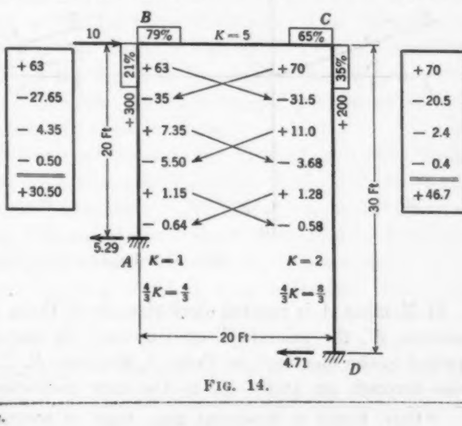

FIG. 14.

[34] Balboa Heights, Canal Zone.

shown in Fig. 14 in which angle changes of 300 and 200 are applied to the column tops, resulting in joint rotations of 30.5 and 46.7, respectively, after continuity has been established. The final moments (see Fig. 14) are,

$$M_B = \frac{1}{2} \times 5.29 \times 20 \times \frac{300 - 30.5}{300 - \frac{3}{4}\,30.5} = 51.4 \text{ ft-kips}$$

and,

$$M_C = \frac{1}{2} \times 4.71 \times 30 \times \frac{200 - 46.7}{200 - \frac{3}{4}\,46.7} = 65.6 \text{ ft-kips}$$

WILLIAM F. LUCE,[15] JUN. AM. SOC. C. E. (by letter).—A valuable tool for the analysis of continuous frames is contained in this paper. Computations by the method introduced involve only simple arithmetic with no simultaneous equations, and can be made, in many cases, in a fraction of the time required by the so-called "exact" methods, such as the slope-deflection method, the method of least work, etc. Furthermore, both the development and the application of the method involve concepts familiar to the structural engineer.

The presentation by Professor Grinter has been so complete that further explanation is scarcely necessary. The following development, however, may help some readers to visualize the balancing process and the determination of the joint rotation factor. In Fig. 15(*a*), the members, *A*, *B*, *C*, and *D*, have stiffness ratios $\left(\frac{I}{L} = K\right)$ of K_A, K_B, K_C, and K_D, respectively.

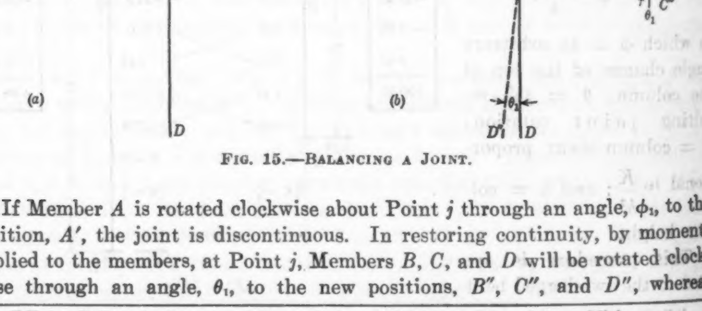

FIG. 15.—BALANCING A JOINT.

If Member *A* is rotated clockwise about Point *j* through an angle, ϕ_1, to the position, *A'*, the joint is discontinuous. In restoring continuity, by moments applied to the members, at Point *j*, Members *B*, *C*, and *D* will be rotated clockwise through an angle, θ_1, to the new positions, *B''*, *C''*, and *D''*, whereas

[15] Univ. Fellow in Structural Eng., Univ. of Michigan, Ann Arbor, Mich.

Member A will be twisted counter-clockwise through an angle $(\phi_1 - \theta_1)$ to the position, A''. The internal moments balance at Joint j:

$$M_A = M_B + M_C + M_D \quad \text{.....................} (12)$$

and, since the moment in a member depends upon the product of its stiffness and the angle through which it rotates:

$$(\phi_1 - \theta_1)\, K_A = \theta_1\, K_B + \theta_1\, K_C + \theta_1\, K_D \quad \text{.............} (13)$$

or,

$$\theta_1 = \phi_1 \frac{K_A}{K_A + K_B + K_C + K_D} = \phi_1 \frac{K_A}{\Sigma K} \quad \text{............} (14)$$

Factor $\frac{K_A}{\Sigma K}$ is termed the joint rotation factor for Member A at Joint j. The development is equally simple if two or more members are given an original angular discontinuity.

It is noted from the paper that members having their ends free to rotate are the norm in this method, and that the stiffness values for fixed-end members are corrected by the factor, $\frac{4}{3}$. This is the reverse of the procedure used in the method of balancing moments.

The writer has solved problems on secondary stresses in trusses, wind-stress analysis of building frames, and joint slip, by the method of balancing angle changes. The structure investigated for secondary stresses was a symmetrical Pratt truss of eight panels. Angle changes were computed by Dean Ketchum's formulas as suggested by the author. The balancing required four to five cycles per joint. The end moments found in this manner balanced within 1% at every joint, providing a check on the work. As a final check, the secondary stresses were calculated by the method of balancing moments, using deflections taken from a Williot-Mohr diagram. The variation of stress values as obtained by the two methods was small in most members, and the maximum difference was 400 lb per sq in. It was observed, however, that the balancing process in either case should be started with comparatively large numbers if the final results are to be accurate.

The first wind-stress problem investigated was that of a 6-story building[18], the analysis being made by estimating the shape of the deflected structure as outlined by the author elsewhere[6]. The final moments obtained, requiring only one balancing process, checked those calculated by balancing moments within 1% to 2 per cent. The latter method, however, seems to be definitely better suited to the solution of wind-stress problems. Only four cycles of balancing moments were required to give the same accuracy as six or seven cycles of balancing angle changes, and, of course, did not require the use of the slope-deflection equations at the end of the process. The analysis

[18] Structural Engineer's Handbook, by the late Milo S. Ketchum, Hon. M. Am. Soc. C. E., 1924 Edition, p. 102.

of the lower stories of another building frame[17], also indicated that the value of the check embodied in the method of balancing angle changes is decreased because of the introduction of different criterion ratios in adjacent stories. The method of balancing moments has the further advantage in the analysis of frames in which joint translations occur, such as wind-stressed buildings, that fixed-end moments may be added during the balancing process to offset joint restraints. A similar procedure for the method of balancing angle changes is not apparent.

The solution of joint slip problems and the plotting of influence lines for continuous beams can be performed very successfully by balancing angle changes.

Ralph E. Byrne, Jr.,[18] Jun. Am. Soc. C. E. (by letter).—Another method for the analysis of continuous structures is presented in this paper. It is a close parallel to the method of moment distribution, but inasmuch as the quantities dealt with are rotations and displacements rather than moments, the procedure must necessarily differ. Some of the most important differences between the two methods occur in the definitions of some of the terms involved. In the moment-distribution method, stiffness is defined as the moment required to produce unit rotation at one end of a member, the other end being fixed; the carry-over factor is defined as the ratio of the moment at the fixed end to the moment at the end being rotated. In the method of balancing angle changes, stiffness is defined as the moment required to produce unit rotation at one end of a member, the other end being hinged; and the carry-over factor is defined as the ratio of the angle change at the hinged end to the angle change at the end being rotated. Likewise, the method by which applied loads are brought into the analysis is different for the two methods In the former method, fixed-end moments are used, these being the moments which would occur at the ends of the loaded member if the ends were fully restrained. In the latter method, the quantities which are analogous to the fixed-end moments are the angles of rotation of the two ends of the member under the applied loads, the ends being hinged. These quantities are easily calculated for use in either method as long as the members are prismatic; the calculation of the quantities becomes a major task when haunching occurs.

Various tables are available giving the values of stiffness, carry-over factors, and fixed-end moments for various types of haunched beams and various loadings, for use in the method of moment distribution. The writer knows of no similar tables giving directly the analogous quantities for use in the method of balancing angle changes. However, simple relationships exist between the various quantities which greatly simplify the calculation of the quantities required for the latter method, those required for the former method being known.

The following notation will be used in establishing these relationships: S and K will denote stiffness, and r and C will denote the carry-over factor,

[17] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 664.

[18] Structural Designer, Pacific Elec. Ry., Los Angeles, Calif.

as defined, respectively, for the method of moment distribution and the method of balancing angle changes; F will be used to denote the fixed-end moment, and ϕ, the angle change at the end of the simply supported member, due to applied loads; and the subscripts, A and B, applied to these quantities will distinguish them for the two ends of the member. In this connection, it should be noted that r_A and C_A denote the carry-over factor to the end, A.

Referring to the member shown in Fig. 16: First, consider the member fully restrained at End B and a moment applied to End A to produce unit rotation of End A (Fig. 16(a)); this moment is defined as S_A. Next, release

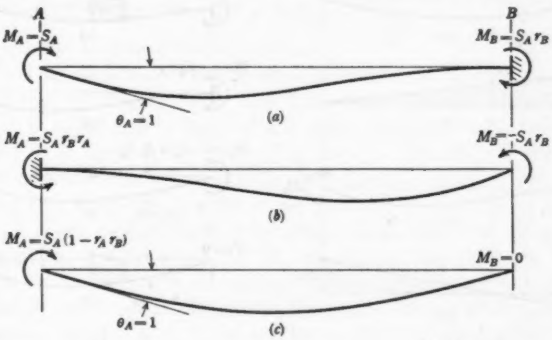

FIG. 16.

End B, the moment at B now becoming zero (Fig. 16(c)). This is accomplished by applying a moment of $-S_A r_B$ to the end, B (Fig. 16(b)). Adding the results of Fig. 16(a) and Fig. 16(b) the results of Fig. 16 (c) are obtained. The angle of rotation of End A is unity, and the moment at End B is zero; hence, by definition, the moment at End A is the stiffness at End A as defined for the method of balancing angle changes. Expressing this relationship as an equation,

$$K_A = S_A (1 - r_A r_B) \quad \text{.....................(15)}$$

Consider the member shown in Fig 17. In Fig. 17(a), a moment, M, is applied at End A, End B being simply supported. The moment diagram is shown in Fig. 17(b). Assuming the origin of co-ordinates to be at End B, the following equations may be written directly, using the two area-moment propositions:

$$\theta_A = \frac{1}{L}\int_0^L \frac{m_x\, x\, dx}{E\,I} = \frac{M}{L^2}\int_0^L \frac{x^2\, dx}{E\,I} \quad \text{...........(16a)}$$

and,

$$\theta_B = \frac{1}{L}\int_0^L \frac{m_x\,(L - x)\, dx}{E\,I} = \frac{M}{L}\int_0^L \frac{x\, dx}{E\,I} - \frac{M}{L^2}\int_0^L \frac{x^2\, dx}{E\,I} \quad \text{.....(16b)}$$

The carry-over factor, C_B, as defined for the method of balancing angle changes, may be expressed, therefore, as follows:

$$C_B = \frac{\theta_B}{\theta_A} = \frac{L\int_0^L \frac{x\,dx}{E\,I} - \int_0^L \frac{x^2\,dx}{E\,I}}{\int_0^L \frac{x^2\,dx}{E\,I}} \quad \ldots\ldots\ldots\ldots\ldots (17)$$

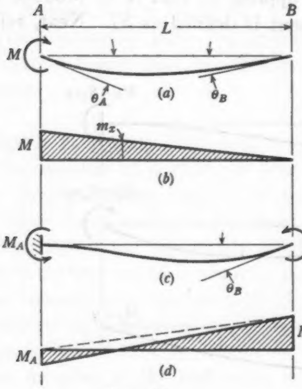

FIG. 17.

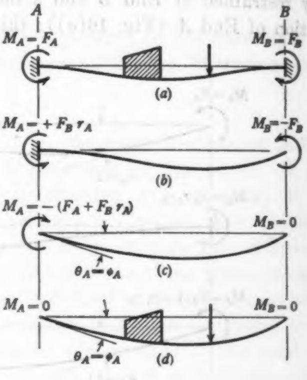

FIG. 18.

Next, consider the same member, as shown in Fig. 17(*c*), fixed at End *A* and a moment, M_B, applied to End *B*. The moment diagram is shown in Fig. 17(*d*). Again, assuming the origin of co-ordinates at End *B*, the following equations may be written directly, using the two area-moment propositions:

$$\frac{M_B}{L}\int_0^L \frac{(L-x)\,dx}{E\,I} - \frac{M_A}{L}\int_0^L \frac{x\,dx}{E\,I} = \theta_B \ldots\ldots\ldots (18a)$$

and,

$$\frac{M_B}{L}\int_0^L \frac{(L-x)\,x\,dx}{E\,I} - \frac{M_A}{L}\int_0^L \frac{x^2\,dx}{E\,I} = 0 \quad \ldots\ldots\ldots (18b)$$

Equations (18) may be solved for M_A and M_B, obtaining,

$$M_A = \theta_B \frac{L\int_0^L \frac{x\,dx}{E\,I} - \int_0^L \frac{x^2\,dx}{E\,I}}{\int_0^L \frac{dx}{E\,I}\int_0^L \frac{x^2\,dx}{E\,I} - \left[\int_0^L \frac{x\,dx}{E\,I}\right]^2} \quad \ldots\ldots (19a)$$

and,

$$M_B = \theta_B \frac{\int_0^L \frac{x^2\,dx}{E\,I}}{\int_0^L \frac{dx}{E\,I}\int_0^L \frac{x^2\,dx}{E\,I} - \left[\int_0^L \frac{x\,dx}{E\,I}\right]^2} \quad \ldots\ldots (19b)$$

The carry-over factor, r_A, to End A as defined for the method of moment distribution, may be expressed as follows:

$$r_A = \frac{M_A}{M_B} = \frac{L\int_0^L \frac{x\,dx}{EI} - \int_0^L \frac{x^2\,dx}{EI}}{\int_0^L \frac{x^2\,dx}{EI}} \quad \text{.............(20)}$$

Comparing Equations (17) and (20), it is seen that,

$$C_B = r_A \quad \text{.........................(21)}$$

Similarly, it could be shown that $C_A = r_B$.

Consider a member under any system of transverse loading fixed at both ends, as shown in Fig. 18(*a*). The fixed-end moments are F_A and F_B. Release End B, by adding to Joint B a moment equal to $-F_B$, resulting in a moment at End A equal to $+F_B r_A$ (Fig. 18(*b*)). By adding, the condition is obtained in which the beam is fully restrained at End A, and hinged at End B; for this condition the fixed-end moment at End A is seen to be $F_A + r_A F_B$. Next, release End A by applying to that end (Fig. 18(*c*)) a moment equal to $-(F_A + r_A F_B)$. It was shown (see Equation (15), that a moment equal to $S_A(1 - r_A r_B)$ applied at End A produced unit rotation at A when End B was hinged. Therefore, the angle change produced at End A when a moment of $F_A + r_A F_B$ is applied to End A must equal the ratio, $\frac{F_A + r_A F_B}{S_A(1 - r_A r_B)}$. This angle change has been defined as ϕ_A for the method of balancing angle changes; hence,

$$\phi_A = \frac{F_A + r_A F_B}{S_A(1 - r_A r_B)} = \frac{F_A + r_A F_B}{K_A} \quad \text{.............(22a)}$$

and, similarly,

$$\phi_B = \frac{F_B + r_B F_A}{S_B(1 - r_A r_B)} = \frac{F_B + r_B F_A}{K_B} \quad \text{.............(22b)}$$

Using Equations (15), (21), and (22), and any tables giving values of S, r, and F, for use with the method of moment distribution, the corresponding quantities, K, C, and ϕ, may be computed. The extra step entailed by these computations may be considered an advantage of the method of moment distribution over the method of balancing angle changes; however, for any case in which tables are not available, it will be somewhat easier to calculate K, C, and ϕ, than the corresponding S, r, and F.

The method of analysis introduced in this paper has both advantages and disadvantages when compared with other available methods. The author has enumerated some of them; others might be mentioned. Inasmuch as the choice of method must depend largely on the designer's preference, it should be to the advantage of each individual designer to list and weigh the various advantages and disadvantages of available methods for himself. In this way, he will be better enabled to judge the most advantageous method to use in any particular case.

L. J. MENSCH,[19] M. AM. SOC. C. E. (by letter).—The analysis of highly hyperstatic structures has not been taught in engineering schools or textbooks in such a practical manner that it can be used by busy engineers. They have avoided such structures, but when compelled to use them, have made safe guesses as to the stresses and, as a rule, have not produced economical designs.

Structures only one degree indeterminate are comparatively easy to solve, although requiring considerably more effort than ordinary beam construction and even such cases are avoided by many. Structures indeterminate in the second degree give twice as much trouble; and, three-degree indeterminacy necessitates much more mathematical skill and can only be designed by experts in this line.

Arched bridges are at least three times indeterminate when no hinges are used, evolve the expenditure of sizeable sums in construction, and have been analyzed regularly in the last twenty years by the classical theoretical methods. A continuous frame may be many times indeterminate, may evolve the expenditure of only moderate sums, and no busy engineer can afford the time for a complete theoretical analysis as taught in standard literature.

There is a crying demand for shorter and reasonably correct methods of design and Professor Grinter has tried to supply this deficiency by some novel procedures. The writer considers this and similar methods a retrograde step in structural engineering. The author makes the bold and gratuitous assumption that no side-sway may occur, or that it can easily be considered afterward. In the writer's opinion the analysis for side-sway is a much more difficult task than the analysis for vertical deformation only, and special short-cuts must be found before these methods are of much value to the profession.

Consider, for example, the case of a railroad trestle with expansion joints over every third or fourth column. Side-sway may occur there. What prevents side-sway in a school building with classrooms on both sides of a comparatively narrow corridor?

The first example in this paper is a flagrant case of disregard of the fundamental condition of equilibrium, namely, that the sum of the forces acting in any of three principal directions must be zero. They are not zero in a horizontal direction by 25%, as shown by the analysis. Would any engineer be satisfied with a solution in which the sum of the computed vertical reactions would differ from the acting vertical loads by 25 per cent? By taking this unwarrantable liberty with statics, the author claims that he has found a new and revolutionary short-cut in the analysis of indeterminate structures.

There are cases in which this and related methods may be used. Symmetrical structures with symmetrical loading have no side-sway. If the side-sway is in such a direction that the structure leans against a rigid body, and temperature and shrinkage may be neglected, side-sway has no chance to act. In skeleton constructions, with many bents, the side-sway may be very small. There is no side-sway in the classical problem of Clapeyron for continuous girders.

[19] Civ. Engr. and Constructor, Chicago, Ill.

In all other cases these methods are only crude guesses at solutions and require more brain work than the classical methods, provided St. Venant's principle is used, namely, that members in a continuous frame which are several spans or stories distant from the girder which is being analyzed have only a very small influence on the necessary elastic equations, as the following demonstration will show: Let AB be a girder under a load forming part of a frame, as shown in Fig. 19; let K, K'_A, K''_A, * * *, be the ratio, $\frac{I}{L}$ of the various members; let M_A, M_B be the negative moments acting in $A\,B$,

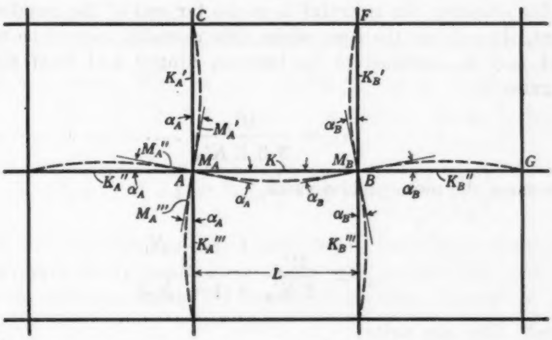

FIG. 19.

at the ends, A and B, according to the classical sign convention; and, let α_A and α_B, be the rotations of the joints, A and B, due to the load and the restraint of the adjoining and further members. When these joints are assumed to be rigid, it is clear that this rotation must be equal to the slope of the elastic line of all members meeting at any joint.

It is known, and may be found in almost any elementary textbook, that,

$$\alpha_A = \phi_A - \frac{(2\,M_A + M_B)\,L}{6\,E\,I} \qquad (23a)$$

and,

$$\alpha_B = \phi_B - \frac{(2\,M_B + M_A)\,L}{6\,E\,I} \qquad (23b)$$

For a uniform load the author gives $\phi_A = \phi_B = \frac{W\,L^2}{24\,E\,I}$; and for a concentrated load in the center, $\phi_A = \phi_B = \frac{P\,L^2}{16\,E\,I}$.

If α_A and α_B are known, the unknown moments, M_A and M_B, can be obtained from Equations (23). The problem is reduced, to as close an estimate of the values of α_A and α_B as possible, from the deformation of the members adjacent to the joints, A and B, and the load on AB.

It is known from mechanics that for a member, AC, for example,

$$\alpha_A = \frac{M'_A}{m'\,E\,K'_A} \quad \text{.....................(24)}$$

in which m' is a factor depending on the restraint at the end, C. When C is hinged, $m' = 3$; when fixed, $m' = 4$; when AC is deformed so that the elastic line has a point of contraflexure just at mid-length of the member, $m' = 6$; and when AC is deformed so that the elastic line is symmetrical about the mid-point, $m' = 2$. In a previous discussion on this subject[20] the writer has shown that the final results for the unknown bending moments, M_A and M_B, do not greatly differ whatever the restraint is at the far end of the members adjacent to the joint, A, and for the case where this restraint cannot be readily estimated and may be assumed to lie between hinged and fixed conditions, a practical guess is:

$$\alpha_A = \frac{M'_A}{3.6\,E\,K'_A} \quad \text{.......................(25a)}$$

In rare cases the more precise value,

$$\alpha_A = \frac{M'_A}{E\,K'_A}\;\frac{1 + \frac{4}{3}\,N_C}{4\,(1 + N_C)} \quad \text{.................(25b)}$$

may be used. One can write:

$$\alpha_A = \frac{M'_A}{m'\,E\,K'_A} = \frac{M''_A}{m''\,E\,K''_A}$$

$$= \frac{M'''_A}{m'''\,E\,K'''_A} = \frac{M'_A + M''_A + M'''_A}{\Sigma\, m\,E\,K_A} = \frac{M_A}{\Sigma\, m\,E\,K_A} \quad \text{.....(26a)}$$

and, similarly,

$$\alpha_B = \frac{M_B}{\Sigma\, m\,E\,K_B} \quad \text{.......................(26b)}$$

Let,

$$N_A = \frac{3\,K}{\Sigma\, m\,K_A} \quad \text{.......................(27a)}$$

and,

$$N_B = \frac{3\,K}{\Sigma\, m\,K_B} \quad \text{.......................(27b)}$$

then, by combining Equations (26) with Equations (23) one easily obtains for a uniform load:

$$M_A = \frac{w\,L^2}{4}\;\frac{1 + 2\,N_B}{4\,(1 + N_A)\,(1 + N_B) - 1} \quad \text{..........(28a)}$$

[20] *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 1682.

and,

$$M_B = \frac{w\,L^2}{4}\;\frac{1 + 2\,N_A}{4\,(1 + N_A)\,(1 + N_B) - 1}\;\ldots\ldots\ldots\ldots(28b)$$

For a concentrated load in the center, $\frac{w\,L^2}{4}$ must be replaced by $\frac{3\,P\,L}{8}$.

Once the moments, M_A and M_B, are computed they can be distributed to the adjoining members, AC, for example, as:

$$M'_A = M_A\,\frac{m'\,K'_A}{\Sigma\,m\,K_A}\;\ldots\ldots\ldots\ldots\ldots\ldots\ldots(29)$$

The moment, M'_A, produces a moment at the far end of AC, depending on the value of m', as follows: When $m' = 2, 3, 3{:}6, 4, 6$, or $4\;\frac{(1 + N_C)}{1 + \frac{4}{3}\,N_C}$,

$$M_{CA} = M'_A\left(-1, 0, \frac{1}{3}, \frac{1}{2}, 1, \frac{1}{2 + 2\,N_C}\right)\ldots\ldots\ldots\ldots(30)$$

The moment, M_{CA}, can again be distributed to the adjoining members meeting at C, if found desirable; but this is generally unnecessary. In most cases it is near enough to compute the maximum positive moment in AB as the center moment by,

$$M = \frac{w\,L^2}{8} - \frac{M_A + M_B}{2}\ldots\ldots\ldots\ldots\ldots\ldots(31)$$

If it is desired to compute the maximum negative moment in AB at B, one must assume also that the girder, BG, is loaded, and compute from Equations (28) the negative left end moment, and then by distribution according to stiffness, as shown in Equation (29), the moment, M_{BA}, which has to be added to the moment, M_B, previously found.

This is the classical method of moment distribution, except that the distant spans have so little influence, in most cases, on the elastic equations of the particular member, which is being analyzed, that they may be neglected in practice. This holds true whether Castigliano's theorem, the Maxwell equations, or the principle of virtual velocities are used. These are only different names for the identical elastic equations.

Experts in the analysis of hyperstatic structures of the continuous-frame type have rarely used the latter principles and have found that the moment-area principle, in combination with the rotation of the joints, offers a number of short-cuts, not inherent in the foregoing methods, as may be found in the excellent works of Professor E. Winkler[21], the works of W. Ritter[22], W. Gehler[23], A. Strassner[24], etc.

[24] "Neuere Methoden", Berlin, 1916.

By the method herein presented by the writer an attempt will be made to analyze the structure shown in Fig. 2. All the K-values are shown in that diagram and $m = 3$, except for DC where $m = 4$.

From Equations (27), for Beam BD: $N_B = \dfrac{3 \times 4}{3 \times 2} = 2$; and $N_D = \dfrac{3 \times 4}{3 \times 2 + 3 \times 3 + 4 \times 3} = 0.445$; and, from Equations (28): $M_B = 0.0289\ w\,L^2$; and $M_D = 0.0765\ w\,L^2$.

It is clear that the moment, M_{BA}, at B is also $0.0289\ w\ L^2$; and the horizontal reaction at $A = 0.0289\ w\ L$. The author did not give the inclination of the member, BA, as implying no importance in his opinion, and one may assume the member to be vertical. The moment, M_D, must be distributed in the proportion, $3 \times 2 : 3 \times 3 : 4 \times 3$, into the members, DE, DF, and DC, respectively, and these moments are easily found to be 0.017, 0.0255, and $0.034\ w\ L^2$, which lead to reactions of $0.017\ w\ L$, $0.0153\ w\ L$, and $0.0567\ w\ L$, at Points E, F, and C, respectively.

The horizontal reactions at Points A and E are acting to the right and their sum is $(0.0289 + 0.017)\ w\ L$, whereas the horizontal reaction at Point C is acting to the left and is only $0.0567\ w\ L$—or the opposing reactions to the latter are more than 24% greater, an impossible condition. Sideway will occur in the girders to the left so that the moment, M_B, is increased about 20% and the moment, M_D, decreased a similar amount.

The girder, DF, may be analyzed as follows: The stiffness of the member, DF, beyond the hinge, F, being zero, as there is no restraint to the right, $N_F = \infty$. From Equations (28),

$$M_D = \frac{3\,P\,L}{8}\ \frac{1 + 2\,N_F}{4\,(1 + N_D)\,(1 + N_F) - 1} \quad \ldots\ldots\ldots\ldots (32)$$

Dividing the numerator and the denominator by the infinite value of N_F:

$$M_D = \frac{3\,P\,L}{8}\ \frac{2}{4\,(1 + N_D)} = \frac{3\,P\,L}{16\,(1 + N_D)} \quad \ldots\ldots\ldots\ldots (33)$$

in which, $N_D = \dfrac{3 \times 3}{3 \times 2 + 4 \times 3 + 3.6 \times 4} = 0.278$; and $M_D = 0.148\ P\ L = 4\,930$ ft-lb. This negative moment will be diminished by the cantilever moment at F of 20 000 ft-lb, as follows:

From Equation (25b),

$$m = \frac{4\,(1 + N_C)}{1 + \frac{4}{3}\,N_C} = \frac{4\,(1 + 0.278)}{1 + \frac{4}{3} \times 0.278} = 3.73$$

From Equation (30)

$$M_{DF} = \frac{20\,000}{2 + 2 \times 0.278} = 7\,830 \text{ ft-lb.}$$

which is a positive contribution to the moment in *DF* at *D*, producing there a positive moment of 7 830 − 4 930 = 2 900 ft-lb; which must be distributed according to the stiffness ratios of 3 × 2: 4 × 3: 3.6 × 4 to the members, *DE*, *DC*, and *DB*, respectively. These additional moments will decrease somewhat the sum of the horizontal reactions found for the uniform load on *BD* alone, but will still leave a serious difference.

The writer claims that Equations (28) are so simple that they can be used by busy engineers and will give reasonably correct results in a few minutes without deep thinking and less likelihood of mistakes than the new methods, such as that proposed in this paper. He would advise the author to improve his scholarly paper by showing more practical methods of estimating the influence of side-sway, which is of greater importance at present than the computation of the primary moments. There are plenty of methods for finding primary moments in engineering literature, whereas side-sway has generally been overlooked, or, if treated at all, unbalancing of the vertical reactions has often resulted.

MARVIN A. GRAY,[28] JUN. AM. SOC. C. E. (by letter).—The purpose of the following discussion is to test the theory of this paper in all its technical phases. Throughout, Professor Grinter uses such terms as "slope" and "deflection", apparently without realizing that it is, in fact, "slope deflection", because he uses ϕ in special cases instead of the more generally known symbol, θ, that is used in connection with slope deflection. He presents some values of ϕ derived by the conjugate-beam method (a variation of moment areas) and each of these ϕ-values needs a separate derivation. This type of method is meant to displace slope deflection, which needs only one proof or derivation and the single set of unknowns (θ-values) instead of θ-values and ϕ-values.

To show how closely this paper follows the slope deflection method the writer herein develops the ϕ-values by using the slope deflection equation,

$$M_{AB} = M_{F\text{-}AB} - \frac{2\,E\,I}{L}\,(2\,\theta_A + \theta_B) \quad \text{.............. (34)}$$

in a simple beam. For a concentrated load at mid-span, $-\,\theta_B = \theta_A$; so that (with $M_{AB} = 0$) Equation (34) yields for θ_A (or for ϕ_A and $-\,\phi_B$): $0 = \dfrac{P\,L}{8} - \dfrac{2\,E\,I}{L}\,(2\,\theta_A + \theta_B)$; or,

$$\theta_A = \frac{P\,L^2}{16\,E\,I} = -\,\theta_B \quad \text{..................... (35)}$$

For a uniform load on the entire span, θ_A (or ϕ_A and $-\,\phi_B$) equals $\theta_A = \dfrac{w\,L^2}{12}\,\dfrac{L}{2\,E\,I} = -\,\theta_B$, that is:

$$\theta_A = \frac{w\,L^3}{24\,E\,I} \quad \text{........................ (36)}$$

---

[28] Chicago, Ill.

For a concentrated load not at mid-span, in a similar manner, Equation (34) yields, for θ_A (or ϕ_A);

$$\theta_A = \frac{P\,a\,b^2}{L^2}\,\frac{L}{2\,E\,I}\left(\frac{2}{3} + \frac{a}{3\,b}\right) = \frac{P\,a\,b}{2\,E\,I\,L}\left(\frac{2\,b}{3} + \frac{a}{3}\right) \ldots\ldots (37a)$$

and, for θ_B (or ϕ_B):

$$\theta_B = -\,\frac{P\,a^2\,b}{L^2}\,\frac{L}{2\,E\,I}\left(\frac{2}{3} + \frac{b}{3\,a}\right) = -\,\frac{P\,a\,b}{2\,E\,I\,L}\left(\frac{2\,a}{3} + \frac{b}{3}\right) \ldots (37b)$$

For an induced moment, M, at End A, with $\theta_A + 2\theta_B = 0$; and $\theta_A = -\,2\,\theta_B$, Equation (34) yields, for θ_A (or ϕ_A):

$$\theta_A = \frac{L}{2\,E\,I}\,\frac{2M}{3} = \frac{M\,L}{3\,E\,I} \ldots\ldots\ldots\ldots\ldots\ldots (38a)$$

and, for θ_B (or ϕ_B):

$$\theta_B = -\,\frac{\theta_A}{2} = -\,\frac{M}{6\,E\,I} \ldots\ldots\ldots\ldots\ldots\ldots (38b)$$

and if the result appears with the wrong sign, the author's sign reversal explains that the author has taken reaction instead of action. The writer has now proved definitely that the ϕ-value is a special value or solution obtained directly by slope deflection from the value of θ.

Having stated his thesis, the author next proceeds through part of the paper to give a proof for the moment distribution method, and succeeds in demonstrating that it is really based on, or derived from, slope deflection; as, for example: "Accordingly, it follows that the carry-over factor [θ_A or θ_B] for angle change is of negative sign, namely, -0.5". * * * "All of the carry-over angles to the far ends of the other members meeting at the joint are simply -0.5θ", etc. The balancing process of the slope deflection method (which is a part of all similar "methods") is based on the following equations:

$$M_{AB} = M_{F\text{-}AB} - \left(\frac{2\,E\,I}{L}\right)(2\,\theta_A + \theta_B) \ldots\ldots\ldots\ldots (39a)$$

and,

$$M_{BA} = M_{F\text{-}BA} - K\,(2\,\theta_B + \theta_A) \ldots\ldots\ldots\ldots (39b)$$

The balancing part of Equation (39a) is $-\left(\frac{2\,E\,I}{L}\right)(2\,\theta_A + \theta_B)$; and that of Equation (39b) is $-\,K(2\theta_B + \theta_A)$. If, momentarily, the direct effects of M_{AB} and $M_{F\text{-}AB}$, are disregarded, the following result is obtained due to M_{BA}: $0 = 0 - K\,(2\,\theta_A + \theta_B)$. Then, $\theta_A = -\,0.5\,\theta_B$, or,

$$K\theta_A = -\,K\,0.5\,\theta_B \ldots\ldots\ldots\ldots\ldots\ldots (40)$$

In the moment distribution, $K\ (2\ \theta_A)$ is solved for directly and $K(2\ \theta_B)$ in Equation (39b) is $-\ 0.5\ (K\ 2\ \theta_A)$, as in Equation (40). In other words by slope deflection, the writer has proved in a truly direct method, that an angle at one end, A, of a beam induces an angle (or its equivalent moment) at the other end, B, opposite in sign and one-half its value; or θ_A induces a value, $-\ 0.5\ \theta_A$ (or $-\ 0.5\ K\ \theta_A$), at Point (B), the far end of the beam; and, conversely, Angle θ_B, from an external moment, produces a rotation (or a moment), $-0.5\theta_B$ (or $-0.5\ K\ \theta_B$), at End A, the rear end of the beam, which is what the author terms the rotation "balancing angle". Expressed in terms of moment distribution multiplying by K ($K\ \theta$ is a moment), a moment induced at one end creates a moment (or angle) at the other end equal to $-\ 0.5$ of the original induced moment (or angle), the correction or carry-over factor that is used in the moment distribution method. Thus are the foregoing quotations from the paper explained; and the contention that moment distribution (of which the method of balancing angle changes is a branch) is a variation of slope deflection by changing symbols, is proved conclusively.

The subject of continuity at joints is by far the most important phase of rigid frames as far as practice is concerned, because without this knowledge, all the theory pertaining to it does little good. However, if in a homogeneous beam it works on the basis of plastic flow as the author infers, the entire beam would deform until it acts like a cable. It is more probable that one of two conditions may exist: (1) The member may be free to move due to loose rivets, or there may be "play" in the connection; or (2), rivets or the connection may yield because they are overstressed until the ends finally hold or balance the load. The first case seems illogical, and failure of the material is very probable in the second case; but in either case a definite θ-value can be given for the movement, with a solution by slope deflection.

The publication of this paper affords an opportunity to clarify the relation between rigid frame methods (solutions) and their basis, the slope deflection method. The author is correct in emphasizing the superior virtue of angle movement, or the balancing of angle changes; such advantage has been shown many times in papers on slope deflection.[26] The adaptation of the standard Slope Deflection Equation[27] constitutes the most accurate, as well as the fastest, method having a theoretical proof based on angle movement. Slope deflection and its method of solution by converging approximations will be of great value in the new fields of structural analysis, such as airplanes, airships, light-weight trains, and high-strength large bridges.

A. FLORIS,[28] ESQ. (by letter).—The analysis presented in this paper is a complicated variation of the well known and widely used simple method of moment distribution.

[26] See, for example, *Engineering News-Record*, Vol. 107, No. 20, p. 770, November 12, 1934.

[27] "Engineering Studies," *Bulletin No. 1*, Univ. of Minnesota, March, 1915.

[28] Dipl.-Ing., Los Angeles, Calif.

As a base system the author takes a beam that is freely supported or free to rotate at the ends. This is one of the limiting cases. The other limiting case, the fully restrained beam, used in the moment distribution method[1] could not be utilized as a base system in the author's analysis, because the tangent to the elastic curve at the supports being horizontal, there are no angles to distribute.

However, the advantage of the choice of the angle changes instead of the fixed end moments is debatable. In general, engineers are not concerned with angle changes of bars framing into a joint. It is true that in the slope-deflection method these changes are introduced in the analysis, but this is done for the purpose of reducing the degree of statical indeterminacy of the structure. The procedure of balancing the statically indeterminate quantities is the same in the author's method as in the moment-distribution method. Hence, there is no need to use the less convenient angles, if the required moments can be found more directly by moment distribution.

In the author's analysis, the angle changes at a joint must be distributed to all members framing into it, in such a way, that, by changing the slopes, the continuity of the structure is restored. By doing this, however, moments are induced at the ends of these bars. In the moment distribution method the moments produce the angle changes. In the author's analysis the angle changes produce the moments. Consequently, the angle changes at the ends of bars are inversely, and not directly, proportional to the K-values, as the author states. A simple analysis will prove it. In spite of this discrepancy, the results obtained are correct because of the fact that the distribution is made by taking percentages of the stiffness of the bars framing into a joint.

With the use of the base system in the moment distribution as well as in the angle distribution methods, the continuity of the structure is destroyed. To restore the continuity by unlocking or restraining the joints, the moments or angle changes must be distributed to the members framing into a joint in proportion to their capacity to resist such moments or angle changes. This is the balancing process which, in turn, influences the opposite end of the bars under consideration. This influence upon the opposite end of the bars is the carry-over process. The moment distribution method is based upon these two simple steps.

The author's explanations regarding the application of his method to side-sway produced by lateral or unsymmetrical loading are extremely vague. In this case, the freely rotating bar at both ends cannot be used as a base system throughout the structure. The insertion of hinges in all joints necessitated by the choice of this beam produces a system that does not possess lateral stability. Perhaps the frames with columns fixed at the base, connected to beams that are hinged at the ends, can be chosen as a base system. The interesting properties of these frames, which are stable against lateral forces, have been discussed by the writer elsewhere.[29]

[29] "Types of Rigid Frames for Existing Buildings to Resist Shocks", by A. Floris. *Southwest Builder and Contractor*, July 13, 1934, p. 22.

FRED J. BENSON,[30] JUN. AM. SOC. C. E. (by letter).—The method of analyzing continuous frames by balancing angle changes, presented by Professor Grinter, is a valuable alternative to the method of balancing fixed-end moments. Professor Grinter discusses briefly the use of the device of successive distortions in applying his method to structures having more than one story or one panel. This important application seems to deserve more attention. The following analysis will serve to illustrate and clarify the points emphasized in the paper.

The two-story bent shown in Fig. 20 has two degrees of freedom of horizontal movement. Hence, two successive distortions must be produced in order to determine the moments produced by the lateral loads. In order to produce the first distortion it is assumed that Joints E, F, and G are fixed in position and that the remaining joints are pin-connected. An unresisted horizontal movement of Joints B and D is produced in the direction of the load, P_2. This

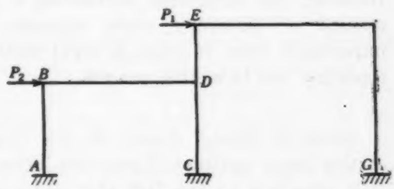

FIG. 20.—TWO-STORY BENT WITH LATERAL LOADS

movement produces equal angle changes at the top and bottom of each column affected. Such angle changes are then balanced by Professor Grinter's method. The shear in each column is computed from the balanced angle changes and the produced horizontal movements by Equation (5). The total shear in each story is determined by the summation of the column shears. These shears may be designated as V_{1a} and V_{2a}. In order to produce the second distortion it is assumed that Joints A, B, and C are fixed in position and that the remaining joints are pin-connected. An unresisted horizontal movement of Joints E and F is produced in the direction of the load, P_1. Again, the angle changes produced by this movement are balanced and the story shears, V_{1b} and V_{2b}, are obtained.

The two distortions must be combined in such a manner that the true story shears are obtained. Therefore, it is necessary to determine the factor by which the balanced angle changes and produced horizontal movements for each distortion must be multiplied to obtain the true story shears. If x represents the factor for the first distortion, and y, the factor for the second distortion, the following equations may be written:

$$x V_{1a} + y V_{1b} = P_1 + P_2 \quad \text{(41a)}$$

and,

$$x V_{2a} + y V_{2b} = P_1 \quad \text{(41b)}$$

Equations (41) are solved simultaneously for x and y. The true rotation of any joint is found by multiplying the balanced angle change for each

[30] Hot Springs, N. Mex.

distortion by the corresponding factor and then adding these two corrected angle changes. The true horizontal movement of any joint is found in the same manner by applying the factors to the produced horizontal movements. The movement in any member at any joint is then found by using the slope-deflection equations. Since the summation of moments at any joint must equal zero, it is quite evident that the method is self-checking.

The rapid use of either the methods of balancing fixed-end moments or angle changes requires considerable practice. In general, the final moments can be obtained more rapidly by balancing fixed-end moments. However, for structures containing a number of joints, the fact that the method of balancing angle changes is self-checking is of considerable importance since it offers a rapid method of checking the solution without repeating the balancing process.

DAVID B. HALL,[31] ASSOC. M. AM. SOC. C. E. (by letter).—In the section of this paper entitled "Haunched Beams and Curved Members," the author calls attention to the fact that end-angle changes, and other factors, must be specially calculated for such members. The following observations may assist in the calculation of the angle changes due to loads.

A haunched beam with a unit moment at the left end is shown in Fig. 4 (Point A), and below it is shown the deflection curve. This diagram is the influence line for the angle change at Point A due to loads anywhere on the span, because, by the theorem of reciprocal deflections, the deflection at any point due to a unit moment at the end is identical to the rotation at the end due to a unit load at that point.

If the method of elastic weights is used to compute this curve, it will be found expedient to use a double summation process, adding up elastic weights to obtain shears between successive points, and adding up these shears, times length of divisions, to obtain moments. If this plan is regarded as a subterfuge, the identical operations may be performed, treating the elastic weights as angular changes (which they are); adding them to obtain slopes, beginning with ϕ_A as the slope at the end; and summing up the products of slopes and division lengths, to obtain the deflections.

P. CRAIG LIVESAY,[32] ESQ., AND WILLIAM M. SIMPSON,[32] ESQ. (by letter).—In opening his paper Professor Grinter has stated that the method of balancing angle changes has been presented as an additional tool to be used by the engineer wherever it may be found superior to other methods or an aid in checking a special problem. The relative merits of balancing angle changes as compared with other methods will depend upon the problem considered and the preference of the engineer who is making use of the method, which, again, will depend upon his familiarity with the various methods.

[31] Asst. Engr., State Dept. of Public Works, Albany, N. Y.

[32] Teaching Assts., Dept. of Civ. Eng., Agri. and Mech. Coll. of Texas, College Station, Tex.

The writers have used the method of balancing angle changes to solve a variety of problems most of which have been checked by the method of balancing moments, or by the column analogy, in order to prove the self-checking features of the method. No difficulty has been experienced in obtaining results to any desired degree of accuracy, and no problem has been encountered to which this method could not be adopted. The types of problems solved include the following: Secondary stresses: bent analysis, involving side-sway; joint slip; wind-stress analysis in building frames; influence lines for continuous beams; and settlement of supports.

Because of the briefness of the treatment of side-sway by Professor Grinter, it was thought that an illustration of two special cases of joint translation would be useful.

The first example chosen to illustrate the method of handling side-sway is a slant-leg bent with an applied horizontal load. The analysis by balancing angle changes is shown in Fig. 21. An unresisted side-sway similar to the one shown by the dotted lines has been assumed. (*E* has been omitted throughout, since it will cancel as may be shown by setting up the equations for the angle changes and the shears.) The angle changes

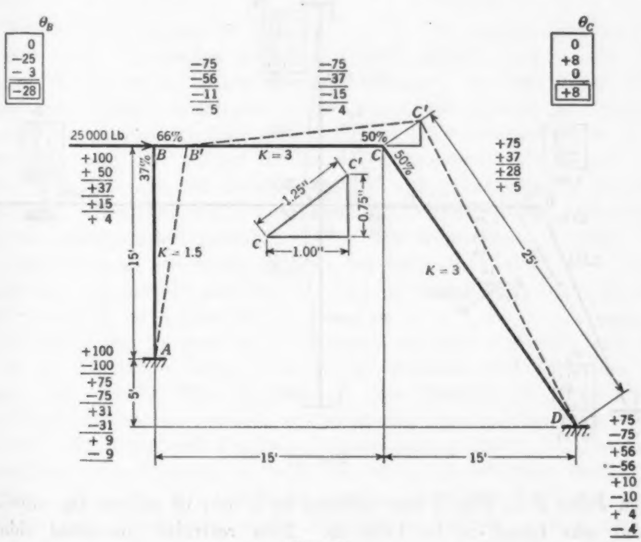

FIG. 21

were assumed as convenient values taken in proportion to the angles for a side-sway of 1 in. The small triangle above Joint *C* shows movements for a 1-in. deflection. These angles were then balanced by following the procedure outlined by Professor Grinter (under the heading, "Procedure of Balancing Angle Changes"). All joint rotations due to this balance are enclosed in rectangles near the joints. After the balancing of angles was

completed, the horizontal shear in the vertical leg and the horizontal components of the shear and the direct stress in the slant leg were computed. The sum of these horizontal forces was found to 379 lb. The correction ratio was $\frac{25\,000}{379}$, or 65.9. The true joint rotations in the structure due to the horizontal loading were then found by multiplying the enclosed joint rotations by this ratio. The true ρ-values were found, similarly. This bent analysis illustrates the method of using a correction factor, as explained by Professor Grinter (see heading, "Bent Analysis").

The second example (Fig. 22) is an analysis of the frame presented by the author in Fig. 2, with the exception that the fixed support, F, has been replaced by a nest of rollers. Points A and C were assumed to lie in the same horizontal plane. This example illustrates the method of side-sway correction for an unsymmetrical structure carrying loads which are not in the direction of free movement. The author's example permitted no side-sway because of the fixed support at F and thus no correction for side-sway was necessary.

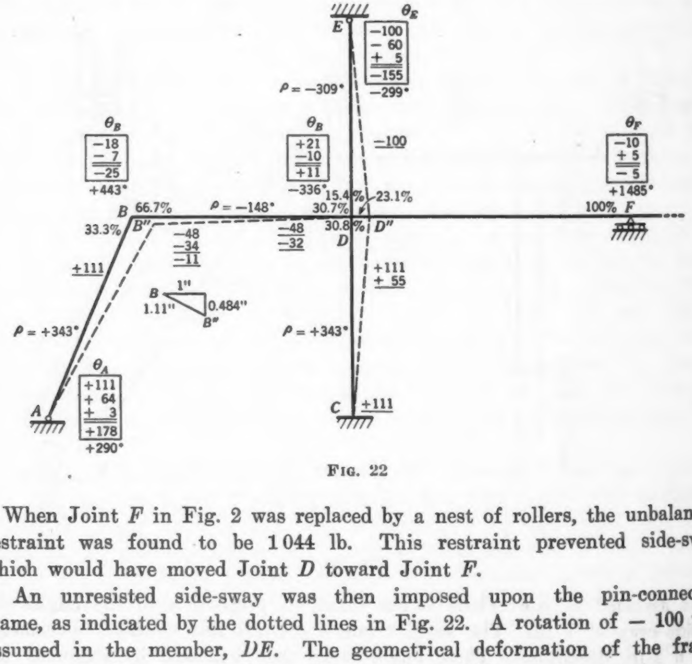

FIG. 22

When Joint F in Fig. 2 was replaced by a nest of rollers, the unbalanced restraint was found to be 1 044 lb. This restraint prevented side-sway which would have moved Joint D toward Joint F.

An unresisted side-sway was then imposed upon the pin-connected frame, as indicated by the dotted lines in Fig. 22. A rotation of − 100 was assumed in the member, DE. The geometrical deformation of the frame determined the rotations of the other members. The member rotations used in balancing angles were $\rho_{AB} = 111$, $\rho_{BD} = -48$, $\rho_{CD} = 111$, and $\rho_{DE} = -100$. All joint rotations due to this balance are enclosed in rectangles near the

joints. The unbalanced horizontal force in the structure was found to be 338 lb. The modulus of elasticity has been neglected.

The joint rotations and the ρ-values of the assumed side-sway were multiplied by the ratio, $\frac{1044}{338}$. These corrected values were then added to the joint rotations indicated in Fig. 2 (multiplying the author's values by 10 before adding). Each final joint rotation and ρ-value is marked with an asterisk in Fig. 22. This completed the analysis for side-sway. In applying the slope-deflection equations to these values, the modulus of elasticity should be omitted.

When applying this method to particular problems many advantages and disadvantages, as compared to other methods, may be found. Regardless of the type of problem to which this method is applied there is one improvement over other methods. This advantage is its self-checking feature. There is a chance for compensating errors, of course, but that chance is very slight. In addition, the method has been very useful to the writers in giving them a clearer picture of the physical deformation of a structure under any given set of conditions.

L. E. GRINTER,[28] ASSOC. M. AM. SOC. C. E. (by letter).—The unusually clear and useful discussions have undoubtedly added much to the clarification of the paper on balancing angle changes. As anticipated by the opening and closing paragraphs of the paper, the method has interested those who were either familiar with the slope-deflection method of analysis or who had used the method of balancing moments. It is not to be expected that others would find the method either immediately convenient or attractive, since they would not only be faced with a new and uniquely disturbing procedure but probably with a new terminology as well. However, many persons are being exposed regularly to contact with modern methods that are now in use by some one in nearly every office so that a gradual evolution is in progress.

It is interesting to observe the different opinions expressed with reference to the similarity between balancing moments and balancing angle changes Mr. Floris, Mr. Byrne, and Mr. Mensch are seemingly of the opinion that the two methods are practically one and the same. On the other hand, Mr. Gray and Professor Maney seem positive that the method of balancing angle changes is really the old slope-deflection method in a new dress. However, Mr. Goldberg answers adequately Professor Maney's contention that "'balancing angle changes' is merely a new group of words to describe what has been done for years in the solution of the slope-deflection equations," when he points out that "throughout the entire slope-deflection analysis the concept of continuity is firmly maintained," while in balancing angle changes "continuity is first destroyed and then * * * re-established." The resemblance that Professor Maney noticed was for a special case of secondary stress analysis to which discussion the writer devoted only two sentences of the paper.

[28] Dept. of Civ. Eng., Armour Inst. of Technology, Chicago, Ill.

Several discussers, notably Mr. Floris, Mr. Goldberg, and Mr. Mensch had some difficulty in analyzing for side lurch by balancing angle changes. Mr. Floris will find that Mr. Andersen has solved this problem most excellently without the use of an "unresisted side lurch" whereas Messrs. Livesay and Simpson and also Mr. Benson apply, effectively and brilliantly, the conception of an "unresisted side lurch." The interesting problem of a two-level bent, analyzed accurately by Mr. Benson, will clarify the misconceptions of Mr. Goldberg that the method would necessarily become an approximation for a two-story frame. Evidently, the work involved in each of the examples presented by the discussers is much less than by any of the classical methods. The final moments can always be obtained to any degree of accuracy desired.

Mr. Andersen questions the writer's procedure of "carrying-over" from one joint before "balancing" at adjacent joints, as in Fig. 2. Experience with the several methods of successive corrections has shown that the procedure used in Fig. 2 produces the fastest possible convergence. The number of terms involved in Fig. 14 could probably be reduced considerably without the sacrifice of accuracy by adopting the balancing procedure from Fig. 2.

Mr. Gray stated in his opening sentence that the purpose of his discussion would be "to test the theory of this paper in all its technical phases." Since his discussion does not mention the use of balancing angle changes for any of the many purposes considered in the paper, it appears that this purpose was not carried to a conclusion. His discussion is composed mainly of a carefully presented demonstration that the ϕ-values and the carry-over factors can be derived from the slope-deflection equations. Naturally, this is true, but it is also true that these primary factors can be found directly by area moments, by virtual work, or by any of the known methods of deflection and slope computation. Mr. Hall's excellent discussion points out other procedures. It is worth noting that the slope-deflection equations are themselves derived by area-moments in most textbooks.

Mr. Luce has tested the method of balancing angle changes on a sufficiently wide variety of structures to speak with assurance as to its general application. The difficulty that he has found with reference to its use in wind-stress analysis has probably occurred to others; namely, that criterion ratios are based upon shears rather than angles and, therefore, a correction ϕ-value or ρ-value in a story is not easily determined. This difficulty can be overcome, however, by a study of the influence of an unresisted side lurch in a typical story upon adjacent stories when joint continuity is restored. This study will involve a correlation of ϕ-values and θ-values with story shears. An investigation of these relationships has been performed successfully under the writer's direction.

The thoughtful discussion of Mr. Byrne was pointed mainly toward the need for obtaining ϕ-values, stiffness factors, and carry-over factors for starting the process of balancing. The integral signs in his discussion give it a rather formidable appearance, particularly when it is compared with the paper in which the ideal of mathematical simplicity was para-

mount. However, Mr. Byrne does show conclusively how factors for moment and angle distribution are related. In answer to Mr. Byrne's questioning statement that he knows of no tables giving directly the quantities used for balancing angle changes, the writer submits Table 3 which was prepared during a study that he made in 1925. The source of these data is now unknown, although it is recalled that they represented only a slight revision of standard tables. They supply values of Factors A and B for substitution in the formulas for symmetrically haunched beams:

$$\theta = \frac{L\,A}{1\,000\,E\,I} \qquad \text{(42a)}$$

and,

$$\beta = \frac{L\,B}{1\,000\,E\,I} \qquad \text{(42b)}$$

in which θ and β, respectively, are the rotations at the ends of a beam which is simply supported, symmetrically haunched, and loaded with a unit moment at one end.

Mr. Hall may also be interested in Table 3, since the constants obtained from this table are for haunched beams to which his excellent discussion refers. Mr. Hall has contributed the very brilliant and useful suggestion that the deflected curve for the effect of a unit end moment is an influence line for end angle change. The writer would add that the angle change caused by the unit moment is an inverse measure of stiffness from which distribution factors are obtained and that the ratio of the angle change at the far end to the angle change at the near end is the carry-over factor for angle distribution. Hence, one loading (applied unit end moment) and a single analysis will give rise to all data for balancing angle changes. It is suggested that the haunched beam is best analyzed for end slope and elastic deflections by area moments preferably modified by the conjugate-beam conception. Table 3 gives the end angle changes for a wide range of haunched beams.

Mr. Mensch states that the effect of side lurch was overlooked in Fig. 4 of the paper. The fact that side lurch was not discussed was not an oversight but was premeditated and to this end Support F was shown by the standard convention of a non-movable support. If lateral movement had been permitted, the support, F, would have been shown by the standard convention for a rocker or roller nest. These conventions do not ordinarily receive explanation in a technical paper. Hence, it seems that Mr. Mensch erred in making his statement that this example is a "flagrant case of disregard of the fundamental conditions of equilibrium" about as seriously as he over-stated the writer's actual claims when he wrote "the author claims that he has found a new and revolutionary short-cut in the analysis of indeterminate structures." These very modest "claims" are stated in the concluding paragraph of the paper as; (1) The method is self-checking; and (2) it offers the clearest possible picture of the physical action of the structure.

The discussion of Messrs. Livesay and Simpson shows how the introduction of a roller nest at Support F would change the calculations.

* n = the ratio of the length of the fillet, a, to the span length, L. † m = the ratio of the moment of inertia, I, at the center of the span, to the moment of inertia, I_o, at the support.

Mr. Benson, Mr. Andersen, Professor Maney, and others have generously emphasized the self-checking features of the method. That the method is definitely self-checking is its greatest single advantage over methods that deal with moments or stresses alone. Others have mentioned the fact that the method gives a clear physical picture of the action of the structure corresponding with the various mathematical steps in the analytical process. Some would conclude, apparently, that this same advantage exists in all slope and deflection analyses, but this is most decidedly not true. No one would attempt to visualize any connection between the elastic action of the

structure and the steps performed in solving a group of simultaneous equations either directly or by successive routine corrections. In decided contrast, it will be noted that every step in the process of balancing angle changes has a physical significance that is easily visualized.

Professor Maney and Mr. Gray seem to have misunderstood the use of the word, "plastic." The writer's use of the word was consistently that denoting "inelastic." The profession will make no mistake that elasticity means straight-line variation of stress with strain whereas plastic or inelastic deformation denotes permanent or non-recoverable deformation. Such a fantastic idea as "time yield" or "continued flow" in a structural steel joint which would practically eliminate end restraint is a proved fallacy that formed no part in the choice of the word, "plastic." This fallacy formed the design basis for the steel building frames of two decades ago.

In closing this discussion, the writer wishes to express his appreciation of the time and effort which the discussers gave to the clarification of the subject matter of the paper. This also seems an appropriate time to express the conviction that the expanding group of modern methods of analysis based upon successive corrections which emphasize physical action under load will soon complete the displacement of the long entrenched classical methods dependent upon the solution of groups of simultaneous equations.

Paper No. 1977

THE MODERN EXPRESS HIGHWAY

By Charles M. Noble,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Fred Lavis, Joseph Barnett, G. E. Hawthorn, John F. Fairchild, Leslie R. Schureman, C. H. Purcell, Elmer R. Haile, Jr., H. W. Giffin, T. T. Wiley, F. L. McRee, Theron M. Ripley, W. W. Crosby, Richard S. Kirby, Harold M. Lewis, George Conrad Diehl, William E. Rudolph, A. C. Dennis, J. C. Carpenter, Henry B. Alvord, Robert Eugene Hiles, Chandler Davis, R. A. Moyer, and Charles M. Noble.

Synopsis

The purpose of the paper is to present for criticism and discussion a process of reasoning and analysis in highway design rather than to set forth definite rules and data; to suggest necessary test and research projects; to emphasize that design should provide positive safety at the speeds of which vehicles are now capable, or may be capable, in the near future; and to suggest an immediate raising of design standards for trunk highways.

The paper presents only an outline of a broad subject and is intended principally to direct attention in a positive manner to safety in highway design.

Introduction

The enormous loss of life and property on American streets and highways is a compelling reason for pausing to take cognizance of location and design practice and of the manner in which it should be improved to meet the increased speed of the present and future motor car. No other engineering structure has such a death record as the highway. Table 1 is a compilation of the accident record in the United States for 1935. Certainly many more accidents are chargeable to the highway itself than statistics indicate. The failure to attribute accidents to faulty road design is due to several causes principal of which is the subtlety of the problem. Police

Note.—Published in September, 1936, *Proceedings*.

[1] Asst. Engr., Port of New York Authority, New York, N. Y.

officials are not always trained to analyze the basic causes of accidents properly, and there is a definite temptation to blame the driver because such a course is more concrete and along lines of least resistance.

TABLE 1.—TYPES OF ACCIDENTS RESULTING IN PERSONS KILLED AND INJURED IN 1935

Collision with	Accidents		Persons Killed		Persons Injured

The motor-car designer has set a pace which the highway designer has not anticipated properly. New automobile models appear each year, but new highways to replace outmoded highways cannot be produced so quickly. This imposes on the designer the task of producing a highway suitable for the car of ten or fifteen years in the future. So far, in general, this has not been done. The result is a staggering economic loss in life, property, and capital expenditure. To-day (1936) there is a large road mileage, less than ten years old, which is hopelessly obsolete so far as the safe and efficient operation of the present motor car is concerned. As an example, in 1935 several manufacturers of motor vehicles (some cars in the medium-price class) advertised that their cars would maintain a sustained speed of 100 miles per hr. The roads to accommodate these cars are not now in existence.

The rise in the accident and death rate is recognized to be due to increased speeds. The vehicle itself is far safer than formerly, but the higher speeds result in more serious accidents, involving more cars with a consequent greater loss of life. At high speed there is less time to correct an error of judgment, and it must be recognized that this time element is the new factor of importance which has entered the problem. Therefore, basic safety must be designed into the highway, taking this factor into account in such manner that the motorist is allowed sufficient time to cope with driving hazards. The reckless and unsafe driver must be considered. He affects the life and property of the innocent safe driver and cannot be disregarded with a shrug as formerly. In the past emphasis in design has been based on highway economics founded on vehicle operating costs and time losses. Broad highway economics founded on loss of life and property, as well as operating costs, has not received much attention. The injuries and the loss of life and property on American highways are issues squarely facing the highway engineer. It is his duty to design the highway so that the traveling public is safeguarded.

Fundamental Concepts

A consciousness of driver psychology is gradually emerging although a knowledge of its "laws" is only vague and half-formed. More knowledge is necessary, but, in the meantime, there should be a consciousness of its existence, and such facts as are now known should be applied to design. For instance, in many cases, it is possible to design a highway so that the motorist is led unconsciously to choose the safe act rather than that which is unsafe.

The trend of the times indicates the desirability of designing the highway on the basis of a constant rate of vehicle speed between large terminal points. It is evident that the decision as to the design speed should be arrived at only after very thorough study of the country to be traversed and that it should be made personally by the principal officer in authority. In the interest of safety it is also evident that the motorist must be notified on any change in the design speed. From present indications it would appear not unreasonable to design for a speed of 100 miles per hr in country not too mountainous. This will result in trunk highways having better alignment and curvature than the high-speed passenger railways. Generally, the present railway maximum speed is approximately 80 miles per hr. The drivers of trains are trained, picked men, familiar with their runs, riding on fixed rails, with definite orders and under close supervision. The reverse is true on the highways.

At every step in design the question should be asked: Is this safe under all driving conditions—darkness, snow, ice, rain, fog, ice and snow on the pavement, snow plowed on to the shoulders? Every conceivable accident hazard must be analyzed. Always there should be the consciousness of the number of feet per second a vehicle travels at any given speed, the length of headlight beams, the chances of visibility, all combined with the distance required to bring a vehicle to a stop.

The Dual Highway

The dual highway appears to be the only type of design developed so far to accommodate successfully the present high speeds with safety. A suggested minimum design is shown in Fig. 1. To provide increased speed with safety, wider lanes will be necessary. It is suggested that two 12-ft lanes in each direction may be sufficient if truck traffic is relatively light.

In the case of heavy truck traffic two lanes in each direction may be constructed in the unused center portion of the dual highway, but without any physical connection with the high-speed lanes. Access to the truck lanes may be provided at intervals by the use of "fly-under" crossings beneath (or over) the high-speed lanes. It does not appear likely that trucks will travel much in excess of 70 miles per hr and, therefore, the standards of design for these center lanes, except for ruling grades, need not be as high as for the outer lanes. A most effective method of eliminating time losses is to bypass all towns and cities between terminals, in addition to separating all high-

way and railway grade crossings. A safety factor is to prevent frontage of any type on the highway and to exclude farm and local road entry. It appears reasonable to restrict access to approximately 10-mile intervals.

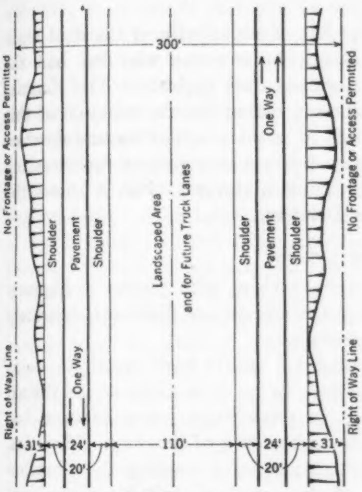

FIG. 1.—SUGGESTED MINIMUM DUAL HIGHWAY DESIGN

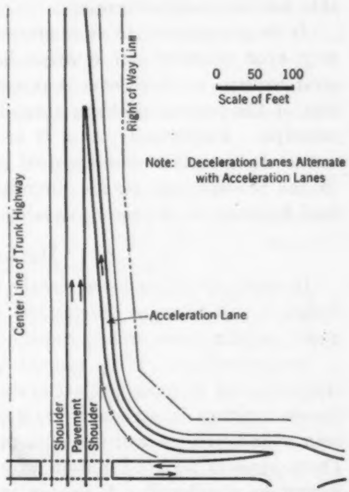

FIG. 2.—ONE QUADRANT OF SUGGESTED ACCESS ROAD DESIGN; OTHER THREE QUADRANTS ARE SIMILAR

Fig. 2 illustrates a simple type of design for rural access which has much to recommend it from a safety standpoint. The acceleration and deceleration lanes are the feature of the design. They provide full visibility on the trunk highway over a period of time sufficient to enable the motorist to adjust himself to the entrance and exit of other vehicles.

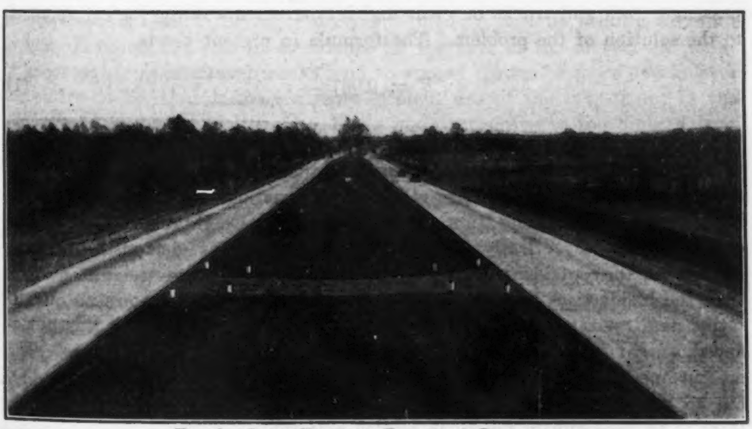

FIG. 3.—DUAL HIGHWAY DESIGN IN DELAWARE.

In the interest of economy the dual highway may be constructed in stages, but upon a full-width right of way. Two lanes may be constructed on one side and used as a two-way road until such time as funds become available for the complete project.

It is unnecessary to enumerate the points of superiority of the dual highway over conventional multiple-lane design to any one who has had the good fortune to drive over a properly designed dual highway. The elimination of the passing problem alone is sufficient reason for the adoption of this principle. Esthetically, also, it is capable of great possibilities and development. It is certain that the dual highway deserves very serious consideration in the present and future planning of trunk highways. Fig. 3 shows the dual highway as at present developed in Delaware.

Details of Design

In order to define more clearly the writer's views with respect to highway design it will be more illustrative if details of design are discussed separately under certain more or less specific sub-divisions.

Superelevation.—With present and probable future high speeds it seems untenable not to bank (superelevate) curves. In many sections of the United States banking is standard practice, but in some States superelevation has been abandoned on multiple-lane projects on the plea of drainage difficulties. There appears no good reason why effective means of meeting the situation cannot be developed. A proper study of drainage and suitable design can eliminate nearly all the accumulated water which would normally flow transversely across the pavement. Certainly the motorist has a right to expect the protection of superelevation around curves. Negotiating at high speed a curve with "reverse" banking when the surface is covered with ice or snow is far from a pleasant or safe experience.

As far as the writer is aware the proper rate of banking for any given speed-radius combination is unknown. Comprehensive tests using modern passenger cars and trucks on clear and icy pavements is the logical approach to the solution of the problem. The formula in present use is,

$$E = 0.067 \frac{V^2}{r} \qquad (1)$$

in which E equals superelevation, in feet per foot of width; V equals velocity, in miles per hour; and r equals radius, in feet. Equation (1) yields rates somewhat higher than are required for practical driving conditions. It is based on the superelevation maintaining equal weight on the inside and outside tires. Practically, this is not necessary, as demonstrated from experience the outside tires may have considerably more weight on them than the inside tires without danger. The point is that there are no quantitative data upon which conclusions can be based as to how much this unbalanced weight may be for safe, comfortable operation around curves. The present method of determining the superelevation is to use Equation (1), but to assume some arbitrary speed lower than the actual speed expected. Here is an opportunity for much needed research.

Curves.—From an analytical standpoint the minimum radius will depend on the maximum permissible rate of banking and the speed assumed. For example, suppose it is desired to design for a speed of 100 miles per hr, assuming 1 in. per ft of width as the maximum rate of super-elevation and, further, that Equation (1) will bank the curve safely if V is taken as 60 miles per hr. Substituting in the formula, a minimum radius of 2 900 ft is indicated. This method of determining the minimum radius is superior to the present practice of arbitrarily setting up a standard minimum radius based upon judgment only.

It is doubtful whether spiral curves will be necessary. The vehicle is free to spiral the slight amount necessary within the wide lane in order to accommodate itself to the large radii required by present speeds. Opinion is not of much value in solving this problem, however. Practical road tests are necessary before design practice can be established definitely.

Careful thought and designing are necessary in providing the transition between the normal crown and the banked section. It does not seem reasonable to adopt a standard length and treatment regardless of the radius and rate of banking. Certainly the treatment should be such that there is no tendency for the vehicle to be "thrown in" toward the center of the curve, or to swerve out. The ideal is for the design to be such that the vehicle may enter and leave the curve smoothly—almost automatically.

The distance between reversed curves depends on the time required for the driver of a vehicle to "come out" of one curve and prepare to enter the next one. As an illustration, if a 7-sec period and a speed of 100 miles per hr are assumed, the minimum distance between reversed curves will be approximately 1 000 ft. The writer is unaware of any observations upon which to base any conclusion as to the proper reaction time between reversed curves. This time interval may have some relation to the radii of the curves.

Grades.—The realization is growing that long smooth grades and vertical curves are essential for confident and safe operation at high speeds. Rolling grades create a hazard for night driving. Shadows cast by headlights result in lack of vision and loss of confidence on the part of the driver. A policy of encouraging night travel would tend to spread the traffic more evenly over the entire 24 hr, thus making a more efficient use of the investment in the highway. Long, sustained profiles, being more attractive to the night driver, may prove more economical than rolling grades when considered in the light of broad economics.

At a speed of 100 miles per hr a car travels 146 ft per sec. It would appear reasonable to provide uniform grade conditions for a period of at least 10 sec. If this speed is assumed in the design, a minimum length of profile tangent of 1 500 ft is indicated. The lengths of vertical curves should be such that, within the limit of vision of the headlights, shadows will not be cast and the normal length of the head-light beam will not be reduced. This will result in much longer vertical curves than those now in use. In general, definite data from which the proper length of vertical curves may be set are not available. Tests or optical computations will be necessary before definite values can be presented.

Present thought appears to favor good alignment in preference to low maximum grades, but it would seem desirable to limit maximum grades to about 5% in order to provide reasonable safety in descent on icy pavements. If commercial traffic is present in sufficiently large volume ruling grades may need to be limited in proportion to the economic importance of this class of traffic. It may be enlightening to study the operating efficiency and speed of various classes of trucks, loaded in accordance with current commercial practice, upon different rates and lengths of grades and allowing for motors not operating at "brand new" efficiency. It is well known that practically all trucks overload beyond the rated capacity of the vehicle. At present, manufacturers present data covering speeds and operating efficiency for different rates and lengths of grades, based on rated capacity and new motors. A test program simulating actual commercial conditions, in co-operation with motor manufacturers, may change present conceptions somewhat as far as economic grade design is concerned, as applied to trucks.

Sight Distance.—The proper approach to this problem, if the dual highway principle is utilized, would appear to be related to the distance in which a vehicle can be brought to a stop. This is dependent on the braking power and the interval of time required for the operator to start the application of the brakes after he has observed a danger. This latter interval may be termed the lag. The result of computations based on the laws of motion and using the 1931 rules of the New Jersey Vehicle Commission for stopping distances indicates a deceleration factor of 17.4 ft per sec per sec for four-wheel brakes. This is slightly higher than the factor deduced (approximately 16 ft per sec per sec) from the figures of the National Bureau of Standards[3]. The formula, based on well-known principles of motion, is:

$$s = \frac{1.075\ V^2}{17.4} \qquad \text{(2)}$$

Equation (2) will give the distance, s, required to bring a vehicle equipped with four-wheel brakes to a stop, neglecting the lag. The lag has been observed by various authorities as ranging from 0.75 sec to 1.5 sec. for an emergency stop. In connection with the deceleration factor of 17.4, tests conducted by a New York, N. Y., Taxicab Company indicate that a deceleration of about 19.0 ft per sec per sec will throw the occupants of a car out of the seats. This suggests a limit to a further increase in braking power.

Applying Equation (2), using V equals 100 miles per hr, a distance of 617 ft will be required to bring a car to a stop (on level grade) after the brakes are applied. Using a lag of 1.5 sec, a sight distance of 836 ft is required (617 + 219), at a speed of 100 miles per hr. The sight distances calculated, using the factor, $d = 17.4$, should be considered the minimum.

Fig. 4 shows the stopping distances for different speeds and rates of grades. Let S = grade, in feet per foot (− = down grade and + = up grade);

[3] Manual on Uniform Control Devices for Street and Highways, National Bureau of Standards, Appendix *C*, dated March 4, 1935.

m = mass; and, d = the deceleration of the car, in feet per second per second; then, since total work = kinetic energy + potential energy:

$$m\ d\ s = \frac{m}{2}\left(\frac{5\,280}{3\,600}\ V\right)^2 + 32.2\ m\ (-S)\ s \ldots\ldots\ldots\ldots (3)$$

For properly adjusted four-wheel brakes, using the New Jersey State traffic rules for 1931 a value of d equal to 17.4 is deduced from which it is possible to derive an expression for s in terms of S, as follows:

$$s = \frac{1.075\ V^2}{d + 32.2\ S} \ldots\ldots\ldots\ldots (4)$$

If the dual highway principle is not used and the design consists of a two-lane, two-way highway, passing distance becomes the controlling element. For this case a sight distance of more than 2 000 ft may be required for reasonably safe passing. Even this distance does not take into consideration the speed of an approaching car. The passing menace is one of the serious problems facing the highway designer.

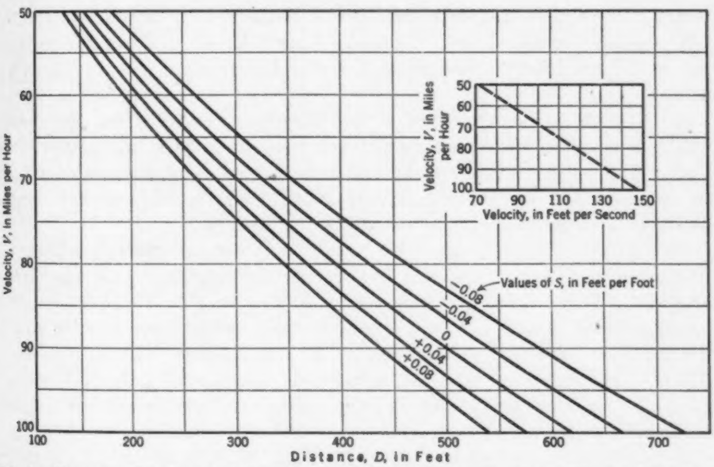

FIG. 4.—DISTANCE REQUIRED TO BRING A MOTOR CAR EQUIPPED WITH 4-WHEEL BRAKES TO A STOP AFTER BRAKES ARE APPLIED.

Shoulders.—If the shoulder is looked upon as a factor of safety a healthier attitude toward its cost will develop. In case of accident or mishap it may prove as important as the pavement itself. Many minor accidents develop into major accidents when cars swerve on to the shoulder and strike some fixed object, or over-turn. In many cases it is necessary for a car to dodge out on to the shoulder to miss a sudden accident ahead. For these reasons it is apparent the shoulders should be wide (preferably not less than 20 ft), level with the pavement, paved suitably to accommodate vehicles safely at high speed, and cleared of all obstructions. Ditches are recognized hazards

and are being eliminated in present modern designs, but obstructions, such as poles, trees, warning signs, head-walls, light standards, etc., are not so generally recognized as sources of danger. The writer has often wondered why public officials permit private utility companies to locate poles within a few feet of pavements instead of along the right-of-way lines.

Curbing is another element of danger which has not been generally recognized. It is recommended that it be used very sparingly and only in places where it will prove to be a safety device instead of a hazard. It is well to keep in mind that the essential function of a curb is to protect pedestrians on sidewalks, to form drainage channels in urban areas, and as a first line of warning and defense on bridges, etc.

Signs.—The setting of warning signs as fixed objects near the roadway was probably derived from railway practice. Since the motor vehicle is not confined to fixed rails, signs set in this manner constitute a hazard.

Signs may either be suspended from overhead cables or mounted on flexible standards. To be effective they should be illuminated at night in such manner that the motorist is not blinded and so that objectionable shadows are not cast. The ideal would appear to be a luminous type visible for a sufficient distance, but with a limited light source. Reflectors are not always effective under certain conditions and, of necessity, must be set in a position to intercept head-light beams. In such a position the reflector usually becomes a menace.

A criticism frequently heard is that direction signs are not placed sufficiently in advance to permit the motorist time to make a turn properly and safely. This safe distance will be increasingly important because of advancing speeds. Braking power and feet traveled per second are the factors. Duplication of direction signs will also prove helpful.

Guard-Rail.—Probably no other single highway structure has been the cause of so much loss of life and property as the guard-rail. Because it is a hazard at best it is desirable that as little of it be placed as possible. For fills of moderate height it would appear logical, therefore, to substitute extra wide shoulders and flat side slopes. This would eliminate many miles of railing. In locations where the guard-rail is essential, only rail of such design that damage to the vehicle and injury to the occupant are avoided, should be installed.

The enlightening paper by Searcy B. Slack, M. Am. Soc. C. E.,[8] covering fundamentals of guard-rail design, points the way toward more rational design.

Lighting.—Practically all authorities agree on the present inadequacy and unsuitability of highway illumination. With increasing speeds and night travel this inadequacy assumes serious proportions. The lighting of to-day creates bright areas around which are pools of blackness difficult for the eye of the driver to penetrate. Indeed, some types of units defuse the rays laterally and upward leaving the pavement and an area some distance above the pavement in semi-shadow when compared with the brightness of the light itself. The effect on the motorist is to create a series of blind spots. Rain, snow, sleet, and fog increase this hazard. In this connection roadside stands

[8] *Engineering News-Record*, June 9, 1932.

with their brilliant lighting are very troublesome. Some of these stations produce a blind interval of several seconds. Proper legislation could eliminate this latter hazard. If highways are to be illuminated it is apparent that a radical departure from present methods will be necessary.

Pavements.—Present thought in pavement design appears concentrated on providing only sufficient strength, with a small factor of safety, to prevent actual failure. It may be that too little thought is being given to providing sufficient thickness and steel reinforcement to perpetuate the good riding qualities originally built into the pavement. The natural forces of weather, temperature, frost, and plastic flow in concrete tend to distort the riding surface. It is established that profileometer readings increase each successive year. Thus, after five or six years, the riding qualities are greatly impaired. The public is as interested in smoothness during the entire life of the pavement as in the first two or three years of its life. At present speeds, such roughness may not be unsafe, but at the speeds which may be common in the near future, it may be vital. A thick slab heavily reinforced top and bottom, with transverse joints less than 100 ft apart, may be the answer. Such a slab will be relatively stiffer and will have less deflection at transverse joints, and thus tend to lessen present troubles at the joints. A test program would do much to throw light on the problem.

At present, joints are receiving much deserved attention. They will be increasingly important in the future. Noise caused by the joint may be equally as important as smoothness. At a speed of 100 miles per hr with joints on 50-ft centers, a vehicle will pass over three transverse joints per second. If the joint causes noise it may prove more annoying and conducive to driver fatigue than the "clicking" of rail joints on the railways.

Terminals and Interchange Facilities in Urban Areas.—In such areas speeds may have to be limited to approximately 40 miles per hr in the interest of safety. Because of the specialized nature of the problem, the scope of this paper does not permit a detailed discussion. Each location presents individual design problems and must be treated on its merits. In the writer's opinion the simplest possible layout is best. A complicated design that confuses the motorist may be more conducive to lost time than a less mechanically perfect design that is simpler. The motoring public objects to "getting lost." The present tendency to eliminate all left turns on the secondary street may be unnecessary in most cases and may lead to undue complication. The decision as to the use of a design with no left turns depends on the peak-hour volume of traffic using the ramp and the street to be entered. If traffic on the street to be entered is light and not moving at high speeds, left turns may be permitted with safety. If the street to be entered is equipped with traffic lights the criterion will be that no more traffic shall accumulate in the ramp than will clear during a light interval. Observations show that at least ten cars in two lanes, will clear out easily during a 1-min. light interval. This is equal to not less than 300 cars per hr.

The principles of the traffic circle, the grade separation with ramps, and the clover leaf are well understood. The traffic-circle design is based on the volume of traffic as related to the diameter and the number of

entrance streets, to the end that free weaving action may occur. The charge that traffic circles are dangerous is true if the circle is inserted in a high-speed highway where speeds are greater than 40 miles per hr. At speeds of about 40 miles per hr, a circle can be made safe with proper lighting, adequate illumined over-head warning signs placed sufficiently in advance, and by eliminating curbs and obstructions within and adjacent to the circle.

Center ramps, which require the main traffic to by-pass around them, are exceedingly dangerous. Heads of all turn-out ramps should be designed so that traffic does not tend to run into them. Curbs, if any, should be low and walls should be started sufficiently back from the nose to allow the motorist time to avoid crashing into them. Obstructions (signs, reflectors, light standards, etc.) placed on the nose are an added hazard. Proper lighting in the form of spot-lights and advance, over-head, illumined warning and direction signs will be of assistance in making ramp heads safer. Many of them have been designed in improper positions, and then loaded with signs and reflectors. Such installations have resulted in many serious accidents with accompanying loss of life and property. No part of the design deserves a more careful accident analysis than ramp heads. It is not necessary for the motorist to enter the ramp at breakneck speed; nor is it necessary to use curves of large radius. The ramp should be a definite turnout, a subsidiary of the highway, and should be so designed. If properly "signed" far enough in advance, the motorist will find it even if it is off to one side of the highway.

It is well to repeat that simplicity of layout consistent with safety and traffic-handling capacity is sound policy when designing terminal facilities.

Conclusion

Most of the highways designed twelve or fifteen years ago (before about 1920) are obsolete as far as alignment, grades, and details are concerned. These shortcomings are the cause of untold suffering and loss of life as well as an enormous economic waste in property loss and capital outlay. Unless there is a radical revision upward in design standards, history may repeat itself as far as the trunk system is concerned. Motor-car design and the public will dictate the speeds which will obtain. The engineer will have little voice in the matter.

There are evidences in various parts of the country of an awakening to the principles outlined in this paper, but nothing really concrete has been initiated on a national scale. Germany, on the other hand, actually has under construction the first unit of a system designed for speeds as great as 115 miles per hr.

The highway engineer is facing a tremendous responsibility. He must have courage and vision. He controls the destiny of billions of dollars and tens of thousands of lives. Safety for the motorist must be the watchword.

DISCUSSION

Fred Lavis,[4] M. Am. Soc. C. E. (by letter).—There can be little question that the facts and opinions expressed by the author should receive careful attention from engineers and others responsible for future design and construction of main trunk-line highways. This paper is timely and important. However, it raises a question that is fundamental. Mr. Noble seems to assume that it is the duty of the State (and by that is meant any governmental agency) to provide ample facilities for the operators of motor vehicles driven at high speeds on highways. It is a serious question, however, how far one should, or could, go in the expenditure of public monies for this purpose.

There is no doubt that future trunk-line highways, or future reconstructions of such highways, should be designed with reasonable consideration for future requirements, and at least one of these requirements is the operation of motor vehicles, trucks, buses, and private cars at high speeds.

Since the days of Wellington at the end of the Nineteenth Century, wherever proper engineering methods have been used, railway design has envisaged and provided for future traffic. In 1930 the writer[5] pointed out the desirability of applying Wellington's formulas, modified to suit the conditions, to the design of highways. Mr. Noble has amplified this suggestion to include safety of operation as well as the economic operating factors cited by the writer.

The fact must be borne in mind, however, that, although the highway accident record is bad and involves a considerable economic loss, and although it is in many ways a real disgrace, the development of high-speed operation imposes on the State a much more serious duty than that of providing a safe roadway—namely, the duty of carefully selecting, testing, and supervising the operators of those vehicles which are driven at high speeds. There is a further duty in the periodic inspection and testing of the vehicles themselves. Simply to provide speedways and let any one and every one use them who meets certain very minimum requirements—people whose responsibility is not frequently checked and verified—is really criminal and far more a subject of criticism than any charge that can be directed against the structure of the highways even as they exist to-day. Perhaps, some day the Utopia may arrive, in which all vehicles and drivers not meeting certain requirements will be limited automatically to certain comparatively low speeds.

An interesting commentary on this phase of highway safety is the statement of the Commissioner of Motor Vehicles of the State of New York of the revocation or suspension of licenses for the two-week period ended September 19, 1936. For the State the total was 733 and among the causes listed were: Driving while intoxicated; leaving scene of accident; failure to pay registration fee; false statements on application; reckless driving; speeding; etc.

---

[4] Cons. Engr., New York, N. Y.

[5] "Highways as Elements of Transportation", by Fred Lavis, *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 1020.

The fact that 733 licenses or registration certificates were suspended or revoked in only two weeks in one State indicates the extreme importance of the human element and it is, of course, almost certain that many other drivers than those who were discovered and penalized are not competent to drive at all and certainly not at high speeds. It will be noted also that no mention is made in these lists of the physical condition of the vehicles being driven.

There is also another phase to be considered in connection with the author's proposals for roads with large radius curvature, comparatively smooth profiles with light rates of gradient, and smooth rigid pavements. From the standpoint of safety, the effect on the driver of this monotonously even surface should be taken into consideration. There is some evidence that it may tend to dull the senses and produce a state, at least, of semi-somnolence which does not develop in driving over roads on which vigilance is obviously necessary. It may be admitted that the tendency of the future is likely to be toward the construction of highways of the very high type suggested by Mr. Noble but this argument, in turn, brings the subject back to the greater need of testing, licensing, and supervising the operators of the vehicles using the modern highway, and the vehicles themselves.

One statement is made in the paper in regard to pavements to which, perhaps, more particular attention may be drawn. Considerable has been said and written about the effect of heavy motor vehicles on highway costs, with the fairly general assumption that there is some more or less definite relation between the two and that the cost of highways is increased in some more or less direct ratio to the weight of the vehicles using it. More definite, perhaps, is the assumption that pavements (as also, to some extent, the alignment gradients, and width of roads) are controlled by the requirements of heavy motor trucks.

In December, 1934, the writer pointed out[6] some of the fallacies of this assumption and it is of interest, therefore, to note the author's statement that safe operation of modern private cars requires such widths and thicknesses of pavements that they will be amply sufficient for the heaviest vehicles.

In his "Conclusion", Mr. Noble states that "the highway engineer is facing a tremendous responsibility. He must have courage and vision." This sense of responsibility, courage, and vision have not been lacking, and the engineers of the United States have been far in advance of those of Europe in designing and building various types of so-called super-highways. It must be borne in mind that much of the policy of the development of transportation in Europe is based on military needs and cannot be assumed to be caused entirely by anxiety to provide for the speeding of private cars, although this latter may develop as an incidental factor.

The construction of the Westchester County Park System, in New York, incorporating the most advanced thought in widths of pavements, elimination of grade crossings, etc., was begun in 1913. The New Jersey State Highway from the Holland Tunnel to Elizabeth, N. J. (Route 25), was envisaged in 1923 and construction was begun in 1924. Boston, Mass., Philadelphia, Pa.,

[6] "Effect of Heavy Motor Vehicles on Highway Costs", National Research Council, 1934.

Chicago, Ill., and other centers have contributed ideas and proceeded with construction.

The real question is not the courage and vision of the engineer, it is the reasonable adaptation of construction to future needs without unduly taxing certain classes of people, or all the people, for the benefit of the few.

The question as to how far one should go in making the expenditures necessary for the extension of these super-highways, is one of statesmanship just as much as engineering. One suggestion offered by Mr. Noble may be emphasized and that is the desirability of advance planning of such highways and the acquisition of the necessary land, the restriction of encroachments, etc., so that when the proper time comes the actual construction will not be unduly burdensome.

It should be stated that the author has done a service in emphasizing some of the factors that should be given consideration if, as, and when, such highways are required and the funds for their construction are made available.

JOSEPH BARNETT,[7] M. AM. SOC. C. E. (by letter).—In reading this paper one is given the impression that "Express Highway", "High-Speed Highway", and "Dual Highway" are considered to be synonymous. They are not so necessarily.

An express highway is one which may be traveled without undue interruption between terminals or other designated control points, much as express vehicles in any other form of transportation. It need not be high speed, necessarily, but the speed is higher, generally, than is common on adjacent local highways. The Westchester County and Long Island Parkways, in New York, properly may be classified as express highways. They may not be traveled at high speeds as that term is understood now, but may be traveled without undue interruption, in comfort, and with a sense of the beauty of Nature not possible on high-speed highways.

Dual highways are composed of two one-way highways. They need not necessarily be high speed or express. All highways carrying more than 10 000 vehicles daily should be constructed as dual highways. Increased safety and only a small additional cost over that of four-lane two-way highways are sufficient justification. Expensive 300-ft rights of way are desirable, but far from necessary. The largest part of the possible additional safety is attained as soon as opposing traffic is separated physically, even if the separation is only 3 or 4 ft of curb. All additional effort and expenditure, such as wide landscaped areas between highways resulting in wide shoulders to aid in avoiding collisions, reduction of head-light interference, etc., are worth while but they are subject to the law of diminishing returns in providing additional safety.

It should be possible to travel at high speeds on all modern express highways. However, the fact that motor vehicles are being constructed to travel safely at 100 miles per hr is not in itself sufficient justification for the adoption of this speed for design. It is only one of the factors which should be considered in weighing the problem. Of great importance are the topography, which is a factor in the determination of cost, and eco-

[7] Senior Highway Design Engr., U. S. Bureau of Public Roads, Washington, D. C.

nomic justification. One of the most important transcontinental highways in the United States would be included by many in any program for developing modern express highways, and yet hundreds of miles of this highway, where not under the influence of local urban traffic, carry about 300 vehicles daily. A two-lane, two-way highway designed for a speed commensurate with the particular topography is all that is justified.

Where traffic justifies the construction of four one-way highways, two lanes in each direction for trucks and two lanes for passenger vehicles, many advantages accrue to locating the truck or slow traffic highways outside rather than inside the fast traffic highways. "Fly-under" crossings are expensive, especially in flat country and the entrances to the slow traffic high-

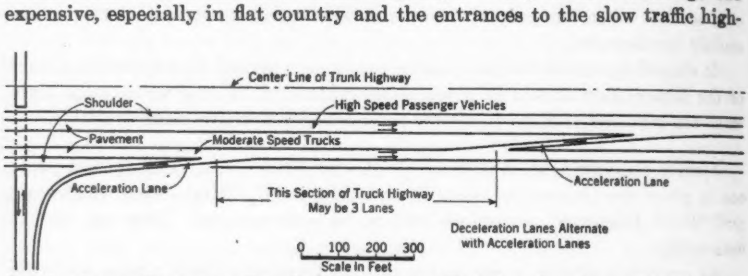

FIG. 5.—ACCESS PLAN FOR A FOUR-PAVEMENT TRUNK HIGHWAY. ONE QUADRANT IS SHOWN; OTHER QUADRANTS ARE SIMILAR.

ways are comparatively numerous. By placing the slow traffic highways on the outside, fast-moving passenger vehicles may use the slow-moving highways for short distances to enter and leave the dual highway. Fig. 2 would then be modified, as shown in Fig. 5.

Details of Design.—The complete formula for super-elevation (see Equation (1)) is,

$$E + F = 0.067 \frac{V^2}{r} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

in which, in addition to the notation of the paper, F equals the side friction factor. On the assumption that there is an ample margin of safety against skidding when a vehicle rounds a curve at the minimum speed at which side pitch is noticed by driver or passenger, the U. S. Bureau of Public Roads has received reports on nearly 900 road tests to determine this speed. The results have not been analyzed thoroughly, but they lead to the conclusion that a side friction factor of 0.16 may be used with safety for vehicle speeds as great as 60 miles per hr. The results indicate lower factors for speeds greater than 60 miles per hr, but the combination of highway, vehicle, and driver capable of driving safely on curves at speeds greater than 60 miles per hr is rare, and few observations at higher speeds were received.

It is suggested that the minimum radius of curves be determined by the use of Equation (5); for example, for a speed of 60 miles per hr, a super-elevation of 1¼ in. per ft, and a safe side friction factor of 0.16, the limiting radius is 915 ft. For a speed of 100 miles per hr and an assumed safe side

friction factor of 0.08, the limiting radius is 3 640 ft. This method seems superior to one in which side friction is ignored, and a lower velocity is assumed to compensate for it.

The writer cannot urge too strongly the adoption of transition curves. Mr. Noble states that the necessity for such curves is doubtful because the vehicle is free to make its own transition, necessary within the wide lane. It is not sufficient that highways be designed so that it is possible for vehicle operators to remain in their lanes. They must be encouraged to do so if safety is to be built into the highways. "Cutting corners" is one of the important factors contributing to the number of accidents on two-way highways which constitute the largest part of the highway system of the United States. Vehicle operators "cut corners" regardless of whether or not it is possible for them to keep to the traveled lane, chiefly because of a natural tendency to reduce the shock of the sudden application of centrifugal force. They are further encouraged to "cut corners" by the fact that the change from a crowned to a superelevated cross-section is placed on the tangent because of the lack of a transition curve. To keep from sliding down the inclined cross-section, the operator must turn his wheel slightly against the direction of the curve ahead, a most unnatural action, the necessity for which encourages him to head toward the inside of the curve. With transitions, superelevation increases with curvature, and no complicated methods of changing from crowned to superelevated cross-sections are required. Reverse curves need no special treatment and the ends of adjacent transitions may be a common station. With adequate tables the design and location of curves with transitions are not complicated and require no more time and effort than curves without transitions.

The required length of transition depends upon the rate at which the final constant centrifugal acceleration is approached. If a vehicle travels at a constant speed on a curve it is accelerating toward the center at the rate of $\frac{V_s^2}{r}$, in which V_s represents the speed, in feet per second. The total time required to traverse the transition curve is $\frac{L_s}{V_s}$, in which L_s represents the length of transition, in feet. The average rate at which the vehicle on the transition approaches this final constant centrifugal acceleration, therefore, is $\frac{V_s^2}{r} \div \frac{L_s}{V_s} = \frac{V_s^3}{r\,L_s}$. This average rate will vary for different drivers and numerous scientifically controlled tests are needed to determine the most desirable value. The few observations available indicate that a value of 2 for $\frac{V_s^3}{r\,L_s}$ is a fair average. Equating and changing to V, in miles per hour, results in the formula,

$$L_s = 1.58\,\frac{V^3}{r} \qquad (6)$$

For a speed of 100 miles per hr and a radius of 3 640 ft, the required length of transition is about 450 ft.

Regardless of the assumed design speed an alignment of curves with adequate transitions is greatly superior to an alignment of tangents and curves without transitions, in appearance and in ease and comfort of travel. Any one doubting this statement should operate a vehicle on a highway, such as the Mount Vernon Memorial Highway between Arlington and Mount Vernon, Va., on which all curves are constructed with transitions.

A deceleration of $d = 17.4$ ft per sec per sec is equivalent to a uniform rolling friction factor between wheels and pavement of 0.54. Although this is not too great for a motor vehicle on clean pavements even when wet, it is felt that in computing minimum sight distances for one-way highways a friction factor that would apply to most vehicles on pavements not altogether clean should be used. This friction factor is likely to be about 0.4. The general equation for braking distance based on a uniform rolling friction factor between wheels and pavement follows:

$$s = \frac{V^2_s}{2\,g\,(F \pm S)} \quad \text{.........................(7)}$$

Converting Equation (7) by substituting V to represent the velocity, in miles per hour, and 32.2 for g, results in the following:

$$s = \frac{0.0334\ V^2}{F \pm S} \quad \text{.........................(8)}$$

For an assumed uniform friction factor of 0.4, a vehicle at 100 miles per hr on a level highway would stop at a distance of 835 ft after the brakes are applied. What Mr. Noble terms "lag" is the sum of two reactions times, brake reaction time, and what may be termed "awake" reaction time. Brake reaction time has been tested widely and varies between 0.5 sec and 1 sec for most vehicle operators. Awake reaction time may be defined as the time it takes for a vehicle operator to come to the realization that the brakes must be applied. In this case, the operator must come to the realization that an object in his lane is stationary. It may take a few seconds to come to this realization if the object is a stationary automobile. Tests for awake reaction time are needed.

Conclusion.—The use of an assumed design speed of 100 miles per hr may be justified on many highways in many sections of the United States. Indeed, some engineers (notably those of the Oregon State Highway Department), are constructing highways designed for critical, as distinguished from assumed, design speeds as great as 100 miles per hr. The final determination to construct great systems of highways for this speed depends not on the vision and courage of the engineer, who is well endowed with these attributes, but on financial ability and justification.

However, to be safe, any highway on which the expected vehicle speeds are greater than 40 or 50 miles per hr should be designed with a refinement not thought necessary a decade ago. It is in this broad field that the principles

outlined in Mr. Noble's excellent paper can be put to use. In many cases, little if any additional cost is involved. The principal requirements are more care in design and construction and the services of a high type of engineer, of which there is a plentiful supply.

G. E. HAWTHORN,[8] M. AM. SOC. C. E. (by letter).—The ever-increasing speed of automobiles presents a serious problem for the highway engineer. There does not seem to be any definite upper limit for speed which automobile designers will build into their vehicles of the future. At the present (1936) rate of increase, automobiles capable of speeds of 150 miles per hr may be expected within the next 10 yr. Mr. Noble, as well as many other highway engineers, fixes the maximum speed for which express highways should be designed at 100 miles per hr.

A decade ago the highway engineer had the problem of ever-increasing weights of vehicles. This problem has been solved, at least temporarily, by rigidly enforced laws limiting maximum size and weights of vehicles. This has been accomplished by co-operation between automobile designers and users with highway engineers.

The problem of speed is similar but more serious, in that loss of life and destruction of property, instead of destruction of pavement only, are involved. Unless some rigid upper limit of speed is established, either by mutual agreement between motor-car designers and highway engineers or by a rigidly enforced law, engineers will continue to design highways that will become obsolete as to safety features every decade. There is some question as to whether it is desirable to design main highways for speeds as high as 100 miles per hr just because some automobiles can travel that fast. Possibly 70 miles per hr would be more desirable; certainly, it would be much safer. The driver's control over his vehicle varies, other conditions being equal, with the square of the speed. The vehicle traveling at 100 miles per hr requires twice the distance of one traveling 70 miles per hr, and four times the distance of one traveling 50 miles per hr to be brought under control in an emergency. All possible safety features that can be built into both the automobile and the highway can in no way change these ratios. They hold also as to the violence of the impact resulting from any accident.

Minimum speeds on express highways are also important. Even on dual highways fast traffic may be "boxed" by one slow vehicle passing another, resulting in serious accidents.

The two main safety features that can be built into the highway itself are: (a) Proper superelevation on all necessary curves; and, (b) sight distances of sufficient length to allow vehicles operating at maximum speeds to be brought under control or stopped at all times in case of an emergency.

Safety Feature (a).—The superelevation used on curves can be considered from several angles. Equation (1) of the paper gives the theoretical superelevation desirable for vehicle operation on curves with the same safety as on tangents. Unfortunately, the maximum superelevation that can be used

[8] Asst. Prof. in Civ. Eng., Univ. of Washington, Seattle, Wash.

safely, if the road is to be used by slow traffic, is limited approximately to a 10% cross-grade, which allows a maximum superelevation of about 0.1 ft per ft of width. Using this value, the minimum radius of curve that could be used would be:

$$r = 0.67 \; V^2 \qquad (9)$$

or for speeds at 100 miles per hr, $r_{min.} = 6\,700$ ft. Automobiles can be operated on curves which are under-superelevated, however. Railroad engineers have determined that an under-superelevation of 3 in. in a gage width of 4.71 ft, may be used without discomfort to train passengers. Using this value for comfortable riding,

$$E = \frac{0.067 \; V^2}{r} - 0.053 \qquad (10)$$

On curves where the superelevation is not enough, theoretically, the vehicle has a tendency to turn out and follow a curve of greater radius. This is an added hazard, particularly at high speeds. It can be shown that, if the deficiency in superelevation is equal to the coefficient of friction between tires and surface, vehicles will skid sidewise. At the skidding superelevation:

$$E = \frac{0.067 \; V^2}{r} - f \qquad (11)$$

in which f is the coefficient of friction. Equation (11) is important only at high speeds or on slippery pavements.

Deficient superelevation may also cause overturning. It can be shown by the equilibrium of forces that the vehicle will overturn when,

$$E = \frac{0.067 \; V^2}{r} - \frac{b}{2\,h} \qquad (12)$$

in which b = the width of the car from center to center of tires and h = the height of the center of gravity of the vehicle above the roadway.

Safety Factor (*b*).—The sight distance required for safety on highways depends on the distance the vehicle will travel while being brought under control or stopped. A fundamental formula for the required sight distance can be derived, using the relation of work and energy. Considering the kinetic energy of the rotating parts of the vehicle, its total kinetic energy is equal to $\frac{1.05\,W\,V^2}{2\,g}$, in which W = the weight. Then changing velocity from feet per second to miles per hour, $0.03511 \; W \; V^2 = W \; f \; s + W \; S \; s$, and the required distance equals,

$$s = \frac{0.03511 \; V^2}{f + S} \qquad (13)$$

in which S = the grade, in feet per foot ($-$ = down grade and $+$ = up

grade). A term should be added to Equation (13) representing the distance traveled during the time used by the operator in applying the brakes. If s_a equals this time, in seconds,

$$s = \frac{0.03511\ V^2}{f + S} + 1.47\ s_a\ V \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

For values of $f = 0.4$, $S = -0.05$ ft per ft, $V = 100$ miles per hr, and $s_a = 1$ sec.: $s = 1\,002 + 147 = 1\,149$ ft. The rate at which the vehicle decelerates varies with the value of the coefficient of friction, f, and $d = 32.2\ f$, in which $d =$ the deceleration, in feet per second per second. Substituting d for f in Equation (14):

$$s = \frac{0.03511\ V^2}{\dfrac{d}{32.2} + S} + 1.47\ s_a\ V \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

The first term of Equation (15) can be readily reduced to Equation (4) of the paper.

Sight distance and superelevation are built into the pavement and can not be changed once it is laid. The only unknown factor in these equations is the speed. Automobile designers and users, together with highway engineers, should agree on a reasonable maximum speed for which the main highways and automobiles are to be designed. Then, and only then, can highways be designed which are as safe as it is possible to build them. Speed will still claim its victims, but it will not be the fault of the highway.

Wide smooth shoulders free from poles and signs, flexible guard-rails placed at reasonable distances from the edge of the surface, and the limiting of grades are desirable, but they become really important only when the automobile is out of control. They can be replaced or improved as traffic demands change, at relatively small cost. Great improvement has been made along this line in existing highways in the United States during the last few years.

JOHN F. FAIRCHILD,[9] ASSOC. M. AM. SOC. C. E. (by letter).—A phase of this subject was omitted from the paper which, although it does not affect the construction of the highway itself, might affect its cost materially. For example, Fig. 1 shows a 300-ft right of way on the side lines of which appear the words "No Frontage or Access Permitted." In the paragraph following Fig. 1, Mr. Noble emphasizes this proposal by the statement that "* * * a safety factor is to prevent frontage of any type on the highway and to exclude farm and local road entry. It appears reasonable to restrict access to approximately 10-mile intervals."

If the express highway is in the location of an existing road, the construction of the highway under such restrictions would confiscate a very valuable right to the abutting properties for which compensation must be paid. If the express highway is located on an entirely new right of way, no doubt, it would

[9] Harrington Park, N. J.

cut some properties into separate parcels, so that it would be necessary to furnish under-crossings or over-crossings between the two parcels thus separated. This situation, of course, would vary in different localities, which fact should be taken into consideration in estimating the cost of the express highway.

LESLIE R. SCHUREMAN,[10] ASSOC. M. AM. SOC. C. E. (by letter).—The author renders a valuable service to the Highway Engineering Profession and to the general public in stimulating thought and discussion on what is probably the most pressing problem which confronts the highway engineer to-day—that of safety in highway design. However, any analysis of this problem cannot be complete without some consideration of the highway bridge which, although in itself a problem in design, must be included in any broad approach to the problem of determining and establishing standards of design for safe trunk highways. The accident record offers indisputable testimony in support of the fact that the highway bridge, as it exists to-day, is as hopelessly obsolete as the highway itself for the high-volume, high-speed traffic which must be provided for in the very near future.

The highway bridge engineer must develop design standards and details for a structure which will accommodate such traffic safely and efficiently. Its realization necessarily depends upon the co-operation of the highway engineer in providing straight-line tangents and continuity of grade and alignment at the site. Serious thought must be given to the roadway width of the structure. Obstruction to travel on the shoulder area constitutes a definite traffic hazard which can, and should, be eliminated. Pavement widening or flaring on approaches has proved to be a valuable safety feature. Approach slabs designed to span the back-fill area eliminate the startling end-of-deck bumps so common on present-day bridges. Balustrades must be structurally adequate to resist complete failure from collision and, preferably, should be provided with a first line of defense in the form of a curb. Poorly designed balustrades are much too frequently a contributing factor in serious accidents. Center piers on under-passes are a highly fertile source of motor-car disaster and, unquestionably, should not be used except in locations where the underpassing highway is divided by a center strip of ample width. Low points in the highway profile frequently occur at stream crossings. Adequate deck drainage eliminates the hazard of a wet or icy pavement condition.

Quite aside from purely utilitarian considerations, the structure should undoubtedly possess true grace and beauty. The question of æsthetics has become increasingly important with the growing need for grade-crossing eliminations. The intelligent selection of materials and design of proportions rather than detailed embellishment and ornamentation contribute much to an æsthetically pleasing result. The æsthetic treatment of any structure constitutes a problem in itself and should certainly be given considerably more time and thought than, in most cases, it has received in the past.

C. H. PURCELL,[11] ASSOC. M. AM. SOC. C. E. (by letter).—The line of thought developed throughout this paper is well worth serious consideration. The next stage in highway design will be along the lines of greater safety, although perhaps not to the extent that speeds of 100 to 115 miles per hr will be common. It is quite feasible to eliminate a considerable percentage of accidents now classed, and rightly so, as "fault of driver." This can be done simply by the expenditure of sufficient sums of money. The engineering knowledge and experience are available now and can be applied whenever the work can be financed. The width of lane, radius of curvature, rate of superelevation, etc., for any maximum speed can be determined at a cost that will be insignificant in comparison to the total cost of improvement required. It is very doubtful indeed if all "fault-of-driver" accidents can be eliminated, and certainly not by engineering effort.

Records indicate that approximately one-half of all motor vehicle accidents in California occur in cities. A fair percentage occur, also, on secondary roads. Construction of super-trunk line roads, therefore, can eliminate much less than one-half the problem. In fact, such construction might easily increase the accident rate in cities and rural areas through emphasis of the high-speed complex.

On the basis of records for the first six months of 1936, accidents involving two or more vehicles fall into three groups of vehicle types:

Type of accident	Percentage of total
Passenger *vs.* passenger	69.70
Passenger *vs.* freight	21.67
Freight *vs.* freight	2.67
All others	5.96

Grouped in reference to the course being pursued, these accidents appear in the order of frequency, as follows:

Type of accident	Percentage of total
Approaching on the same road	41
Overtaking on the same road	31
Paths intersecting, but on the same road	16
Paths intersecting, but traveling different roads	12

From the foregoing, it appears that the separation of freight and passenger traffic would eliminate nearly 22% of accidents involving vehicles. The construction of divided lanes and the separation of grades of intersecting roads would reduce accidents by 53 per cent. Construction of pedestrian lanes and cross-overs would greatly reduce such accidents. To the extent that improvements of this kind were successful, the "fault-of-driver" type of accidents would be reduced. The extent of increase of accidents of the "overtaking", "side-swipe", etc., types which might result from increase in speed thus made possible, is entirely a matter of conjecture.

[11] Chf. Engr., San Francisco-Oakland Bay Bridge; State Highway Engr., Sacramento, Calif.

Accidents in which single vehicles are involved are grouped, as follows:

Type of accident	Percentage of total
Collision	35
Non-collision	46
Pedestrian	19

The statement, "drove off the road", accounts for nearly 25% of all single car accidents. What this percentage might be for vehicles traveling at speeds of 150 ft per sec, controlled by a driver with a reaction time of 0.5 to 1.5 sec, is problematical. Certainly, accidents which might result would be spectacular, and perhaps more likely to involve vehicles in a lane 100 or even 200 ft to the left than the farm house or other fixed object an equal distance from the right of way.

In connection with consideration of design speeds, it is interesting to note the detail secured during a survey of actual road speeds at about sixteeen locations, conducted by the Maintenance Department of the California Division of Highways. The speed of approximately 22 000 vehicles was recorded during daylight and of 11 000 at night. Fourteen of the locations were such that any desired speed could be maintained. The average speeds were, as follows:

Vehicle	Average Speeds, in Miles per Hour In daylight	At night
Passenger	47	45
Trucks only	34	34
Buses only	50	50

Of the daylight traffic, 94.09% traveled at a rate of 55 miles per hr, or less, and, during darkness, 94.49% traveled at, or less than, that rate.

Before entering on a program looking toward ultimate development of highways adequate for speed of 100 miles per hr, there are other factors to be considered.

Are public officials prepared to admit, for example, that they are unable to control the careless, the reckless, and the incompetent drivers at present legal speeds? Are the present methods of control of traffic by "stop and go" and other mandatory signals and reasonable regulations a total failure in controlling traffic? Are they certain enough as to what the effect would be if construction were advanced to permit of higher speeds? Are they at all certain that the majority of drivers desire to travel at higher speeds than present roads permit? Have the people reached a stage where they are prepared to submit to the degree of regulation which German authorities, for example, can enforce in the operation of their express roads? What will be the effect of further improvements in airplane operation and construction of machines which can compete, in convenience and first cost, with the automobile?

There have been a number of highway projects constructed along the lines which Mr. Noble has in mind, and others will be developed which, from an experimental point of view, will provide information on which to base design standards.

The problem at present appears to be more politic and sociological than engineering. Every highway engineer should be alive to the situation, not only from a professional point of view but from that of the citizen as well, in order to serve the need in the best possible manner.

Elmer R. Haile,[12] Jr., Jun. Am. Soc. C. E. (by letter).—Since more and more monies are being expended for the renovation of obsolete highways, this paper comes at an opportune moment. It succeeds admirably in outlining the subject of building safety into highway design, and in suggesting desirable researches and tests. This discussion presents the results of experiments pertaining to various design details, refutes the theory that the design of highways for high speeds will lower the accident rate, and suggests an alternate method for lowering the accident rate.

The Design Speed.—The design speed of 100 miles per hr appears to be unnecessarily high. It may be true that automobiles can be built to cruise at 100 or even 120 miles per hr, but that fact in itself does not justify the design of highways for those speeds, because the average driver will never travel that fast. Conceivably, a few drivers might develop high speeds, but their numbers would be far too small to warrant the additional expenditure involved.

Studies indicate that the intelligence of the human race has not increased measurably in the last 100 or 1 000 yr. Hence, it is erroneous to assume that the ability of Man to reach quick decisions or that his tendency to make mistakes will change appreciably in the near future. To quote from the paper, "the present railway maximum speed is approximately 80 miles per hr. The drivers of trains are trained, picked men, familiar with their runs, * * *, with definite orders and under close supervision." Even so, there are instances of trainmen disobeying orders and signals. If men with only average judgment, slight supervision, little training, and perhaps no knowledge of road conditions were allowed to take over the operation of trains, the number of accidents would "sky-rocket." On the highways the personnel is exactly as described in the preceding sentence, with the additional formidable handicap that their vehicles do not run on fixed rails. The path of each car is controlled by the driver and, therefore, may be subject to every possible human reaction. Whereupon it may be reasonably deduced that highway speeds ranging close to the railway maximum of 80 miles per hr are out of the question for the average driver.

A speed of, say, 60 miles per hr might be safe, but even in this case it would be necessary to bar incompetent drivers from the road. In practice, this proves to be almost impossible. There are always those drivers who pass the most rigid of examinations and then proceed to be reckless, or at least lax, in concentrating their attention on driving; not to mention those who become incompetent due to ennui and fatigue, and intoxication.

All of which leads to one conviction, which is, distasteful though it may be to many persons, that the solution is to fix a maximum speed limit. Granted that there are some drivers who know what a safe speed is, and can

[12] Junior Highway Engr., U. S. Bureau of Public Roads, Gettysburg, Pa.

safely "hit 90", yet for every such driver there are a dozen who can not judge whether or not they are proceeding at a safe speed until an emergency arises. Likely as not it is an innocent party who pays with his life for the driver's poor judgment. The proposed speed limit must be enforced, in sharp contrast with most present-day limits. Of the several means of enforcement, schooling is undoubtedly the best in the long run, supplemented with police patroling and, in some cases, mechanical speed control.

After exhaustive tests and observations are made and the maximum safe speed is determined and agreed upon generally, then the minimum design standards for that limit may be established. Lower speed limits will be necessary for secondary roads, and for trunk roads in congested areas and mountainous country. Of course, there is no harm in building a highway safe for speeds greater than the speed limit; such construction increases the factor of safety. The point which the writer wishes to emphasize is that the construction of 100 miles-per-hr highways will not in itself serve to reduce the number of fatal accidents if cars are permitted to attain 100 miles-per-hr speeds. There is a certain speed above which the average driver can not go without appreciable risk of a fatal accident, no matter if the road is theoretically safe for 120 miles per hr. For example, statistics from several sources indicate that the majority of present-day accidents occur in the country, during the day, on dry pavements, and where the road is straight. These accidents are inexplicable; they must be charged to the frailties of Man.

The standard of 100 miles per hr has another vitally important disadvantage, namely, the high cost, not only for the right of way and area of pavement, but particularly for the elimination of grade crossings and points of access, and, except in flat terrain, for the grading. Only a few of the heavily traveled arterial routes can qualify as being sufficiently important to justify such expenditure.

The writer is not prepared to suggest a maximum value for the design speed, but he does conclude that it need not be very much higher than one-half the design speed suggested by Mr. Noble.

Accidents.—Referring to Table 1 in the paper, it is noted that more than one-third of all accidents involve pedestrians. These accidents cannot be reduced by improvement in road design, except by the construction of sidewalks, which, incidentally, must have a surface equally as good as, or better than, the roadway along which they are built or they will not be used by those they are intended to serve. About one-half the pedestrian accidents are due to the carelessness of the pedestrian. Education, particularly in the schools, is reducing that cause of accidents. The other half of the accidents that are blamed on the driver cannot be reduced by building high-speed roads.

Again, referring to Table 1, it is noted that less than 7% of the accidents involve collision with fixed objects. About one-half of these accidents occur on curves, and one-half, on straight sections. Therefore, an improvement in radii of curves will not materially reduce the accidents due to vehicles leaving the roadway, and it may increase them by encouraging higher speeds on curves.

Again, it is noted that about 45% of the accidents involve collision with other automobiles. Of these collisions, about 11% occur at intersections, 9%

are "head-on" collisions, and the remaining 25% occur with vehicles going in the same direction. The 11% part may be reduced by the proper development of intersections. The majority of all intersections, even in congested areas, will probably remain at grade for economic reasons. Much study is necessary to determine some type of intersection that will not be inherently hazardous. For example, islands or circles inserted in high-speed roads may be very dangerous. Higher speeds than those prevailing at present will certainly increase the number of accidents at grade intersections, regardless of their treatment, because of the unavoidable crossing of traffic. The 9% part—"head-on" collisions—may be reduced by the use of 20 or 22-ft roads instead of the usual 16 or 18 ft, by providing ample sight distances, by widening and easing of curves, and, in the few cases where four-lane construction is economically justified, by the use of divided roadways. However, since the great majority of trunk highways (about 95%) will remain two-lane, two-way roads, speeds higher than the present average will increase "head-on" collisions more than the improved design will reduce them. The 25% portion of all accidents can be reduced in about the same manner as the 9% just mentioned. In one instance, statistics show that accidents involving vehicles proceeding in the same direction are fewer on divided highways than on two-lane, two-way highways. yet, in another instance, the accident rate on the new divided highway is greater than the rate on the old two-lane, two-way highway, due possibly to the higher speeds obtained on the improved road.

To summarize, an analysis of the various types of accidents indicates that improvements in highway design will not serve to lower the accident rate as long as correspondingly higher speeds are permitted to develop, thus demonstrating the futility of trying to design roads for the maximum speeds of which modern cars are capable.

The Dual Highway.—The dual highway is undoubtedly indicated wherever a two-lane highway is inadequate in capacity. In at least one instance, the concrete slabs of one-half of a new four-lane highway have been jacked up and moved transversely so as to leave a neutral area between cars traveling in opposite directions.

The writer has observed a serious disadvantage in having a width of pavement in excess of approximately 22 ft, especially for a two-lane, two-way highway. Many drivers use the road as a three-lane highway, despite the narrow clearances, making it even more dangerous than the 30-ft, three-lane design.

Superelevation.—Past practice has been to superelevate according to rule of thumb, or not at all. Consequently, the driver never knows what to expect when he encounters a curve. The greatest danger lies in having a series of curves superelevated for a certain speed followed by a curve superelevated for only one-half that speed, as would be the case if the first-mentioned curves were banked to the limit, and the following curve was very much sharper, but not banked any higher, inasmuch as the limit had already been reached.

The writer has conducted road tests in an effort to determine the proper rate of superelevation for various combinations of speeds and radii. Modifying Equation (1) so as to take into account the transverse frictional force that

is developed whenever the speed of the vehicle differs from the speed at which the gravity force due to the superelevation exactly balances the centrifugal force:

$$F + E = 0.067 \frac{V^2}{r} \qquad (16)$$

in which, in addition to the notation of the paper, F is the coefficient of friction between tires and road surface.

Observing the speeds at which drivers begin to encounter difficulty in keeping their cars under control on curves of known radii and rates of superelevation, substituting these values in Equation (16), and solving for F, values are obtained ranging from about 0.05, at which practically no centrifugal force is felt, to 0.50, at which a severe centrifugal force is felt, throwing passengers against the sides of the car, and resulting in considerable transverse creeping or skidding toward the outside edge of the curve. Upon plotting the coefficient, F, for numerous values of V, a wide band of points results. A curve drawn slightly below the average of these points is reproduced in Fig. 6, and represents the judgment of the more conservative drivers as to the allowable values of F for safe driving.

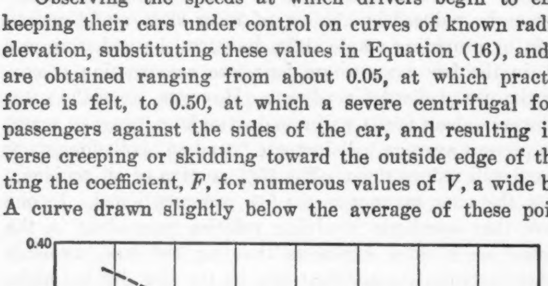

FIG. 6.—ALLOWABLE VALUES OF F FOR SAFE DRIVING ON CURVES.

An interesting feature of the graph is the fact that drivers do not hesitate to develop high values of F when traveling at slow speeds around sharp curves. However, a value of 0.30 for F still allows some factor of safety, for skidding does not occur under normal conditions until F reaches about 0.50. This margin need not be large at low speeds when the car can be slowed down within a few feet. At the other end of the graph, it is noted that much lower values of F are obtained, resulting in larger factors of safety. This is desirable at high speeds when the results of skidding may be disastrous, and when a considerable distance is required for reducing speed in case the car should begin to skid, as might happen if the pavement were uneven, or slippery with mud or grease.

Table 2 gives the maximum allowable curvature for various maximum speeds, the values of F being taken from Fig. 6, and the maximum value of E being assumed arbitrarily at 0.10 ft per ft of width. In sections where ice conditions prevail over a considerable part of the year, a lower value, say, 0.07, may be advisable, in which case the maximum allowable degree of curve would be somewhat less.

Since, in general, the average speed of vehicles will not be as high as the maximum safe speed, all curves flatter than the limiting curve should be superelevated for the average speed, using Equation (1), taking care, however, that the use of a low value of E resulting from that computation will not cause a transverse friction factor, F, greater than the allowable for the maximum safe speed as computed with Equation (16).

TABLE 2.—MINIMUM RADII FOR VARIOUS DESIGN SPEEDS, USING EQUATION (16) AND FIG. 6, AND ASSUMING $E = 0.10$

Maximum safe speed, V (1)	Maximum coefficient of friction, F (2)	Minimum radius of curve, r, in feet (3)	Maximum safe speed, V (1)	Maximum coefficient of friction, F (2)	Minimum radius of curve, r, in feet (3)	Maximum safe speed, V (1)	Maximum coefficient of friction, F (2)	Minimum radius of curve, r, in feet (3)	Maximum safe speed, V (1)	Maximum coefficient of friction, F (2)	Minimum radius of curve, r, in feet (3)
20	0.30	67	35	0.21	265	50	0.13	728	65	0.09	1,490

30	0.24	177	45	0.15	543	60	0.10	1 206	..	....	.....

Spirals.—The writer begs to differ with Mr. Noble's opinion that spiral curves are unnecessary. To illustrate, assuming curves of 2 900-ft radius with 1 000 ft of tangent between reversals, as suggested in the paper, and introducing spirals of 1 000-ft length (which will consume all the tangent), computations show that the offset required for inserting the spiral between the tangent and circular curve is 14.35 ft. This transition cannot be accomplished by a car within a 12-ft lane when spirals are omitted; the driver is forced to make his own spiral rather short in order to stay within the lane. Such an abrupt spiral requires special concentration and judgment, which is foreign to the ideal stated in the paper that vehicles should enter the curve smoothly, without tendency to be thrown in or out—almost automatically. When the spirals absorb all the tangent, as in the preceding illustration, there is no break in curvature—the driver is turning his steering wheel at a constant rate between the curves; but with a piece of tangent between the curves, the driver must adjust his car to run on the tangent for a few seconds, and then adjust his car to the next curve.

Contrary to general belief, the highway with the longest possible tangents is not the ideal to be sought. A flowing alignment is much more pleasing and restful to the traveler than monotonous "straightaways" followed by abrupt (although under the maximum degree) curves. This suggests the use of very long spirals between tangents and circular curves. The ideal treatment of a sharp curve, especially if it is sharper than the standard, is to introduce a spiral (or perhaps a series of other curves) of gradually increasing curvature for a sufficient distance ahead of the curve to enable the driver to release his throttle automatically and reduce his speed enough to make braking unnecessary. In addition, sharp curves should be signed to indicate their safe travel speeds, for the benefit of that great number of drivers who are not gifted with sufficiently accurate judgment. The foregoing treatment is far

safer than the usual method, which is to design a road for high speed until a certain under-pass or topographical feature is encountered and then promptly to forget the standards.

In going around a curve, whenever a vehicle develops a lateral coefficient of friction, designated by F, the body tilts with respect to a line normal to the axle. Upon entering the curve, it is advisable the develop the factor, F, gradually; otherwise, there will be discomfort due to sudden tilting. Since F varies directly with the degree of curve, a transition with uniformly increasing curvature would allow a uniform increase in F. A spiral curve has the property of uniformly increasing curvature; therefore, it is used for the purpose.

If C is the rate of change of acceleration toward the center of the curve, L_s is the length of spiral, in feet, V_s is the velocity of the vehicle, in feet per second, r is the radius of the circular curve, in feet, and, if the curve is not superelevated:

$$C = \frac{V_s^3}{L_s\, r} \qquad (17)$$

Tests conducted by the writer indicate that: (1) A value of C less than 3 ft per sec per sec per sec does not cause a noticeable lurch of the vehicle; (2) a value greater than 6 does cause a noticeable lurch; and (3) a value of C as great as 10 ft per sec per sec per sec causes a bad lurch. Substituting 3 for C in Equation (17), and solving for L_s:

$$L_s = 0.333\,\frac{V_s^3}{r} \qquad (18)$$

Changing to miles per hour, and substituting $\frac{F + E}{0.067}$ for $\frac{V^2}{r}$:

$$L_s = 15.7\ V\ (F + E) \qquad (19)$$

On an unbanked curve, $E = 0$ and Equation (19) reduces to:

$$L_s = 15.7\ V\ F \qquad (20)$$

On a banked curve, the part of the centrifugal force represented by E is balanced out by the gravity force due to the banking, and does not operate to tilt the vehicle with respect to a line normal to the axle; therefore, Equation (20) holds good for both banked and unbanked curves.

This formula gives the minimum length of spiral required for any combination of maximum safe speed, radius of curve, and superelevation. Upon applying the formula in practice, however, it develops that the length of spiral as computed is too short because of other considerations. If, for example, $V = 60$; $E = 0.10$; and $r = 1\,206$; whereupon, $F = 0.10$, it is found that $L = 94$ ft. As shown subsequently, the minimum length of transition from an unbanked section to a banked section, when $V = 60$ and $E = 0.10$, is

240 ft, with a recommended length of twice that amount. In all cases, the spiral should have the same length as the superelevation transition in order to provide uniformly increasing curvature simultaneously with uniformly increasing superelevation Therefore, Equation (20) may be discarded as superfluous.

Superelevation Transitions.—As a vehicle proceeds over a superelevation transition, it rotates about a longitudinal axis. This rotation, or angular velocity, or change per second of the rate of superelevation, may be expressed by $\frac{V_s}{L_s}(E_2 - E_1)$, in which V_s is the rectilinear velocity, in feet per second; $E_2 - E_1$ is the difference in rates of superelevation at the ends of the transition; and L_s is the length of the transition, in feet.

In the case where the superelevation increases uniformly from E_1 to E_2, the angular velocity jumps from zero to a certain value at the beginning of the transition, maintains this value throughout the length, L_s, and then drops back to zero at the end of the transition. This causes the vehicle to lurch at each end of the transition, because the change in angular velocity is very abrupt.

The change per second of angular velocity, or angular acceleration, may be expressed by $\frac{V_s}{L_v} \times \frac{V}{L_s}(E_2 - E_1)$, in which L_v is the length of the vertical curve at each end of the straight-line transition. The length of this vertical curve, or "rounding", may be as great as L_s, in which case there will be no tangent left, or it may be any length shorter than L_s. The writer has used $L_v = \frac{L_s}{2}$, although he cannot prove that that proportion is the best. Substituting $\frac{L_s}{2}$ for L_v, the expression for angular acceleration becomes, $\frac{2\,V_s^2\,(E_2 - E_1)}{L_s^2}$.

Experiments made by the writer show that an angular acceleration greater than 0.06 per sec per sec per sec produces an uncomfortable lurch, but that one-half that value, or, say, 0.027, is satisfactory. Substituting that value for the angular acceleration and solving for L_s:

$$L_s = V_s \sqrt{\frac{2\,(E_2 - E_1)}{0.027}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

which, changing to miles per hour, reduces to:

$$L_s = 12.62\,V \sqrt{E_2 - E_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

If, for example, the maximum safe speed is 60 miles per hr and the change in superelevation is 0.10, the required length of transition is found to be 240 ft, with 120-ft vertical curves. At other maximum safe speeds, with

the same difference in superelevation, the required lengths are in direct proportion. At a reversal of two sharp curves, if $V = 60$ and $E_2 - E_1 = 0.20$, the length, L_s is found to be 340 ft. This is almost one-third less than the 480 ft, which would be used if it were assumed that the length of transition should be proportional to the change in superelevation. This is an advantage in locations where the tangent distance is limited, which is probable where the curves are sharp enough to require the maximum allowable superelevation. On the other hand, if the tangent is not limited, and if the introduction of a longer transition is feasible, the writer suggests that double the values of L_s given by Equation (22) be used. When the transition is quite long, the rounding at its ends may be an unnecessary refinement, in which case a straight-line transition may be used.

Grades.—Safety on icy pavements does not justify limiting grades to 5%, assuming there are no other considerations making such a limit desirable. The extra cost of grading or the disadvantages of the more tortuous alignment necessary to provide a 5% grade may far exceed the accumulated cost of spreading sand or cinders over the icy pavement from time to time during the winter months.

If there is relatively little truck traffic, short lengths of 8% grade on tangent are not objectionable, but long grades should not exceed 7% on tangent, and should be compensated on curves. A gently rolling profile with very few, if any, tangents produces a more pleasing appearance than a series of tangents connected with comparatively short vertical curves. At summits, vertical curves should be flat enough to provide a sight distance equal to the distance required to stop a vehicle. If the design is a two-lane, two-way road, then passing would not be permitted on summits, but would be provided for at frequent intervals by sections of road allowing much longer sight distances on horizontal and vertical curves.

The normal length of head-light beam will not be affected if vertical curves of the foregoing standard are used, because, especially on a black road, the lights are of little value more than 300 ft ahead of the car, or, say, 400 ft with the brightest lights allowed by present regulations. At that distance, the edge of the road cannot be distinguished. An object, such as a cow, in the middle of the road is not recognized as an obstacle until the car is within 400 ft of it.

Sight Distance.—Tests conducted by the writer show that a wet bituminous surface may have a coefficient of friction as low as 0.54, and that when traveling at high speeds, it is dangerous to apply the brakes hard enough to develop all the coefficient of friction, especially on a curve. Using 0.40 as a safe maximum, and allowing 1.5 sec for the average driver to re-act in an emergency, the formula for stopping distance (on level grade) becomes,

$$s = 0.0835\ V^2 + 2.2\ V \quad \text{.......... (23)}$$

Sight distances, both on vertical and on horizontal curves, should be not less than the stopping distance, as computed, using the safe maximum speed in Equation (23).

Conclusion.—The writer endorses the remainder of the paper. Classifying accidents according to three types of contributing factors—faulty cars, roads, and drivers—only 5% of the accidents are found to be the result of faulty cars; about 20% result from faulty road construction, and the remaining three-fourths result from faulty drivers. It is true that there are often poor features of road design involved, but the drivers show bad judgment in not allowing for those poor features. In support of the foregoing, statistics show that, in any one year, about 75% of all drivers have no accidents, and that 5% of all drivers have about 30% of the accidents. Several commercial firms, employing more than 1 000 drivers, have succeeded in reducing their accident rate to one-fifth, by eliminating drivers who were frequent repeaters.

A study of railroad grade-crossing accidents provides some insight into the actions of the average driver. In several million observations, about 10% of all drivers were classified as not exercising reasonable care in crossing tracks. When drivers survive an accident, they often claim that they never saw a train on that particular crossing before, and, further, claim they neither heard nor saw the train, although facts prove that it was impossible for a normal person not to have done so. Perhaps that is why many drivers overtake and pass cars at summits of hills, because they have never been caught by a car coming toward them on that particular hill! No wonder there are so many collisions on the highways if some persons drive "blind" and "deaf", and if 10% do not exercise reasonable care in driving!

The writer recommends that about 5% of drivers, the more prolific accident-makers, be deprived of the privilege of using the highways. Then, with the improvement of highways by designing for a safe, reasonable speed, and the positive regulation of traffic to conform to that speed, the accident rate should be reduced to a point well below one-fifth the present rate. This can be done, as proved by Evanston, Ill., that cut its accident rate to only 7% of its former rate within a few years.

It is to be hoped that there soon will be a nation-wide standardization and enforcement of traffic rules and licensing of drivers, and a standardization of features of road design.

H. W. Giffin,[13] Assoc. M. Am. Soc. C. E. (by letter).—Some interesting questions as to the future of highway systems in the United States is raised in this paper. The subject deserves the attention of highway designers, administrators, and the general public. Before consideration of details of design three questions of a fundamental nature arise: (1) Is there a present need and demand for express highways as described in the paper? (2) Can they be operated safely? (3) Is there economic justification for them? Discussion of some of the phases of the present highway situation may throw some light on the future. Highway safety is much in the public mind and certainly every one concerned with the administration and design of highways should give serious thought to it in contemplating the highways of the future. A favorite method of foretelling the future is to examine the past for

[13] Field Engr., State Highway Dept., Trenton, N. J.

trends and to project these trends forward. Trends have a way of continuing, but many of them decrease in pace and some, finally, come to an end. Each trend should be examined carefully for those factors responsible for its growth and the conditions favoring its continuance.

One of the conspicuous trends of the past is the higher average speed of automobile operation. Four-wheel brakes, low centers of gravity, better tires, better metals in improved power plants, and straighter, wider, and better surfaced highways have supported this trend. Will it continue and, if so, how far? Will it reach 100 miles per hr as an average, or for large numbers of vehicles, on the main roads? To-day, occasional vehicles operate at that speed at a few places. Is this an indication of future average conditions? On the other hand, what tends to arrest this trend?

Perhaps the increase in the accident rate which is now arousing the public will act as a damper. Can accidents be attributed to speed? Perhaps not altogether, but few will deny that speed is a contributing cause. Of ten accidents picked at random, how many would have been avoided by a reasonable reduction in speed? The effect of a reduction in speed is to give a greater margin of time and distance to avoid trouble. As most accidents occur within 2 or 3 sec, an extra second means much in deceleration or in steering clear of an object. Furthermore, the seriousness of many accidents is a function of the speed at contact.

It is maintained by some that the combination of speed and bad driving, and not speed in itself, is the cause of accidents. Most drivers over-estimate their ability to drive safely at the higher speeds. The formation of situations likely to result in accidents is of very frequent occurrence. Often, considerable skill is necessary to avoid contact. Should not good driving prevent the formation of such situations? One might define good driving as always having the vehicle under that degree of control which permits a sufficient margin of time and distance to take appropriate action to avoid contact. By this definition how many drivers would be classed as good? Even the best of drivers have lapses of inattention and absent-mindedness, and are saved from accident by fortunate circumstances. Any interested observer can testify to the many instances of bad driving he has seen. How many drivers never drive faster than is warranted by the range of their lights? What is the proportion of good and bad driving on high-speed highways? Should not something be done about the bad driving before average speeds increase?

Perhaps in the future there will be some method of eliminating the bad drivers and educating the others into being good drivers. How fast, then, can a good driver drive? The manufacturer constantly is improving the "roadability" of the automobile so that the individual can keep the vehicle on its course more easily. No one can foretell what the limit may be. Probably, however, there will always be a need of sudden stops as long as the operation of automobiles remains subject to the whims and judgment of individuals. As far as can be foretold now, the rate of deceleration of the vehicle must always depend on friction. The surfaces of roads, brakes, and tires may be

improved in this respect, but it does not appear that any great improvement can be made in this direction. Certainly, the rate of vehicle deceleration cannot go beyond the possible rate of deceleration of the human body without injury.

With all the engineer can do to build safety into the road he cannot build good driving by individuals into it. That must always remain a matter of individual responsibility. Whether or not the engineer improves alignment, widens pavement and shoulders, separates grades by bridges, separates opposing lines of traffic, and solves the problem of posting adequate and proper signs, there will always be individuals who will drive carelessly and too fast for the conditions. There are some hazards, furthermore, which the engineer cannot remove, such as fog, sleet, and blinding snowstorms. It lies within the ability of the highway designer to design reasonably safe roads for the use of prudent drivers. Is it possible or desirable to try to go beyond this ideal? Many modern roads have all the features of safe design for reasonably prudent drivers, and yet the accident toll on them continues at an alarming rate. It seems that the removal of each hazard adds an increment of speed.

From an economic standpoint the justification of the construction of express highways must rest on their capacity to carry a very large number of vehicles and to save for them something worth the cost of the highway. Either distance, time, annoyance, operating cost, or dangerous conditions must be decreased. Distance often can be reduced by re-alignment, but for the main lines of travel it is doubtful whether this reduction would amount to more than 5% were all the main roads rebuilt on new alignment. Saving in time would depend on the saving in distance, elimination of stops, and a higher rate of speeed. The operating cost of automobiles is a function of speed, the increase being very rapid beyond 40 miles per hr. Improvements in the vehicle of the future will undoubtedly effect greater savings in operating cost, but the relationship of increased cost for high speeds will probably hold. Hazard on the main roads is almost entirely a function of speed and of the volume of traffic.

There is another economic aspect to the subject of express highways. There are now extensive systems of transportation by road, rail, water, and air in the United States. Each system is capable of producing a certain kind of service with the greatest advantage. Some overlapping of service is inevitable, and even essential, so that each system will render the best possible service in its field. The modern highway has already encroached upon the field formerly regarded as belonging to the railroad, forcing the railroad companies to re-adjust the service offered to the public. This development can be regarded as healthy as far as it has gone to-day and perhaps it can go still further without harm; but it seems probable that the principal railroads of the future will furnish a service not economically furnished by the highways. Is there need and economic justification of providing complete duplication? Are there not many highways yet to be built before there is necessity for further rapid encroachment on the railroad field? The railroads are

adjusting their service to provide safe and comfortable means of travel for long distance at high speed. For speeds beyond those which the railroads of the future will provide there are airplane systems. Is the highway, with its individualistic mode of operation, an ideal system for providing all kinds of transportation service?

As better highways are built, the older roads suffer by comparison in the public mind; but all roads not conforming to the highest standards of design should not be thought obsolete. Their useful life is not nearly ended because they must be an important part of the highway system for many years. Day after day many of them are providing a service commensurate with the needs, and producing a return commensurate with the investment in them. Of course, many others can be rebuilt economically and, when rebuilt, should be changed to provide better service; but there are many which, although they are not so efficient as new ones would be, cannot be re-designed for a long time. Nor are they generally regarded as dangerous, inasmuch as they are driven at slower and more economical speeds by those who have become accustomed to them. An examination of the accident records of these roads does not indicate that they should be discarded.

There is one accident for approximately 200 000 miles of driving. If one could witness 200 000 miles of driving by one person—or better, 50 miles by 4 000 persons—over average streets and roads, one would see a wide range of speeds, great difference in the skilful handling of motor vehicles, and all shades of driving between good and bad; and yet only one accident would occur involving injury to driver, passenger, or pedestrian; 3 999 out of 4 000 would come through a 50-mile trip safely. What is a reasonable conclusion to draw from this fact?

Although the automobile manufacturer has done a good job in production, both from an economic standpoint and from that of convenience and safety, modern automobiles are now equipped with power plants far beyond the needs or even desires of the average motorist. This excess power is seldom used; it is an economic waste and probably a contributing cause for much bad driving. It has been said that excess power is very convenient in an emergency. On the other hand, the mere possession of it often invites the creation of such an emergency. The lack of it would force a reduction in high speed and, by and large, would be far safer. It is emergencies of this nature which require exceptionally good driving by others on the road. Is the fact that the manufacturer is providing something not needed and not in the public interest a valid reason for building roads to keep pace with it? If permitted, the manufacturer of the future will probably be able to supply power plants capable of speeds of 200 or even 300 miles per hr. Imperfections of the mechanical machine are gradually being overcome; but the human machine is the limiting factor in the attainment of highway safety.

The problem of the future highway, then, is related to the capacity of individuals to drive safely, to their economic needs, and to the standard of living of the motorist on which the cost of improvement must rest. There

is much that is not clear, much that is unknown, and many questions to be answered before the specification for the future highway can be written. In the meantime, the highway engineer will continue to do what he can to interpret the immediate needs of the large majority of motorists, to build well in accordance with the funds provided, and to try to eliminate road hazards which conceivably are contributing causes of accidents. What lies beyond must await future developments.

T. T. Wiley,[14] Jun. Am. Soc. C. E. (by letter).—In presenting this paper the author has afforded a timely opportunity for discussing some of the factors that affect the design of the modern highway. The design of many highways and highway structures under construction to-day is scarcely adequate for safe driving at modern-vehicle road speeds and, if the present progress in motor-vehicle design is continued, the roads being built to-day will be obsolete almost before they are completed. A discussion of superelevation and curves seems especially pertinent, because these are features of design that have a direct bearing on safety and that have not been given the attention and study that they deserve.

It is true that Equation (1) yields rates of superelevation that are higher than required for safe and comfortable riding. However, the practice of using a speed lower than the design speed in this equation is not satisfactory. A more scientific attack on this problem can be made by considering the forces that prevent side-slip outward when the speed of travel is such that the resultant of the mass of the vehicle and centrifugal force is not normal to the pavement. When these frictional forces are considered, Equation (1) becomes,

$$E = 0.067 \frac{V^2}{r} - f \text{ ....(24)}$$

in which f is the average coefficient of friction developed between the tires and the pavement in order to prevent side-slip.

Values of f varying from 0.15 to 0.20 have been used, but investigations have indicated that they are too high for comfortable riding and safe driving. The writer conducted a brief series of tests to determine the safe speed on curves, using Equation (24) and the definition that the safe speed was "the minimum speed at which the driver or passenger feels a side pitch outward." Two cars with a driver and one or two passengers were used for this investigation. One car was equipped with knee action and the other with transverse springs.

Test runs were made in both directions on seventeen curves, and the speeds at which side pitch became noticeable were determined Additional runs were made at speeds calculated from values of $f = 0.15$ and $f = 0.10$. Table 3 gives the curve data, test speeds, and values of f.

[14] Junior Highway Engr., State Div. of Highways, Springfield, Ill.

TABLE 3.—Tests to Determine Safe Speed on Curves

Curve No.	Degree	Superelevation, in feet per foot	Speed for side pitch, in miles per hour	Coefficient of friction, f, for side pitch	Velocity, V, in Miles per Hour: For $f = 0.15$	Velocity, V, in Miles per Hour: For $f = 0.10$	Curve No.	Degree	Superelevation, in feet per foot	Speed for side pitch, in miles per hour	Coefficient of friction, f, for side pitch	Velocity, V, in Miles per Hour: For $f = 0.15$	Velocity, V, in Miles per Hour: For $f = 0.10$
1	11	0.05	35	0.11	39	34	9	3	0.058	60	0.07	77	67
2	17	0.062	30	0.12	33	28	10	5	0.092	50	0.06	64	57
3	11	0.075	30	0.04	42	37	11	5.5	0.067	45	0.06	59	51

6	5	0.017	35	0.07	53	45	14	5.5	0.083	45	0.05	60	53
7	9	0.042	33	0.07	41	37	15	5.5	0.083	45	0.05	60	53
8	3	0.000	50	0.09	65	53	16	13	0.054	30	0.06	36	32
							17	12	0.062	30	0.07	39	34

The following conclusions were obtained as the unanimous opinion of all persons who participated in the tests:

(1) The speeds at which side pitch first becomes noticeable are slower than necessary for comfort or safety;

(2) The speeds which require a friction coefficient of 0.15 create very definite side pitches of such magnitude as to be uncomfortable, require undue effort in steering, and often border on being dangerous, particularly when meeting traffic; and,

(3) The speeds which develop a friction coefficient of 0.10 create definite side pitches that are reasonably comfortable, require appreciable but not excessive steering effort, are not dangerous, and are fast and reasonable speeds in every case.

In the author's example for determining the minimum radius by using Equation (1), the design speed was 100 miles per hr and the rate of superelevation was 1 in. per ft of width. Then, the assumption was made that it would be satisfactory to design for 60 miles per hr and the minimum radius was calculated as 2 900 ft. The danger in making such an assumption is shown by taking the same example and solving for the radius, using the true design speed of 100 miles per hr and Equation (24) in which f is taken as 0.1. From this formula, the calculated minimum radius becomes 3 700 ft. The difference between this radius and the one obtained by using the methods now in common use certainly indicates the need for more scientific design of curves, particularly for high speeds.

Table 3 shows a considerable range in the values of f for speeds which first create side-pitch. There are several reasons for this, one of which is the personal element which existed in noting side-pitch. However, certain physical characteristics of the curves also cause these differences. Such items as grade, length of run-off, and roughness of the pavement, undoubtedly affect the results of such tests and indicate that these items must be considered in design. This leads directly to the author's discussion of the transition

between normal crown and superelevation, and his statement that "it is doubtful whether spiral curves will be necessary."

If the design is "to be such that the vehicle may enter and leave the curve smoothly—almost automatically", the spiral will be necessary on all superelevated curves. Although engineers know that the spiral provides a uniform rate of change in degree of curve, many of them fail to realize that its principal advantage is that it also provides a uniform rate of change in the superelevation so that the superelevation at any point on the spiral or curve is in exact agreement with the degree of curve at that point.

There is no need for presenting the theory of the spiral because several useful spirals have been developed. However, railroad engineers have learned considerable about curves and spirals, and their knowledge can, and should, be applied to highway design; for example, they have found that superelevation cannot be introduced across the track gage at a rate greater than $1\frac{1}{4}$ in. per sec without creating an uncomfortable riding condition. Therefore, superelevation on a highway should not be introduced at a rate exceeding 0.02 ft per ft per sec, and the length of spiral on a curve with a superelevation of 1 in. per ft should approximate the distance traveled in 4 sec at the design speed. On this basis, curves designed for a speed of 100 miles per hr, with superelevation of 1 in. per ft, should have a spiral approximately 600 ft long.

Highway engineers are loath to accept the spiral as a necessary feature of design, partly because they do not realize the ease with which it can be calculated and applied. The writer was taught a type of spiral which requires about 10 min of calculation in preparing the field notes and a negligible amount of excess time in staking out the spiral and curve. Resort to tables is unnecessary.

The author states that "failure to attribute accidents to faulty road design is due to several causes principal of which is the subtlety of the problem." This is probably true especially with respect to accidents at curves, which too often are listed as being caused by driving too fast for conditions.

An automobile entering a curve is subjected to new forces and, at modern fast speeds, these forces often change in magnitude and direction very rapidly. Superelevation for curves is usually introduced on the tangent over a distance termed the "run-off." A vehicle traveling over the run-off is subjected to a lateral force which must be overcome by turning the steering wheel in a direction opposite to that of the curve. Otherwise, the vehicle will move toward the inside of the curve, thus crowding the center line or pavement edge with occasional disastrous results.

The instant the car enters the curve, forces acting on the car change instantaneously, requiring a very rapid and usually complete reversal in the direction of steering. The changes may be so great that the steering wheel cannot be turned rapidly enough and the car is thrown partly or wholly out of control and an accident results. The subtlety of the problem now enters, for the accident report states "driving too fast for conditions." Is the mistake in the driving or in the conditions? The common assumption is that it is the driving. Engineers familiar with the spiral will claim that the conditions are at fault. There is absolutely no reason why the driver should have to attempt

to overcome the sudden change in forces because a properly designed curve will be spiraled and a sudden change of any appreciable magnitude in the forces which must be overcome by steering will never occur.

The writer has expressed the opinion that Equation (24) gives satisfactory results in computing curve requirements. This formula was not advocated because it is better than Equation (1), but because it is better than Equation (1) as ordinarily used. In other words, Equation (24) is a logical way to take into consideration the degree of overbalancing that can be tolerated in rounding a curve, whereas the attempt to do this by substituting a speed less than the design speed in Equation (1) is not based upon scientific analysis and is often unsatisfactory. Equation (24) should afford a desirable "minimum standard", but if highways are to be designed for the greatest safety, why not adopt the best available, which is Equation (1) using the true design speed rather than a guess at a "safe" speed? Similarly, spiraled curves are certain to be safer than non-spiraled ones. Use the spiral.

Incidentally, this contention is applicable to many other design standards. Too often a "minimum standard" becomes "the" standard, so that, in many instances, standard curves of 1 500-ft radius have been built where flatter curves would have been just as economical and certainly more desirable. The highway engineer must remember that a minimum standard is the worst that he is permitted to use, and that good design requires the use of something better than the minimum allowable if it is reasonably practical. To use minimum standards when better can be obtained is usually "penny wise and accident foolish."

The writer cannot agree with the author's general contention that signs constitute a hazard. Wooden posts, 4 in. square, furnish excellent mounting for signs and, if struck by a car moving at a fair rate of speed, they snap off without causing appreciable damage to the car. The types of signs now in use would be useless because of lack of visibility, if suspended from overhead cables. Flexible standards of sufficient rigidity to furnish adequate support for standard signs subjected to wind pressure, vandalism, and other buffetings would be just as dangerous as wooden posts.

A properly designed modern highway should require few signs. If the design speed is to be placed at a limit, such as 100 miles per hr, the "standard" signs now advocated will be wofully inadequate.

The author is to be commended for emphasizing the fact that the highways being built to-day are scarcely abreast of the car of to-day, not to mention the car of the future. The highway engineer must exercise his imagination to visualize the conditions that will exist in the years to come, and base his work upon the conviction that the best design is scarcely good enough.

F. L. McRee,[15] Esq. (by letter).—Considerable food for reflection and thought is presented in the paper by Mr. Noble. There is no doubt that steps should be taken to reduce the appalling death rate on highways in the United States. However, it is a moot question whether or not increased

[15] Associate Prof. of Civ. Eng., Texas Technological Coll., Lubbock, Tex.

safety in design will bring about the desired result. Since a large percentage of the automobile accidents are caused by a small percentage of the drivers, can engineers produce a design that will be safe for these few inherently reckless drivers?

The trend is, and will continue to be, toward faster motor-vehicle speeds, unless legal steps are taken to prohibit the increase. Motor-vehicle manufacturers have increased the speeds of their vehicles from year to year because the people have demanded it. As the author points out, there are few existing highways that can accommodate these speeds. John W. Wheeler, M. Am. Soc. C. E., has made[16] the statement that some highways are antiquated before they are built—a very broad statement, but which, nevertheless, may be true.

The author's idea of a dual highway appears to be good, but will the people submit to the cost of the suggested wide right of way? It seems to the writer that the width could be reduced considerably and still serve the purpose. It is doubtful whether truck traffic will need two lanes in each direction for many years to come. Furthermore, why should the people have their money tied up in an extensive investment to provide for truck lines of the future?

Restricting rural entries to 10-mile intervals makes it very difficult for the rural resident who may have to travel 10 miles to visit his neighbor who lives directly across the highway. Rural entries are undoubtedly a source of danger, but it seems unreasonable to restrict these entries to such long intervals. The people living in rural communities help pay for the highways, and, in return, expect to make use of them. The only basis on which rural entries could be restricted would be to provide parallel slow-speed roads which would increase costs and still impose a hardship on rural residents.

It is very necessary that curves be properly superelevated. The flat or insufficiently superelevated curve becomes a source of great danger with present high motor-vehicle speeds. The frictional resistance between tires and pavement surfaces should be given serious consideration in determining the superelevation. Investigations conducted at the Iowa Engineering Experiment Station[17] indicate that a working coefficient of 0.30 can be used safely, even for wet pavements. This will permit much higher speeds than the theoretical for which the curve is superelevated.

Equation (1) can be modified to take account of the frictional resistance. From mechanics, it can be shown that,

$$\tan(\theta + \phi) = 0.067 \frac{V^2}{r} \qquad (25)$$

or, in terms of the degree of curve, D,

$$E = \tan(\theta + \phi) = \frac{DV^2}{85\,800} \qquad (26)$$

in which θ = the angle of superelevation; $\phi = \tan^{-1} f$; and f = the coeffi-

[16] *Civil Engineering*, June, 1935.

[17] *Bulletin 120*, Iowa Eng. Experiment Station, Iowa State Coll., Ames, Iowa, August, 1934.

cient of friction. If the coefficient is used as 0.3, ϕ becomes 16° 42′. As an example, suppose that the minimum superelevation is required for a 3° curve and a speed of 100 miles per hr: $\tan(\theta + \phi) = \frac{3 \times (100)^2}{85\,800} = 0.35$; and $\theta + \phi = 19° 17'$. For $f = 0.30$, $\phi = 16° 42'$; and, therefore, $\theta = 2° 35'$; $\tan 2° 35' = 0.045$; and, by Equation (26), $E = 0.045$ ft per ft.

A solution of the author's problem of finding the sharpest curve for a maximum superelevation of 1 in. per ft by the foregoing would be: $\theta + \phi = 4° 46' + 16° 42' = 21° 28'$; $D = \frac{85\,800 \times 0.393}{(100)^2} = 3° 22'$; or, $r = 1\,700$ ft.

In any consideration of superelevation of curves, minimum speeds should be considered. When ice forms on a pavement the coefficient of friction sometimes becomes very small and vehicles tend to slip toward the inside of the curve. This is particularly true for slow-moving, heavily loaded trucks. These considerations should limit the maximum superelevation to be used.

The minimum speed on superelevated curves is given by Equation (26) solving for V.

Assuming a coefficient of friction equal to 0.10, the minimum speed for the example noted would be zero since the friction angle is 5° 43′; that is, $\theta - \phi$ is negative, showing that, theoretically, a negative speed could occur without skidding.

Fig. 7 shows the minimum superelevation for a speed of 100 miles per hr and a coefficient of friction of 0.30, and also the maximum for a speed of 10 miles per hr and a coefficient of friction of 0.10, 10 miles per hr being assumed as the minimum speed likely to occur. It is not reasonable to assume that the curves would be built flat up to 2° 30′, therefore, the suggested superelevation is indicated. Diagrams similar to Fig. 7 can be drawn for any coefficient of friction that is assumed to be reasonable.[37] Table 4 shows values of the maximum speed for $f = 0.30$; maximum and minimum speeds for $f = 0.10$; and the theoretical speed for which the curve is superelevated ($f = 0$), all based on the suggested values of superelevation.

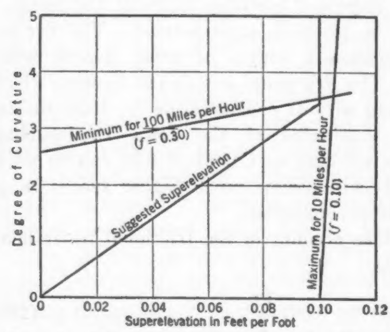

FIG. 7.—MINIMUM SUPERELEVATION FOR A SPEED OF 100 MILES PER HOUR; MAXIMUM SUPERELEVATION FOR A SPEED OF 10 MILES PER HOUR; AND THE SUGGESTED SUPERELEVATION.

The writer cannot agree with Mr. Noble that spiral curves are unnecessary, or that a motor vehicle has sufficient room within its lane to form its own spiral. For a motor vehicle to enter or leave a curve smoothly the curve

should be spiraled and the spiral should be of sufficient length to accommodate the maximum speed for which the highway is designed.

TABLE 4.—MAXIMUM AND MINIMUM SPEEDS, AND THE THEORETICAL SPEED FOR WHICH THE CURVE IS SUPERELEVATED

There is considerable disagreement among highway engineers as to the proper length of spiral. Past practice has been to use spirals that are too short. The American Railway Engineering Association has found by experiment that the maximum rate at which the tilt of superelevation can be attained without discomfort to passengers is about 2 in. per sec. There is no valid reason why the same rule will not apply to highway curves. Using 58 in. as the average width of automobile tread and E as the superelevation, in inches per inch of width, the total tilt would be 58 E in. The minimum time in which this tilt should be attained is $\frac{58\,E}{2} = 29\,E$ sec which gives the minimum length of spiral in terms of the velocity, V_s, in feet per second, as $L_s = 29\,E\,V_s$. Changing the velocity, V, to miles per hour the expression becomes,

$$L = 42.5\,E\,V \quad \text{.......................(27)}$$

in which E = the superelevation, in feet per foot.

Another method proposed for determining the minimum length of spiral is based on the maximum rate at which a motor vehicle may change its radial acceleration without discomfort and danger. Experiments conducted at the Iowa Engineering Experiment Station[17] indicate that this value is from 2 to 3 ft per sec per sec per sec, with 2 ft as the recommended value. The engineers of the State Highway Department of Oregon use a value of 3 ft per sec per sec per sec for their spirals in planning their highways for a speed of 100 miles per hr. The radial acceleration varies from zero at the beginning of the spiral ($r = \infty$) to $\frac{V^2}{r}$ at the end. The time in which this acceleration is attained is $\frac{L}{V}$ sec. The rate of change of acceleration, then, will be:

$$d = \frac{V_s^2}{r} \div \frac{L}{V_s} = \frac{V_s^3}{L_s\,r} \quad \text{.....................(28)}$$

Using a value of 3 ft per sec per sec per sec for this rate of change, changing V_s to miles per hour, and replacing r by $\frac{5\,730}{D}$:

$$L_s = \frac{DV^3}{5\,450} \quad \text{.........................(29)}$$

The writer favors using the expression that gives the greatest length of spiral.

Some engineers follow the practice of spiraling the center line of the pavement and offsetting to obtain the line for the pavement forms. It is much easier, and more accurate, to run separate spirals for each edge of the pavement. With widened pavements separate spirals should always be run on account of the longer length of the inside spiral. A good method is to compute the minimum length of spiral from one of the foregoing expressions, use this length to the nearest 10 ft for the outside edge of the pavement (unless the run-off of the superelevation requires a longer spiral), and then compute the length for the inside edge. This inside length is fixed by the length of the outside spiral and the widening.

Referring to the preceding statement that a motor vehicle does not have room to form its own spiral within its lane, it can be shown that the shift or offset, p, for a spiral is given by the following formula:

$$p = \frac{D^3\,V^6}{408 \times 10^{10}} \quad \text{.........................(30)}$$

The derivation is based on the A.R.E.A. spiral expressions and Equation (29). Using a 3° curve and a speed of 100 miles per hr, the offset is $p = 6.6$ ft. If a value of 2 ft per sec^3 for the maximum rate of change of radial acceleration had been used in developing Equation (29), the spiral offset for this degree of curve and velocity would be 15 ft. Obviously, a motor vehicle cannot form its own spiral within a 10 or 12-ft lane when the offset is so large.

It appears that there is a tendency among highway engineers to avoid the spiraling of highway pavements because of the supposedly complicated computations involved. The A.R.E.A. spiral can be adapted easily to highway pavements, and the writer cannot agree that the computations involved are too complicated. Even if they were complicated the engineer should be willing to do the necessary work when increased safety is the goal.

THERON M. RIPLEY,[18] M. AM. SOC. C. E. (by letter).—The "express highway" is given as the principal antidote for accidents and fatalities and in this development the highway engineer is implied to be the contributing cause of the present accident record due to improperly designed travel lanes. The experience of seventeen years in the design, construction, and maintenance of highways and the study of traffic compels the writer to take issue with the foregoing assumption. He has seen the 14-ft, the 16-ft, and the 18-ft, two-way pavement, each in turn, abandoned for the 20-ft lane with all the attendant improvements in grade, alignment, and crossing elimination. The self-pro-

[18] Cons. Engr., Buffalo, N. Y. Mr. Ripley died on November 30, 1936.

pelled vehicle has changed from an oddity and a toy to the commonplace and a necessity, and the dirt road to a paved street; yes, for many hundred miles, to a boulevard.

The discussion of the highway traffic situation, apparently, has arrived at that stage which can be represented by the man suddenly awakened by an unusual sound: when he is so awakened his first impression is one of bewilderment and he attributes the sound to one of great magnitude and danger. This is a natural reflex from the first law of Nature—self-preservation. In May, 1934, under the title, "The Balance Wheel", the president of a large corporation attempted to keep the feet of his organization on the ground by writing a few truths which are as applicable to the present highway situation as they then were to the petroleum industry. He said in part:

"This is a time when mental indigestion is epidemic. The seats of learning have become sounding boards for intellectual jazz, and the Doctor Cooks of economics are having a field day.

"The statement that two and two are four lacks intrigue or interest, and arguments to the effect that, in this modern time, two and two make five are the sex appeal of current economics. It is a day of intellectual emancipation, and it should not be turned into a period of mental anarchy.

"These observations apply only to current discussions on religion, morals, politics, business, art, and science. Otherwise, things are normal.

"The balance wheel has its uses even though it is not spectacular."

Under "Introduction" the first subject mentioned by the author is "the enormous loss of life and property on American streets and highways" and, included in this paragraph, is a table (Table 1) showing the number of persons injured, the number killed, and the total number of accidents in 1935. For the convenience of the reader the original table[19] is reproduced as Table 5 for the record.

After stating that "the reckless and unsafe driver must be considered", the author finishes his "Introduction" with the statement that "the injuries and the loss of life and property on American highways are issues squarely facing the highway engineer. It is his duty to design the highways so that the traveling public is safeguarded." A study of the accident record, perchance, may show where the engineer has failed.

As Table 5(*a*) shows that 79.0% of all accidents, 87.2% of all fatalities, and 78.6% of injuries happen "going straight", it seems reasonable to assume that doing away with all curvature is not the answer to the prevention of trouble. If the engineer is to blame he must look further into the causes.

Table 5(*b*) is a breakdown of the items in Table 1 of the paper. Of Table 5(*b*) the compilers[19] wrote:

"Although total deaths last year [1935] exceeded fatalities of the year before by around 300, mistakes of drivers figured in nearly 1 500 more deaths than in 1934. That means the time for dilly-dallying about what to do to restrain careless drivers has long since passed. Drivers who will not act safely must be forced to change their conduct. Else they must be kept off the road."

The greatest number of fatalities, under one heading, is seen to be "Pedestrians"; these are segregated in Table 5(*c*). It is believed to be a fair

[19] See "Live and Let Live", Travelers Insurance Co., Hartford, Conn., p. 4.

assumption that all the items in Table 5, from Items Nos. 23 to 38, inclusive, can be assumed as wholly within urban communities. If this assumption is used for argument, then it is found that 12 020 fatalities occur in cities and villages and 3 030 fatalities in rural communities, with 980 fatalities to be distributed. If the 980 fatalities are divided between the two known localities on the basis of the assumed known amounts, the 16 030 total will be divided into 12 805 urban and 3 225 rural. It is self-evident that rights of way of 300 ft, or more, in width cannot be secured in urban centers; therefore, in order to save 80% of the disappearing pedestrians the engineer must look to some other savior than the width of the highway.

TABLE 5.—Conditions Resulting in Persons Killed and Injured in 1935

Item No.	Description	Accidents		Persons Killed		Persons Injured	
		Number	Percentage of total	Number	Percentage of total	Number	Percentage of total
	(a) Effect of the Direction Cars Were Traveling						
	Vehicles:						
1	Going straight	653 090	79.0	31 480	87 2	703 690	78.6
2	Turning right	20 670	2 5	610	1 7	23 280	2.6

52	Totals	826 690	100.0	33 410	100.0	793 280	100.0

Considering the remaining 20% of walkers: It is possible that the construction of sidewalks in special localities might be of greater value than widening the right of way or separating the vehicle movements. Pedestrians will not walk over rough ground, through wet grass, or in the mud in greater numbers simply because a change has been made in the pavement or highway limits.

Assuming the statements in the preceding paragraphs to be true as to facts and probable action, the fatalities chargeable to the highways can be reduced by 16 030, to 20 070; but Table 5(*b*) shows 23 570 fatalities due to "Hasty, Needless, and Careless Action of Drivers" and, therefore, some of these quantities overlap. It may be only a coincidence that this overlapping is almost equal to the number "Walking on Rural Highway" (Item No. 35, Table 5(*c*)).

Considering now the matter of pavement condition, attention is called to Table 5(*d*) and Table 5(*e*), which show that 84.6% of all accidents happen on clear days; that 75.0% happen on dry surfaces; that 85.6% of fatalities happen on the former and 77.4% happen under the latter.

When the matter of design is considered in relation to fog, snow, and ice, and their effect upon traffic, it is seen that these "Weather Conditions" account for 14.4% of the fatalities and these "Road Conditions" for 6.9 per cent. The handling of ice and snow conditions upon the highway is, primarily, a function of maintenance. When the designing engineer has provided the necessary room for the proper functioning of the snow-removal equipment and personnel he will have done his duty. Ice and packed snow on the pavement must be looked after by the maintenance organization.

Artificial lighting of improved highways has been discussed for a number of years, but the question of cost and the inadequacy of the lighting equipment available have been deterrents in the adoption of a general policy. An idea of the influence of light upon fatalities and injuries can be secured from Table 5(*f*), which shows that "Dusk" and "Dark" claim 58.1% of the fatalities and 41.3% of the injured. Lighting, properly done, is not merely the placing of electric lamps along the roadside; the writer has seen more than one installation of that character which was more of a hazard than a help. The new lamps in the experimental installation near Schenectady, N. Y., will help to solve this problem.

The foregoing remarks, born of Mr. Noble's paper, may seem to exonerate the designing engineer, but such is not the intention. The engineer has his work to do. The writer desires to impress upon the reader that the principal reason for automotive mortality is the operator of the machine and, in a lesser degree, the pedestrian or his guardian; and that the reduction of accidents is to be accomplished, primarily, by education and law enforcement.

To design for a speed of 100 miles per hr, as suggested by the author, would require a major change in the designing trend. Dr. F. C. Stanley, Chief Engineer for the Raybestos Company, of Bridgeport, Conn., has published a number of papers and graphs relative to the stopping distances required by automotive vehicles under ideal conditions. His studies have resulted in the adoption of an empirical formula which shows that 444 ft is the distance to stop a car traveling at 100 miles per hr—this with a dry pavement and a car in perfect condition, and the operator with a reaction time of 0.75 sec. A speed of 45 miles per hr, which is now recognized as legal in some States, would require, under the same conditions, 90 ft in which to stop.

As the whistling snorer refuses to admit that he keeps the family awake, so, the driver of an automobile refuses to admit his responsibility for the highway slaughter.

Recently the technical and lay press has been writing about "friction" as being a major cause of highway accidents. Vehicle friction, or highway friction, or traffic friction may be good or bad slogans. The writer has never seen or heard brain friction mentioned and yet it may have a legitimate place in the discussion.

As an example of public reaction, to curb highway traffic damage, the State of New York voted $300 000 000 for the elimination of railroad-highway grade crossings. The record then showed that 4.5% of fatalities and 0.5% of all accidents happened at such crossings. Much of this money has been spent and many crossings eliminated but the slaughter continues, the motorist is as discourteous as ever, and traffic rules and laws are broken as of yore.

What the speed of highway traffic will be ten or twenty years hence no one knows and few are competent to make an intelligent guess. What is known is that a nap at the wheel is a free pass to eternity; that alcohol in the stomach and gas in the tank is a combination that can make shambles of the public highway; and that halfwits, nitwits, and morons are at the throttle

of machines of 60 hp and more, driving from somewhere to nowhere to do nothing when they get there and, in their joyously mad ride, they are a fatal menace to all other traffic on the highway.

Looking back to the water-bound macadam days of New York State and the time when a motor vehicle was a "red devil" which scared all the horses, and most of the drivers; and tracing the changes through the years to this day, it seems that both the civil and the mechanical engineer have done a most commendable job. Neither has reached perfection, but one has only to see what has been done adjacent to the larger cities in New York and other States, particularly in New Jersey, to realize that the highway designer is awake to the situation. To find the sleepers one must look in other directions.

The most potent cause of accidents, as well as the most difficult to control, is the driver. Fool-proof highways can not be built; therefore, a sincere effort must be made to keep the fools away from the steering wheel.

W. W. Crosby,[20] M. Am. Soc. C. E. (by letter).—This frank and forceful paper is a subject for congratulation; the cogent statements contained in it are most opportune. The author points out some fundamental defects of present highway designs. These latter are the direct reflections of engineering ideals, imagination, and effort, and he rightly implies that "safety" should be a feature of the results. This latter point the writer has been trying to emphasize for some time[21].

Too often, however, the engineer is restricted by higher authority (such, for instance, as his Highway Commission or Department of Public Works) from developing advanced or new ideas, or from attaining effective results along progressive lines. Even Governors have prevented highway authorities from attempting novelties; and legislatures have usually restricted the authority and activities of highway departments. An illustration of the latter may be found in many States where laws limit the width of public rights of way for roads to 100 ft, or similarly inadequate widths, and compel the highway officials to produce results within that insufficient strip.

Safety can be enhanced by better road design, but room for that must be provided for engineers to use. The provision of this "elbow room"[21], or right of way, generally depends more on the electorate, the legislatures, and the authorities than on the engineers. It is the duty of the engineer of course, to force his higher authorities toward—and even hard against—their limits when his technical knowledge and experience convince him that this should be done; but the extension or removal of those limits is in most cases the responsibility of others rather than that of the engineer.

The author's statement as to "broad highway economics" (see "Introduction") is mild. Until recently the preponderance of discussion on the subject has been along regrettably narrow lines. The writer welcomes the author's assertion because he has tried on various occasions to combat the narrower views expressed[21].

[20] Cons. Engr., Coronado, Calif.

[21] *Roads and Streets*, March, 1926, p. 154, and March, 1936, p. 48; also, "Notes on Highway Location", by W. W. Crosby, Chapter V *et seq.*, Gillette Pub. Co.; and the *Transactions* of the Society.

Under "Fundamental Concepts", the author's brief statement that the highway design should be such that "the motorist is led unconsciously to choose the safe act rather than that which is unsafe" deserves emphasis. The writer has previously expressed himself on this subject[23] and wishes here to applaud the author's statement. Similarly, Mr. Noble's endorsement of the "Dual Highway" has been supported by the writer[24] who, however, offers herein some discussion or emphasis of the details given[25].

If the central "110-ft reservation" (Fig. 1) is intended to be used later for the through ways (and each "pavement-one-way" for "service roadways"), the width (110 ft) may be insufficient. Otherwise, it is probably three to four times as much as is desirable, although the total width of right of way should be preserved.

The "Acceleration Lane" (Fig. 2) may be a questionable provision in many cases. The writer has learned from experience that dangers exist for a driver swerving from a closely parallel lane into a swift traffic current in the same direction. There is inevitably a "blind spot" in the left rear of a driver. It would be much better to bring the traffic from the side in on a track much more nearly normal to the through traffic so that the approach of the latter may be included in the usual front and side vision of the entering driver, even at the sacrifice of speed momentarily by the latter. The tangent of the curve on the turn to the "trunk highway" should go off the first half of that curve as drawn, making the angle with the trunk highway in no case less than 30°, and the "acceleration lane" should be abandoned as such.

Under "Details of Design", the writer agrees with Mr. Noble as to the need for longer vertical curves; but he believes that, for a maximum grade limit, the length of the grade should enter the consideration, together with the actual minimum rate of rise. With the improvements in cars, brakes, and tires, is not an increase of acceptable maxima for rates of grades now justifiable in many cases?

The writer wishes to add whatever emphasis he may be able to contribute to the author's statement following Equation (4), that "the passing menace is one of the most serious problems facing the highway designer."

Although in the past the writer has expressed himself quite fully as to "Signs"[26], he wishes now to applaud the author's remarks as to the need for signs "in advance" (see heading, "Signs"). He also agrees with Mr. Noble as to "obstructions, such as poles", etc., and as to "guard-rails". The writer would point out that, where guard-rails are unavoidable, their main objective should be to assist the driver to regain control of his vehicle on the highway.

In the "lighting" of streets the considerations are different in some respects from those on open roads. In both cases the glare of opposing headlights is a large factor in creating dangers. The dual highway removes this factor,

[22] *Roads and Streets*, October, 1934, p. 362.

[26] "Notes on Highway Location", by W. W. Crosby, Gillette Pub. Co., Chapter VI and p. 72.

and greatly simplifies the problem, if, in many cases, it does not eliminate it. "Roadside stand lighting" would probably be unobjectionable if the stands were back where they belong and where they would be on proper widths of highway right of way.

The author's remarks on "Terminals and Interchange Facilities" are extremely important. Their essence seems to be that these provisions (and many others in the design) should be made so that the driver will go automatically where he should, without delay or hesitation that may create danger for himself or others. "What looks right may be wrong, but what looks wrong cannot be right".[27]

The writer heartily endorses the first two paragraphs of Mr. Noble's "Conclusion." A few States might be credited with actually expressing some of the principles mentioned. The State of Washington is reported to have adopted the "dual highway" for all its East and West State routes. New Jersey seems to be establishing the ideal, and possibly there are other States that should be mentioned. Italy set the example which Germany is developing. Great Britain has provided legal authority for it.[28]

In the third paragraph of "Conclusion" the author seems to go a bit too far when he states that the highway engineer "controls the destiny of billions of dollars and tens of thousands of lives." The engineer is fated to be loaded with the responsibility, of course, but actually the final authority or "control" is beyond him many times. Prompt general recognition of this fact should result in an earlier realization of desirable ideals.

The author's reference (see heading, "Conclusion") to the obsolescence of highways in the United States deserves emphasis and perhaps elaboration. The writer, therefore, ventures to append the following at this opportunity. In these days, "three things are certain: Death, Taxes, and Obsolescence." Obsolescence is a greater and more formidable menace on roads than on any comparable line of approach. It seems that the highway authorities to whom the public has the right to look for relief are actually doing the most to bring about the enormous penalty of antiquated, inefficient, and obsolescent public roads.

Generally, it may be stated that public road authorities are spending hundreds of millions of dollars annually "slicking up" a type of highway, which, when "perfected" will not only be inadequate for its purposes, but which also will *per se* hasten its own condemnation as being antiquated, effete, inefficient, out of date, and as requiring a substitute.

With a few notable exceptions, State and National highway authorities seem to cling to the ideal of the single-roadway type, and seem to be making no provision for its transformation into a better one even if they actually are conscious of its imminent obsolescence.

The opportunity for escape from the impasse ahead is so often neglected that one is almost forced to believe that they are not even looking ahead. Merely securing the extra width of right of way for the double-roadway type (while it is undeveloped and, in many cases, of no considerable value), would

[27] "Notes on Highway Location", by W. W. Crosby, Gillette Pub. Co., pp. 78, 130–132.

[28] *Roads and Streets*, October, 1936, p. 83.

postpone the obsolescence indefinitely, beside securing concomitant benefits of immeasurable value. Instead, the practice seems to persist (even across waste lands) in taking only a 100-ft right of way, or even less, when 300 ft or 500 ft might just as well have been had. Later widening of the right of way is then almost always impracticable.

It is probably too early to forecast accurately all the effects on highway design that may come from the future of "trailers." Their use is estimated as 100 000 in 1936 and this number is increasing rapidly. It is certain that they will hasten the arrival of the "Pairway"[28], and, hence, the need for width in which to build and to operate it.

According to a recent article[29], expenditures of $15 000 000 000 since the turn of the century, in the United States, have yielded a highway system unfit for modern motor traffic. The statement may be a bit extreme, but there is no doubt that the enormous expenditures made and annually being continued are rapidly bringing this country to that position when the highway authorities will have to retrace their steps, or seek a new course, at an immense cost of money and lives.

Highway engineers should urge the authorities that rank above them to adopt a new ideal for the public road. They should visualize divided roadways instead of the single broad pavement as something to work toward more or less gradually. They should urge the provision, as promptly as may be, of ample rights of way for that purpose; and, as engineers, they should do their utmost to have the safety built into, and the absolescence built out of, the highway.

RICHARD S. KIRBY,[30] M. AM. SOC. C. E. (by letter).—It is high time that automobile manufacturers and highway builders interchanged views. The former, in urging the public to invest in cars capable of speeds as great as, and even more than, 100 miles per hr are lacking in a sense of social responsibility and are blinking at certain obvious physical and mental limitations of the average human machine. Perhaps the latter are following where they should lead. It is obvious that there is a need for better designed highways, on which driving will be safer and less nerve-wracking; but why urge that public money be spent so that some Zelik Forlansky, who should be piloting a road roller, or some Percey Asteroid Vandervell, III, who should be attending his classes at college, can tear along over the country at rates 50% greater than that of the speediest limited express trains? What, in particular, is gained for society as a whole? The millions would far better be spent on careful selection of drivers, special training for those who obviously need it, elimination of the unfit, and swift, impartial, and certain punishment for flagrant offenders.

All of which is in no sense a condemnation of Mr. Noble's excellent presentation of a pressing technical problem. Suppose, however, that, ten or twenty years hence, engineers have developed highways which in their perfection of

[29] *Fortune Magazine*, August, 1936.

[30] Prof., Eng. Drawing, School of Eng., Yale Univ., New Haven, Conn.

design are even beyond Mr. Noble's fondest dreams. If there still persists the present *laissez faire* attitude toward those persons who are allowed to drive cars on these superways the taxpayers' good money will have been spent to little purpose, for the killings and the maiming will be going on in ever-increasing volume. The country does indeed need safer highways for rational use; but persons who think they must travel at 2 miles per min will never be satisfied with any highways that engineers may build, because such individuals require three-dimensional space instead, and the good Lord has provided plenty of such space already.

HAROLD M. LEWIS,[n] M. AM. SOC. C. E. (by letter).—The development of express highways has taken place within the last ten years. Only within the last few years has it been recognized that the dual highway, recommended by Mr. Noble, which provides separate roadways for each direction of traffic, should be made a feature of all major express routes. The safety of a highway would thus be tremendously increased and operation at higher speeds made possible.

The first comprehensive system of express highways for a metropolitan area was that presented in the Regional Plan of New York and Its Environs in 1929. This included about 253 miles of routes in the New York-New Jersey Metropolitan Area, only $3\frac{1}{2}$ miles of which had then been developed as express routes. This system was supplemented by a separate system of parkways, most of which would also provide express movement, but all of which would be limited to passenger vehicles. The express highway system was designed for both passenger and commercial vehicles.

Express highways were needed to relieve the interference from cross-traffic on intersecting routes and to provide short cuts between population centers and by-passes around intensively built-up districts. In a few cases they have been developed as viaducts, or on embankments, where there could be no interference from the uses of abutting property, but where they have been built along existing grades, the permanency of free movement has been overlooked. An example is U. S. Route No. 1, between Newark and Trenton, N. J., which was reconstructed over an entirely new right of way and hailed as the first comprehensive express highway. For the first few months after it was opened to use, it was adequate for through traffic which traveled over it, but it soon became lined with gasoline stations, refreshment stands, and other commercial concessions so that parts of it are now little better than the old Lincoln Highway which it supplanted. It is recognized that a new and better route will be required to relieve it.

Mr. Noble has described a type of route which will be a great advance in highway design. He mentions that "a safety factor is to prevent frontage of any type on the highway and to exclude farm and local road entry. It appears reasonable to restrict access to approximately 10-mile intervals." The writer would like to emphasize the importance of this safety factor and believes that it is an essential feature if permanent efficiency is to be maintained.

---

[n] Cons. Engr.; Engr. and Planning Consultant, Regional Plan Assoc., Inc., New York, N. Y.

A highway built with State or Federal funds without local assessment can logically be designed primarily for non-local uses. Why not make it entirely for through traffic and exclude the right of any abutting property to local access, except at those points designated by the agency building the highway and incorporated into its design?

The "freeway" or "limited way" is the term that has been used to designate such a highway, on which general traffic can have some of the advantages which passenger cars now enjoy on the modern parkway. The word, "freeway", was coined several years ago by Edward M. Bassett, Attorney, of New York City. Other countries have made notable advances in constructing modern highways of this type, notably the toll roads built by private corporations in Italy under Government authorization and with Government assistance, and the "Reichautobahnen" under construction in Germany as part of a national highway system.

Thus far, freeway construction has made little progress in the United States due to the necessity of new legislation authorizing public highway agencies to lay out and build highways to which abutting owners will not have the right of access.

Definition.—Probably the briefest definition of a freeway is as follows[30]: "A highway to which there is no vehicular access from abutting properties." In the report from which this definition is quoted a freeway was defined as one type of express highway.

A more complete definition of a freeway is obtained by summing up the various qualities which such a route should possess, as follows. (1) For fast-moving vehicles, long haul as against local traffic; (2) for mixed traffic, including passenger cars, buses, and motor trucks, but excluding horse-drawn vehicles; (3) free from crossings at grade, and left-hand turns, unless in isolated cases in rural areas where the construction necessary to eliminate them would not be justified; (4) providing no right of access to abutting property, except at points provided by the agency designing and constructing the freeway; (5) abutting service facilities, such as gasoline and parking areas, to be provided only by, or under the control of, the public agency building the highway at sites incorporated in the design of the freeway; (6) infrequent connections to other highways; and (7) low grades and easy curvature.

The freeway system should form a part of a more comprehensive system of express routes containing two other types of express facilities. One of these facilities would be a system of parkways, restricted to passenger vehicles and providing attractive, landscaped routes with grade separations at important intersections, expanded at places to provide recreational parks. The other would be express routes composed of highways also serving abutting property, but where freedom of movement is facilitated by occasional grade separations, side roadways for local traffic, or other special treatment.

Design of Freeway.—The general design of a freeway is well indicated by the foregoing Items (1) to (7) which list the qualities it should possess. Although the need of freeways is more acute in the closely developed parts

[30] Rept. of the Committee of the City Planning Division, Am. Soc. C. E., on Street Thoroughfares Manual, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1049.

of metropolitan areas, it is more feasible to establish them in suburban and rural areas. Accordingly, the widths of right of way to be provided will vary with the character of the territory. In congested areas of high land values, compromises with existing conditions will have to be made.

In general, the design should call for three lanes of traffic in each direction, and dual roadways separated by a central unpaved area. Two lanes in each direction will often be sufficient for initial construction and, in some cases, for final development. Border strips should be provided along each side.

The Regional Plan Association of New York City recommends that outside lanes and lanes next to the central unpaved strips be 13 ft in width. Lanes not bordering on unpaved shoulders or central strips could be 11 ft wide. A minimum width of 26 ft, including curbing, is recommended for the central strip. Within this width a screen planting of shrubs and trees will eliminate the glare of head-lights at night from drivers going in an opposite direction. A minimum width of 160 ft would thus provide an adequate right of way for a freeway with an ultimate capacity of six lanes, three in each direction.

In rural areas a width of 400 to 500 ft is advisable, but this might very well vary in accordance with the topography and the ownership of the land through which the freeway passes. In this case a minimum border strip of 50 ft is desirable which might well be supplemented by the prohibition of

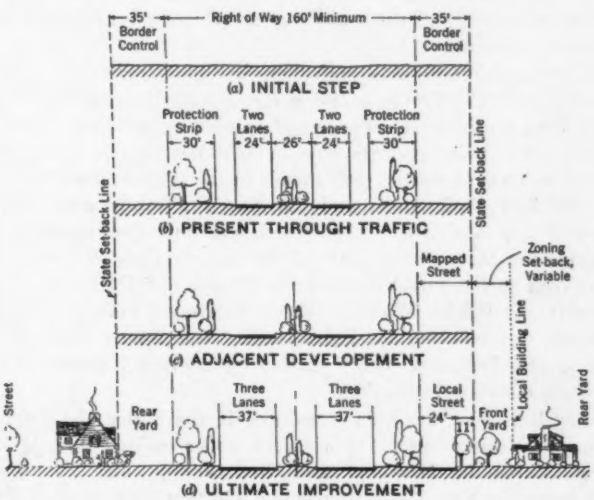

FIG. 8.—ADAPTATION OF ROAD CAPACITY TO TRAFFIC VOLUME AND LAND USE

billboards and signs within 200 ft or more of the right of way. Through rural areas where land is under cultivation a narrower right of way, supplemented by an easement over adjacent land, will reduce initial and maintenance costs and give the motorist a more interesting and informative view of the

country side. As much of the motor travel in the United States is of a recreational nature, many of the parkway features, such as attractively landscaped overlooks at scenic points, picnic areas, and bridle paths, might be incorporated advantageously in freeway design in rural areas.

A series of cross-sections, prepared by the Regional Plan Association and indicating the progressive development of a freeway in suburban areas contiguous to large population centers, is shown in Fig. 8. This calls for a minimum right of way of 160 ft and a 35-ft set-back line to be established by the State (see Fig. 8(*a*)), assuming that the freeway would be constructed by the State Highway Department. Early in the development (Fig. 8 (*b*)), an economical pavement is installed and trees are planted in their final location. As transition from an open area to a more intense use occurs (Fig. 8(*c*)), local circulation can be provided in "control borders." Local building lines should be established at this time. Ultimately, when future traffic justifies it, the roadway can be expanded to three lanes in each direction without disturbing the planting. A more effective separation is possible between traffic and buildings when abutting property is developed as shown on the right side of Fig. 8(*d*).

In urban areas marginal border strips might be cut down to 4 ft and the central strip to 8 ft. With these extreme measures, which should be applied only where local conditions make them necessary, a six-lane freeway could be constructed on a 90-ft right of way, or a four-lane freeway on a 64-ft width. In certain sections the elevated highway or vehicular tunnel must be resorted to for short distances.

Proposed Legislation.—Although there is general agreement as to the need of freeways and legislation to enable governmental departments to build them, there has been considerable difference of opinion regarding the details of such legislation. The only freeways now in existence in the United States are some short sections of general traffic roads in the Westchester County Parkway System, in New York State, and the Norris Freeway constructed by the Tennessee Valley Authority. The Westchester routes were built by the expedient of placing them within parts of the County Park System, turning the roadways over to the jurisdiction of the Division of Highways of the State Department of Public Works. These roadways were constructed with State funds supplemented by Federal aid. The Norris Freeway was constructed by the Tennessee Valley Authority, a Federal agency, without any special State enabling legislation.

Freeway legislation has been introduced in the States of California, Connecticut, and Massachusetts. It has been under consideration by the State Planning Boards in Maryland and New Jersey, and the Division of State Planning in New York. It seems likely that some of these States will soon provide themselves with such legislation.

Application to New York Region.—Fig. 9 shows a study prepared by the Regional Plan Association for the application of the freeway principle to a complete system of expressways for the New York-New Jersey-Connecticut Metropolitan Area. It shows a much more extensive system of general traffic

express routes than was contemplated in the express highway system proposed in the Graphic Regional Plan in 1929, already cited.

In 1933, a report[23] on the preceding four years of progress in the regional development of New York and its environs showed progress on 179 miles of express highways, or 72% of the new mileage proposed in the original plan, which had looked forward to the year 1965. This tremendous growth in the adoption of the express-highway principle justifies an expansion of the original proposals. Fig. 9 might be described as an ultimate plan of expressways for

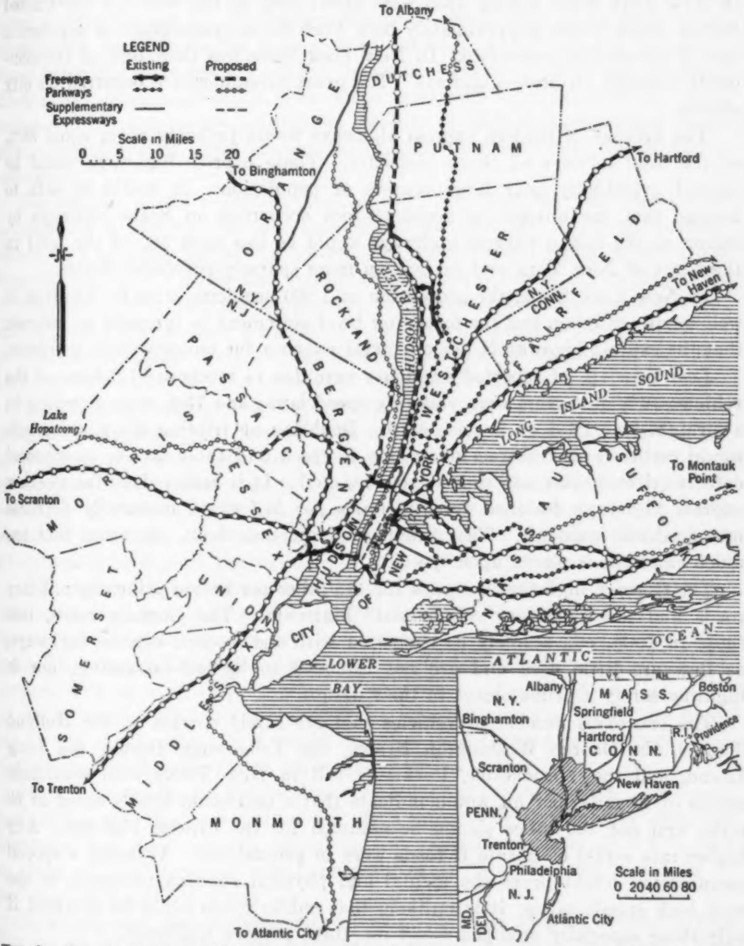

FIG. 9.—STUDY OF RADIAL FREEWAYS FOR NEW YORK AND ITS ENVIRONS, SHOWING THEIR PLACE IN AN ULTIMATE EXPRESSWAY SYSTEM

[23] "From Plan to Reality", Regional Plan Assoc., 1933.

the Region looking even further ahead than the published Regional Plan. Its advantage would be that any routes constructed in conformity with it would be permanently useful for the expeditious movement of vehicles along attractive rights of way and the past sad experience of the clogging of State highways with local traffic to and from roadside development will be eliminated along new routes.

George Conrad Diehl,[34] M. Am. Soc. C. E. (by letter).—Traffic accidents in New York State during 1935 were about 10% of the total for the United States, which is also approximately New York State's percentage of population and of automobile ownership. In New York State less than 10% of the accidents occurred on State highways. The great preponderance occurred on city streets.

The mileage of modern express highways would probably never equal 30% of the total mileage of State highways. These express highways would be located principally near large centers of population. It would be safe to assume that the number of accidents not occurring on State highways by reason of the use of express highways would be less than 3% of the total in the State of New York and far less in more sparsely populated States.

In New York State, the prevention of 1 800 accidents with 60 fatalities is well worth studying, but the foregoing brief statement is intended to indicate that the express highway is not a general panacea for motor-vehicle accidents.

Less than 4% of reported accidents were due to mechanical defects of the vehicle; 10% of drivers were violating speed laws; and 75% were traveling in a straight line (not on curves, etc.). Doubling or tripling allowable speeds would certainly increase accidents due to speed and those due to mechanical defects (tires, brakes, steering apparatus, etc.). It is rather doubtful whether express highways designed for 100 miles per hr. would materially decrease motor-vehicle accidents. They might even increase them. It seems that too much emphasis is placed upon speed.

The German highways designed for 115 miles per hr are primarily military roads and not "peace or commercial" highways. The German roads, like those in Italy, can scarcely be compared with the modern express highways, as they are little used and are not intended to be self-sustaining; nor is highway safety a prime object in their design.

The enormous number of vehicles that are safely carried by the Holland Tunnel, the George Washington Bridge, the Triborough Bridge, the Long Island, and the Westchester, Parkways (all in New York) with maximum speeds of 40 miles per hr, would indicate that a maximum hourly speed of 50 miles and not 100 miles should be assumed for the express highway. Any higher rate would be unsafe if roads were in general use. Although a special examination might prove the mental and physical stamina necessary to use such high speeds safely, it is unlikely that public funds could be obtained if only those especially qualified could use these modern highways.

[34] Cons. Engr., New York, N. Y.

Assuming that the vehicles could be made mechanically safe, the individual operator is certainly limited as to speed, no matter how well the engineer designed the vehicle and highway. Some limit must be fixed in the interest of public safety, and the rate should be less in the case of long, high-speed buses, of trucks, and of cars with trailers, and of vehicles of unusual length.

Often the fact is overlooked that increasing speed beyond certain limits decreases the capacity of the highways. This decrease is due to the extra spacing required for safe operation. Vehicles traveling at 50 miles per hr, according to Fig. 4, can be operated safely at intervals of 150 ft, but at a speed of 100 miles per hr, the spacing should be 600 ft, four times the spacing at twice the speed, reducing the capacity one-half. Only one-half the number of vehicles can be carried safely. The only remaining advantage is speed. Much of this advantage is lost when speed is reduced to minutes saved. This saving will be comparatively small, as sections of such modern express highways, generally considered, cannot be justified economically for extensive mileages.

The various forms of transportation—air, rail, and highway—should be co-ordinated so that all three can be operated successfully. If greater average speeds than 50 miles per hr are desired, rail service could safely be developed from 50 to 100 miles per hr and air service much in excess of 100 miles per hr.

Expensive public improvements must be justified technically, economically, and socially. The express highway is a necessary transportation utility, but it involves unusually large expenditure. Fortunately, the mileage of such highways is very small when compared with the total.

Toll highways have not been popular in the past. In very few cases are there sound arguments in favor of the toll method of financing. If the toll method is not adopted, then the public, as well as appropriating bodies, must be convinced that the cost of express highways is justified and that there will remain in the available highway funds sufficient sums to care for all lesser classes of highways. Doubtless, the public will also insist that the work on all classes be carried on proportionately and contemporaneously.

Modern express highways must be justified by the traffic and probably a safe method of financing would require the users of such highways to pay from present registration or gasoline taxes a considerable part of the total cost. The organized motorist objects to any increase in motor-vehicle taxation, through tolls, or otherwise.

Every express highway which can be financed soundly should be built, but by the same reasoning it would be gross extravagance to construct such highways where less expensive roads would suffice.

If proposed speeds are slowed down the beautiful parkways with picturesque landscaping near the largest cities can often serve as modern express passenger highways, but their mileage should be limited, and recourse should be had to those rules of economy which properly apply to parks and parkways, as well as to business highways.

It would seem that definite general rules could be adopted for the design and construction of express highways for a period of, say, thirty years. This would permit a sufficient lapse of time to care for amortization of bonds or

borrowings. Technical, economical, and social justification could be computed on the basis of thirty years, or on such other period of time as might be more equitable and desirable Proponents of each form of transportation could then develop and solve their own problems without unfair overlapping or competition.

Support for the large expenditure for express highways from legislators and those who plan the budget, whose home localities are not greatly affected by these great arteries, will be dependent upon a general plan which will provide for the equitably apportioned construction of all classes of highways within the sums available.

For at least twenty years the writer has urged the importance of "highway classification" and of "traffic distribution." All the many hundreds of thousands of miles of public highways and streets never can, or should, be designed for equal capacities, loadings, or speeds.

The individuals composing budgeting or appropriating bodies are prone to believe that the highways in their home localities are deserving of the highest and costliest types.

Formerly, the writer had suggested that the highways outside of cities be divided into four classes. Names which would be more or less descriptive to legislators were used: (1) High-cost roads; (2) low-cost roads; (3) little used roads; and (4) remote roads. It was endeavored to work out an economic justification by assuming that the actual payments of registration fees and gasoline taxes should equal one-half the road costs, including construction, maintenance, and amortization.

On this theory: (*a*) High-cost roads were assumed to carry as many as 600 000 vehicles annually; (*b*) low-cost roads were assumed to carry from 200 000 to 600 000 vehicles annually; (*c*) little used roads were assumed to carry 30 000 to 200 000 vehicles annually; and (*d*) remote roads were assumed to carry less than 30 000 vehicles annually.

The weight and length of vehicles to be permitted on high-cost roads were to be the full legal limit. On low-cost roads the maximum allowable capacity was $3\frac{1}{2}$-ton trucks and less in the case of school buses. Long trailer truck trains or long, high-speed buses were to be excluded (Incidentally, this restriction only excludes 1% of the total number of vehicles permitted on high-cost roads.) Little used roads are limited the same as low-cost roads, except that trucks must not exceed $2\frac{1}{2}$ tons. Remote roads are limited to 2-ton trucks and no trailers or buses (except smaller vehicles such as school buses) are permitted on them.

The maximum speeds varied from 35 to 60 miles per hr, with special restrictions on sharp curves of the lower types. Stage construction was planned so that one type could be changed to the next higher type with a minimum of unnecessary expenditure. A more complete description of these types cannot be made within the limits of a discussion of this paper.

The first class, namely, "high-cost roads", should be again subdivided, or at least a new class should be added; that is, the modern express highway. This latter highway could not be justified probably at less than 2 000 000 vehicles annually, and if clover-leaf intersections were adopted generally, a

larger number of vehicles would be required. Very few miles of highways carry 10 000 vehicles daily and then only near large centers of population. Traffic congestion is local.

The mileage of high-cost roads is approximately only 10% of the total. The lower, less expensive types comprised 90% of the total. Formerly, traffic censuses were inadequate in number and scope to calculate the allowable mileage and justifiable costs of the several classes of highways. During the past few years, through Federal participation, there has been a great addition to traffic data and the more populous States have sufficient data to develop a fairly accurate general plan for road classifications and economic planning.

The writer's experience in the enforcement of road rules and restrictions convinces him that the traffic of the various classes could be practically, and readily, controlled. Closely allied to the subject of road classifications is the matter of traffic distribution on city streets as well as on suburban and rural roads On the most crowded Saturdays, Sundays, and holidays, there are, in the vicinity of many large cities, mile after mile of comparatively empty roads used by few vehicles, but open to many. Pleasure seekers use the busy roads because they are not directed to idle roads. Even when one's destination is fixed, little used parallel roads are available for the passenger car and lighter trucks. The average tourist could readily be routed to arrive at or to leave on, busy city streets at other than rush hours with peak loads.

Many city streets permit of easy and undisturbed travel when greatly accepted routes are slow and difficult. For instance, it is possible to drive from mid-town New York City to the Westchester County line by several routes at the same hour of day, one route taking 35 min, another, 1 hr and 15 min, and others at intermediate periods. On the busiest road not only is ½ hr wasted, but the traffic is still further cluttered. A continuing study and control can govern traffic by properly routing drivers who go daily between fixed destinations.

Traffic distribution is an important item in planning city terminals and within certain of the most congested areas, involves the question of compulsory mass transportation as contrasted with the use of these areas by the individual passenger car.

Obviously, the average taxpayer cannot analyze the traffic problem or study its intricate details, and yet he will re-act unfavorably to the enormous cost per mile of the express highway unless provision is made for road classification and traffic distribution. In these days of socially planned legislation one cannot disregard the lonesome vehicles on "forgotten highways" leading into hundreds of smaller cities and serving many thousands of villages and townships. Space does not permit a further discussion of traffic distribution, but much more should be said. It must be apparent that much travel could be taken from the express highway and the busiest high-cost roads.

The statement often made that most highways designed twelve or fifteen years ago are obsolete is true only of some of the crowded main highways near large centers. Literally, thousands of miles of the cheaper types are well designed for the purpose intended.

Such statements give an erroneous impression to laymen and to members of budgeting and appropriating bodies. As a matter of fact, it might better be said that the fine work of highway engineers during the past ten or twelve years has resulted in highways fully adequate for the next fifteen or twenty years. These excellent results should be emphasized so that highway engineers will be highly regarded by the general public, and their recommendations estimated at their true worth.

WILLIAM E. RUDOLPH,[35] M. AM. SOC. C. E. (by letter).—Although there is much of interest and pleasure to be gained from reading this paper, the writer considers that its basis is altogether erroneous. Mr. Noble introduces his subject with a compilation of accidents in the United States during 1935 (Table 1). Having been away from his native land for nearly three years, the writer was not a little surprised to learn that accidents accounted for injury or death to nearly a million persons annually in the United States. Then, upon turning the page, he was still further surprised to find that the author was proposing high-speed highways to accommodate faster cars, in order to "safeguard the traveling public."

Is Mr. Noble "looking in the right direction"? Year after year the manufacturer has been producing cars, each in its turn safer than the previous model, without a doubt, and also faster. Year after year the engineer has been building safer and faster highways, until Mr. Noble now suggests designing for 100 miles per hr.; and yet, with safer cars and safer highways, engineers are confronted with Mr. Noble's tabulation of a single year's terrible toll of accidents. Are they working in a vicious circle?

Safer cars, equipped with safer tires which will blow out gently if they must blow out, will probably present no difficult problem to the super-enlightened automobile manufacturer of the present day. Safer highways can be designed and constructed by the engineer, as outlined in Mr. Noble's excellent presentation of his subject; but the safer driver, the person who is not subject to ordinary human weaknesses, such as fatigue, mental lapse, or a strong cocktail—what is being done about him? Would it not seem in order to correct such factors concurrently with the physical factors, even if it became necessary to establish special schools for instructing the driver regarding the laws of motion, and the proper management of the immense amount of power at his command when he starts the motor of his car? Later, perhaps, with drivers who would depend upon good judgment rather than upon mere good luck for avoiding accidents, there might be a real need for higher-speed highways and the inevitable higher-speed cars; but they should not be projected upon the basis of a tabulation showing an annual total of nearly a million accidents.

It might be that engineers in the United States are taking their cue in this matter from high-speed highways recently constructed in Europe. This is ill-advised—for Europe requires such highways because of the inevitable war she is facing, whereas conditions in the United States are quite different (or at least it is to be hoped they are).

[35] Chf. Engr., Mauricio Hochschild & Co., Ltd., Potosi, Bolivia.

In Bolivia, Nature has imposed great obstacles for the road builder: Highways must wind in spectacular fashion in and out of rugged canyons, over steep mountain passes; at places there is scarcely width to pass another car. Many roads run through river bottoms, where there is no passage during the rainy reason; others become extremely difficult to travel when the clay surface becomes wet, and hard roads are almost unknown. Despite vertical cliffs and other hazards, however, the accident factor in Bolivia is indeed low. Moreover its citizens work and produce and are happy, although they do not live so fast. Road conditions are constantly being improved, but, fortunately, they have not reached the point, thus far, which permits high speeds that might occasion risks quite out of proportion to the useful ends to be gained by such speeds.

A. C. Dennis,[36] M. Am. Soc. C. E. (by letter).—Studied in conjunction with a paper by Fred Lavis, M. Am. Soc. C. E., published in 1930[37], the paper by Mr. Noble constitutes an important advance toward the establishment of correct standards for trunk highways. The technical questions of design standards and economic location can safely be left to the decision of engineers, and the broader question of organization and financing may also be properly the concern of engineers even if the ultimate decision is the responsibility of others. If there is the possibility that certain trunk highways may be constructed, with no addition of taxes to the general public, to provide the users of these highways a safer and faster route free of interruptions at no additional cost to the user, then an engineer's self-interest as well as his duty as a good citizen should lead him to study and discuss this possibility and, if found to be sound, to work for its fulfillment.

The existing highways are, in effect, State toll roads, the toll being paid at the gas station as a State sales tax. These highways have generally been built with local use and convenience as the main objective. Practically all of them are of inadequate capacity for trunk-line traffic and are subject to various traffic interruptions. The result is a condition similar to that of a railway system consisting of many branch lines, but no main line.

Trunk highways are interstate structures beyond the province of the several States, but within the powers of the Federal Government to finance, construct, own, and operate. It appears that a major section of Federal trunk highway of normal cost, carrying about 7 500 vehicles daily on eight traffic lanes, between three or more emergency or parking lanes, may be self-liquidating in that a Federal gas tax collected along the highway at a rate not exceeding that of the local tax, together with revenue from concessions for furnishing service to vehicles and persons, will provide cost of administration, policing, maintenance, and other operating items, as well as interest on the investment with perhaps something toward retirement of investment.

The organization suggested previous to operation, is that a Chief Engineer shall report, possibly, to the Secretary of The Interior, with authority (as far as is practicable for a public servant) similar to that of a Chief Engi-

[36] Gen. Supt., Dravo Corporation, Kerhonkson, N. Y.

[37] *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 1020.

neer of a railway during location and construction. He should select his staff and be allowed to pay salaries sufficient to secure proper assistants. The Highway Engineer of each State traversed should be a member of his consulting staff.

The first duty of the Chief Engineer should be to select the general route for the highway, establish standards, and make a preliminary estimate of cost and an estimate of immediate and future revenue to determine whether the proposed section is self-liquidating, or whether it will become so in the future. When a proposed section appears to be self-liquidating and when authority has been given to proceed, the Chief Engineer should make location surveys, design structures, acquire rights of way and other necessary lands, prepare specifications, let unit price contracts in sections of several hundred miles each, and supervise the construction.

When a major section of the highway is ready for operation, it should be administered by a Manager reporting, perhaps, to the Secretary of The Interior. He should be responsible for the maintenance of the highway, the leasing and regulation of concessions, and the enforcement of operating regulations for vehicles and drivers, with the support of Federal Police and Magistrates.

The near future will probably be an unusually expensive period for highway construction, but some dense traffic sections may be economically sound even at excessive cost, whereas the plans for others, not at present self-liquidating, may contain useful knowledge to have available when the next depression again reduces construction costs.

J. C. Carpenter,[38] M. Am. Soc. C. E. (by letter).—This timely paper covers a subject that deserves most serious consideration by the Engineering Profession. Perhaps the title, "The Modern Express Highway", was selected as a lure to induce some engineers to give thought to the subject of highway safety, who might not be interested in a paper on "The Necessity for Consideration of Safety in Highway Design."

The immediate answer to the problem of highway safety is not the "express highway." Engineers must consider safety in all their designs and cannot wait until funds are available and traffic warrants the construction of divided-lane highways on the large mileage that is now (1937) and will soon be under construction. Mr. Noble's excellent paper covers many features of design that are used in the development of all highway plans and his suggestions are generally applicable to single-lane, as well as to dual-lane, highways. The dual-lane highway is undoubtedly superior to the two-way single-lane, and should be used in every instance where the traffic volume and funds available will allow its use. Unless it is plainly obvious that this design is demanded, it will take more than vision or courage to persuade those in authority that the required extraordinary expenditure is justified. Perhaps this paper will provide the data needed by some engineers to convince the authorities that more dual-lane highways are necessary.

[38] Senior Highway Engr., U. S. Bureau of Public Roads, Fort Worth, Tex.

As soon as the planning movement, now rapidly gathering headway, has advanced to a point where the results are available, the designing engineers will have reliable and convincing information that will allow them to select, and promote with confidence, the designs that are properly applicable to the conditions dictated by traffic, economic development, and a program based on a correct knowledge of future available funds. The planning program is now in its preliminary stages and the most difficult phases are just ahead. The collection of data is a comparatively simple and easy task, and presents no difficulties not previously surmounted by the engineer, but the co-ordination of these data, analysis, and utilization, to prepare a satisfactory plan that will be so perfect that its general features will be permanent, is an unexplored field and will demand the services of men of broad experience, who have the vision and the courage to look ahead and support their ideas with clearly established reasons. Highway engineers have "followed the old road" and built "within the money" for so long that it will be difficult to break new trails, but those who are privileged to work on this phase of the planning procedure have a large responsibility; and the skill, courage, and good judgment they show, will determine the value of the results to the public and all future generations. One important point will undoubtedly be developed, namely, the funds now collected from highway users are not sufficient to carry on the necessary construction and maintenance operations, including building and maintaining safety in the highways, and funds collected for highway uses should not be diverted for any other purpose.

The safety problem involves many features outside of engineering design and practice. The National Safety Council's three "E's" necessary for safety, are "enlightened engineering", "sagacious education", and "judicious law enforcement." The writer's estimate of the relative endeavor necessary on these three general phases of the safety problem is, engineering, 5%; education, 10%; and enforcement, 85 per cent. Reasons for this estimated rating will be given in the following discussion. This low rating for engineering does not mean to imply that engineers can sit complacently and let the public do the educating and enforcement, but rather that the engineer, with his specialized knowledge and training, while concentrating on the improvement in the engineering phases of the problem, should assume leadership in developing ways and means of providing effective programs for education and enforcement. Education can best be developed through the regular school curricula and through courses in safety required as a penalty for law violation. A regularly scheduled and complete course in all phases of safety, with emphasis on highway safety and practical demonstrations and teaching, should be included as an eighth-grade subject in all the schools of the country. Drivers' licenses should not be issued to children until they have completed this course and passed a State examination and the enforcement should fit in with this policy. Children of eighth-grade age are just beginning to drive, and development of this policy and legal recognition through the school system and enforcement authorities, will do more to bring about a citizenship thoroughly "safety minded" than any other means of education. Of the adults, the law breakers are the offenders who need to be educated and the

majority of them are of the type who will not listen to good advice given as newspaper publicity or through other commonly accepted channels. If they were required to take a carefully planned course in safety before being allowed to drive and to pass a strict examination before having their license returned to them there is no doubt that a large number of violators would be converted into careful drivers.

Enforcement, of course, is a police function, but engineers in private practice and public position can, at every opportunity, stimulate popular support of intelligent enforcement of existing laws and encourage the enactment of necessary additional legislation conforming to the principles outlined in the Uniform Acts of the National Conference on Street and Highway Safety, and can insist on the appropriation of sufficient funds to insure thorough and complete enforcement of all traffic laws.

Highway safety is as much an engineering problem as industrial safety, and engineers can devise methods of control that will be as effective as those so successfully used by the railways and other industries. Careful study of information provided by such organizations as the National Safety Council, the American Automobile Association, and other similar agencies will equip the engineer to lead in community and State safety movements.

The statistics quoted in Mr. Noble's paper emphasize the loss of life and injuries due to traffic accidents. Although it may be that more accidents should be charged to highway design, it is believed that the percentage of the total will not be changed very much. When the figures given are analyzed, it is possible to conclude that the percentage chargeable to design is not as large as might be thought. National Safety Council's "Accident Facts" shows that of the total of 36 100 deaths in 1935, 11 800 were in cities of more than 10 000 population, and 24 300 were on rural highways, which are those under consideration. Of these totals, 35% of the casualties were pedestrians. Although improvement in the design may, accidentally, reduce the pedestrian deaths, it is logical to assume that the majority of them were caused by lack of care on the part of the pedestrian and excessive speed on the part of the driver. A closed right of way on the express highway recommended by Mr. Noble, might keep some of the pedestrians where they belong, but there are other complications, legal and otherwise, which would prevent the strict exclusion of the free and independent public from the public highways of the United States. After deducting 35% for pedestrians, there remains a total of 15 795 deaths which may be more or less remotely charged to defects in design.

The data in Table 6 have been obtained on three highways adjacent to Fort Worth, Tex., covering accidents during the fiscal year ending August 31. 1936. U. S. Highway No. 80 across Palo Pinto County was built in 1924, on what were considered modern standards at that time, but it has many sharp curves, steep grades, and a rough surface 16 to 18 ft wide, with more crown than is necessary. U. S. Highway No. 80, across Parker County, was completed in 1922 as a surface-treated gravel road about 16 ft wide, and approximately one-half of it was reconstructed to a higher standard and wider surface in 1927. State Highway No. 34, from Azle to Jacksboro, Tex., was

built in 1934 on excellent alignment, the location having been selected from an aerial survey map, with low degree curves and much better sight distances than on the other two roads; it is surfaced with a bituminous top, 22 ft wide, built to a good section, and generally is in excellent condition. The three sections are about the same length, traverse the same type of terrain, and, except for their age, the surfaces are similar in character. Traffic is heavier in volume on the Parker County Section than on the other two roads, but the difference is not enough to affect the results materially.

TABLE 6.—ANALYSIS OF ACCIDENTS ON EXPRESS HIGHWAYS IN TEXAS

(a) GENERAL				(b) CAUSES OF ACCIDENTS				(c) TYPES OF ACCIDENTS			
Description	U. S. HIGHWAY No. 80		STATE HIGHWAY No. 34	Description	U. S. HIGHWAY No. 80		STATE HIGHWAY No. 34	Description	U. S. HIGHWAY No. 80		STATE HIGHWAY No. 34

Total injured......	26	48	49	Miscellaneous.....	1	21	23	Miscellaneous.....	2	20	34

Table 6 indicates that there are more accidents on the roads of more modern design than on the older types. It is not logical to conclude that one should return to the older design, but one should analyze more carefully all accidents and determine exactly what is the cause; and if design is responsible the engineer must determine what changes are necessary to correct it. It would also seem that the modern design is likely to induce sleep and that about 25% of the accidents are caused by overtaking other automobiles. A change to the dual type will not prevent overtaking accidents, nor will it stop drivers from going to sleep. On all the roads, speed is responsible for a large percentage of the accidents; it is responsible for two-thirds of the total on the oldest road.

It is obvious that a greater volume of accident reports is needed and more complete detailed information on the reports that are made. It is difficult to get the entire "picture", for it is impossible to follow every car and to be on hand to obtain accurate and complete details of each accident. Any information furnished by a driver involved in an accident is usually prejudiced. The fact remains, however, that engineers need considerably more data than are now available, if they are to design intelligently. Congress, in 1936, appropriated $75 000 for use in investigating conditions and formulating legislation on highway accidents. The Bureau of Public Roads, in co-operation with the Highway Research Council, has appointed an advisory committee to study the causes of highway accidents and conditions contributing to them. These studies will be made in the States that have kept records of

accidents and will consist of an analysis of the accident records of a large number of drivers. Publication of the results of this study and wide distribution among engineers will undoubtedly stimulate the more universal collection of accident data; bring about uniformity in the procedure; make available much valuable information for use in design; and result in the enactment of corrective legislation.

This and other recent papers on this subject[30] set a speed of 100 to 120 miles per hr for the design of highways. Such a high rate is out of all proportion to the capabilities of the present-day driver. Perhaps if there were a uniform drivers' License Law, administered in such a way as to classify all drivers in accord with their skill and dependability, one might allow a select few to pilot automobiles at this rate of speed. Highways designed for this rate of speed will be perfectly suited for the lower speeds that are required, and will provide a factor of safety against obsolescence; but encouraging high speeds will increase accidents, as is emphasized by National Safety Council's "Accident Facts", which shows that at speeds of 20 miles per hr., one accident in 61 is fatal, whereas if the speed is 50 miles per hr., or more, there is 1 death to each 11 accidents. It is believed that practically all the travel over the rural highways of the country can be executed without exceeding 50 miles per hr. and without serious loss of time and money due to this conservative rate. The deaths due to accidents, property damage, and other supplementary losses can undoubtedly be reduced materially if this maximum speed is adopted and the achievement of this control is as much an engineering function as the reduction in degree of curvature, or the determination of the correct rate for superelevation. This same source indicates that in the fatal accidents nine out of ten cars were going straight ahead when the accident happened, thus relieving curvature of the responsibility for a large proportion of the fatal accidents, and indicating that speed was probably at fault.

The dual highway is undoubtedly the correct design where traffic and planning data indicate the location to be of such a permanent nature that the extraordinary expenditure is justified. In a large percentage of the area to be served by an extension of the present highway service the construction of additional routes will better serve the territory than the development of one route to carry a large volume. To illustrate this point, the Fort Worth-Dallas area covers about ten miles in a north and south direction, the centers of the two cities being about thirty-two miles apart. The construction of four 2-lane highways will relieve traffic congestion on the one main-line route now heavily crowded, and these four routes will not cost much more than the dual type on one route. One or two of these routes can be planned for future development as a dual highway, in the manner suggested by Mr. Noble.

The formula for superelevation of surfaces on curves should include a factor for side friction. A superelevation of $1\frac{1}{2}$ in. is about the maximum that can be used. All curves should be superelevated and it would seem to be a simple process to compute the rate between zero for a tangent, and $1\frac{1}{2}$ in. for a 6° curve, using the formulas, including the friction coefficient. There should

[30] See, for example, "Highway Design Applied to the State System", by R. H. Baldock, *Civil Engineering*, October, 1936, p. 643.

be very little justification for curves sharper than 6° on any highway that will develop later as a location for a dual highway. If sharper curvature is demanded by the topography it would seem that another route should be investigated. In all highway location the smallest reasonable degree of curvature should be used. It is quite common practice to use a higher degree than necessary, even in new country, due to the fact that the use of a low degree of curvature has not been considered necessary. Many 4° to 6° curves have been used where a 1° curve would fit better, and some 1° curves have been placed where a 10′ or a 30′ curve is easily possible.

Spirals should be used for all changes of direction. The spiral is the natural curve for fast traffic and will tend to keep the cars in the proper lane without cutting corners and, hence, will be a safety measure.

There should be no objection to a reasonable degree of undulation in grade line, provided the sight distance is not reduced. A break of this kind will hide the headlights of an approaching car and will be a welcome relief in some cases. An undulating grade line is almost always less expensive in construction cost, will allow shorter culverts, lower fills which may be sloped so as to avoid the construction of guard-rails, and thus be safer and less expensive to maintain. Grades should be fully compensated for curvature. Where dual highways are justified it would seem that a maximum of 5% grade should be demanded, but on the major part of the important highways of the country where the 2-way lanes are to be used, economy would appear to dictate a 7% maximum, unless ice is a factor to be met. In a similar line of reasoning, it seems that a sight distance of 700 ft is a reasonable minimum for the large percentage of the highways but, of course, in all cases, the longest reasonable obtainable distance should be used.

Except in very rough topography, the roadway section should provide a gradually changing slope away from the traveled way, eliminating the defined shoulder point, and providing the maximum of travelable surface on the right of way. All unnecessary obstructions should be removed, but signs are not as much of an obstruction as Mr. Noble indicates. More signs are hit by gunners than by automobiles, and, when judiciously used, signs are a necessary safety provision. It is impracticable to suspend signs in a windy country. The recently developed center-line reflector button has much merit as a safety device on 2-way traffic lanes.

Guard-rail should be used only where absolutely necessary. For fills less than 10 ft in depth, it is generally more economical to flatten slopes than to use guard-rail, and for deeper fills the additional safety will often justify extra expenditure to eliminate the use of the rail.

There is no immediate possibility of lighting any considerable mileage of rural highways, but with the development of rural electrification the prospect is encouraging. Where conditions demand a dual-lane highway it is logical to assume that lighting will be included.

Mr. Noble suggests the possibility of increasing the thickness of the pavement to provide smoothness. It is the writer's opinion that more detailed

study of the supporting sub-grade and provision for adequate control of the moisture content (and, consequently, more uniform supporting power) are the most important phases of design for present study.

HENRY B. ALVORD,[40] ASSOC. M. AM. SOC. C. E. (by letter).—If for no other reason than that it brings to a focus the relation of considerations of safety to the design of a highway, this paper is a timely one. Safety should be a dominant principle in the design of through, or express, highways as it already has been accepted in the design of other structures, such as bridges, buildings, and dams.

In order that this problem may be further particularized the writer presents herewith, a tentative set of suggestions in outline form which would apply to the design of an express highway. The attempt is to present a complete yet concise summary that will include all features necessary in a safe design. The writer may have omitted some points or given incorrect values in some instances; but if ideas such as these could be formulated and studied, they might help toward an agreement as to what is, and what is not, essential in such a program.

Competent engineers consider the following items to be necessary features of a safely designed through-traffic artery or express highway:

(1) Maximum allowable speed, 100 miles per hr;

(2) Two roadways of three lanes each, separated by a center strip having a width of 20 ft and a 20° sloping curb, each roadway to consist of two 12-ft lanes, the surface of the outside 20-ft parking lane to be of rough texture;

(3) Minimum radius of horizontal curve, 3 000 ft;

(4) Transition (spiral) curves;

(5) Horizontal curves to be superelevated for speed of 60 miles per hr;

(6) Maximum grade, 5%;

(7) Minimum vertical curve length = 160 times the percentage change in rate of grade. (This corresponds to a tangent offset of $\frac{5}{16}$ ft, 100 ft from any point of tangency);

(8) Minimum profile tangent, 1 500 ft;

(9) Minimum sight distance, 800 ft;

(10) Minimum horizontal tangent, 1 000 ft;

(11) Overpasses for all important cross-traffic. (No crossings of traffic at grade);

(12) Restriction of all side entrances to a minimum spacing of 5 miles. (No break in center strip at side entrances nor within 1 000 ft of a side entrance, and all breaks in center strip protected by a deceleration and acceleration lane of 500 ft);

(13) Acceleration and deceleration lanes at all side entrances (minimum length, 500 ft);

(14) White stripes separating lanes to control passing;

(15) Adequate lighting to provide clear visibility of all objects in roadway for a maximum distance of 2 000 ft, such lighting to be entirely in addition to, and independent of, automobile headlights;

[40] Prof., Civ. Eng., and in Chg. of Dept., Northeastern Univ., Boston, Mass.

(16) Surface textures to provide at least a coefficient of friction of 0.5; smoothness of profile to be consistent with operation at 100 miles per hr;

(17) Surface of extreme right-hand lane of extra rough texture and to be used for emergency stops only; all other lanes to have specified minimum speed limits;

(18) No entrance or egress permitted from roadways to and from adjacent land; all use of marginal land for commercial purposes to be eliminated by the non-access feature herein contained;

(19) Utility wires to be placed in conduits or on poles adjacent to right-of-way boundary lines;

(20) Directional signs restricted to a few words, placed sufficiently in advance of the point to which they refer, and to be of such size of type as to be easily legible by an observer passing at a rate of 100 miles per hr; and,

(21) Any installation of traffic lights of any type at any place in this express highway is clearly incompatible with proper design as indicated heretofore.

Any set of numerical requirements such as Items (1) to (21) probably will not be consistent for use in the entire United States. At least three classifications are necessary: One for a climate where frost and ice never cause a serious problem; one where ice and snow are common during the winter months; and one where the topography is exceptionally rough.

The Civil Engineering Profession is charged with the technical responsibility inherent in highway design. It is evident that the demands of highway traffic have grown (like "Topsy") out of all bounds. These demands have swamped the highway designing engineer. Either his recommendations often have been inadequate, or his design has been emasculated by his superiors under the guise of economy, falsely so-called.

If a structural engineer allows a design of a building to pass his desk when he knows it is unsafe, he is not commended for the economy of the design. Safety properly takes precedence over economy. Safety principles accepted in building design apply equally to highway design, namely, safe capacity and safe use. If this premise is correct, the conclusion is obvious—an inadequate design of a highway from the standpoint of safety is unprofessional.

ROBERT EUGENE HILES,[41] ASSOC. M. AM. SOC. C. E. (by letter).—In the paper by Mr. Noble, attention is called to the distinctive need for an inventory of the present worth of the modern express highways, as regards the purposes for which they were built, and the additional services that they are now rendering. He has suggested tests, research projects, and methods of handling the present and future requirements of heavy traffic conveniently and safely.

Briefly, the writer proposes that the modern express highway should be built and operated in a manner similar to the present modern express railroads, which have most certainly handled their large volume of freight and passenger traffic safely and conveniently for the public welfare.

---

[41] Res. Engr. Insp., P.W.A., Little Rock, Ark.

In introducing this discussion, it might be interesting to call attention to the astonishing fact that during the same year (1935) that Mr. Noble used to show that there were 36 100 deaths due to automobile accidents, there was not a single death of a paid customer due to accident on the railroads. No other test than that should be needed, therefore, to prove that the system of turning 50 000 000 vehicles, more or less, loose on an open highway with just any one operating and guiding them at any rate of speed, perhaps to 120 miles per hr, proved to be wrong in the 36 100 cases in 1935. It would also be just as wrong to put a steering wheel on a modern stream-line train and turn it loose on the open highway at 100 miles per hr. The modern highways handle much more traffic than the railroads; so why not control them as rigidly as the railroads? No recommendations are made herein to handle local traffic, except that which is permitted entrance at established express terminals after complying with and passing certain rigid regulations and inspections for road-worthiness, safety, etc. The construction of these express highways and facilities would require the building of new roadways where they could not follow the alignment and otherwise utilize the present highways. The adequacy of the present system of handling the express highway will certainly and surely be tested in time of war when man power will be scarce to guide all the machines of war besides all the vehicles for domestic and military transportation. Finally, the payment for this proposed project would not only be made from tolls charged on vehicles using the express highway and rents charged for concessions in the terminals, etc., but also by reason of the savings accrued from reducing the present type of highway pavement to that actually required per lane width of the proposed express highway track.

Express-Highway Tracks.—Why not put the modern express vehicles on tracks or in guides so that the personal element of guiding will be eliminated from the many duties of the driver? The design of these tracks should be effective and of sufficient strength to guide the standard design trucks and truck trains without the aid of a driver in the vehicle and should give due consideration to the following factors: Installation, replacement, and adaptability to present highway slabs and bridges; adaptability of present vehicles to a standard express vehicle and track gage; selection of materials for guides; hazards of the elements; alignment and right-of-way clearances; automatic control devices with particular attention to the photo-electric cells and other safety devices for warnings and control under all hazardous conditions and locations along the right of way; design of track appurtenances, such as switches, frogs, cross-overs, sidings, passing tracks, and terminal facilities; and, finally, the adoption of a guide that will permit the use of the present type and design of automobiles, so that with slight delay local traffic, upon reaching an express terminal, may enter and be permitted the better facilities of safety and convenience afforded by the modern express highway system.

Physical Characteristics.—As shown by the record of accidents in Chicago, Ill., where certain sections of highway were increased from normal to 100 ft in roadway widths, the number of accidents increased instead of

decreased. Apparently, then, this is not the solution, but rather the separation or division into lanes by mechanical means.

The proposed double-track express highway would handle, safely and conveniently (if properly regulated), as much as the present highways handle in perhaps four lanes. Passing tracks and sidings would be required, however, for cases of emergencies and convenience at various intervals along the system.

Any speed could be maintained either by law or by governors on the vehicles which could be checked at the terminals from previous tickets showing previous records of tests, "roadability" performance, accidents with rating as to frequency and seriousness, etc. By maintaining certain legal speeds the necessity and hazards of passing vehicles are eliminated.

Truck and passenger trains controlled by the express highway system, or privately owned passenger and freight train and single vehicles, could be operated over the same system.

Design.—Photo-electric cells, lights, neon tubing, and other control equipment could be placed on the front and rear of all vehicles and at certain necessary points along the right of way to maintain certain desired distances between vehicles and otherwise to control the speed and operation of the moving vehicles.

Certain familiar design assumptions (such as the increase in load or eccentric loading to trusses and girders, due to the shifting about of the design load from one curb to another, in order to produce probable maximum design conditions on the present type of bridge floor) would be eliminated by the proposed track system and in many structures this would effect a material saving in cost. Furthermore, the entire road-bed would not have to be paved. This advantage, however, would depend on the type of tracks or guides adopted.

Control.—Vehicles that failed to meet the requirements of speed, safety, and "roadability", while using the express highway, would be fined or otherwise penalized or disbarred in accordance with the severity and frequency of the offense. The routing and train, or vehicle, movement would be controlled by express dispatchers. The design and construction, supervision, inspection, collection of tolls, rentals, fees, fines, etc., operation, and maintenance would be under the direction of the present State highway commissions.

Payment.—The basis for payment in the form of tolls or express highway charges would be in accordance with the weight per mile hauled over the roads, payable and collected in advance at the express highway terminals. As noted under the heading, "Control", rentals, or leases for concessions at the express terminals, together with fines and penalties collected, would apply on operation and maintenance costs. Any saving by reason of design, in favor of the proposed modern express highway system should be credited toward payment. However, the greatest saving anticipated by this system is not financial, but is the saving of human lives, which at the present rate is a loss of 100 per day; and, the ultimate goal of the modern express highway should be the almost perfect record of the modern express railroads.

Conclusion.—The recommendations and suggestions contained herein are submitted for consideration, as suggested by Mr. Noble, for: Design, construction, operation, test, and research, to determine a safe and convenient modern express highway; and, perhaps, to prove that this can be accomplished by eliminating, as much as possible, the personal element from the control and operation of modern express vehicles on the highways.

CHANDLER DAVIS,[42] M. AM. SOC. C. E. (by letter).—The modern express highway, as described by Mr. Noble, is undoubtedly the highway of the future. Whether it will be feasible to permit driving at 100 miles per hr is very doubtful.

For 1935, Table 1 records 826 690 accidents of all kinds on American streets and highways, of which 374 490 were collisions between automobiles (that is, 45.3% of the total number), resulting in killing 24.6% and injuring 50.3% of the total reported for the year—this large and appalling list in spite of the numerous laws and ordinances.

Suggestions for minimizing such accidents and making the high-speed roads safe is treated by the author, who states that a car traveling at 100 miles per hr requires 617 ft in which to stop, provided the car is fitted with four-wheel brakes. To this value is added 219 ft for a lag of 1.5 sec for an emergency stop; that is, a total of 836 ft is required if a car should be required to stop suddenly. Naturally, each vehicle on the road will require the same space for a factor of safety and, consequently, each mile of road is limited to seven cars, if a speed of 100 miles per hr is to be maintained. This seems an absurd conclusion. Where can one find the data which will prove that, for safety, the road spaces given by Equation (2) are correct and conform to the proper use of highways. The United States Army has made a thorough study of the problem of moving supplies by truck and in developing rules of the road for motorized trains have reached conclusions, which seem to be based on Equation (2), or on some similar formula. It must be borne in mind, however, that the military units do not, and are not permitted to, exceed a speed which has been worked out as safe, although at times in case of an emergency the highest possible speeds are permissible; the safe rate for moving long columns (military) has been limited to 12 to 18 miles per hr.

The Army unit is the motor company, consisting of fifty-four trucks. Each vehicle is allowed a road space of 30 yd, which permits a maximum safe speed of 40 miles per hr. This is approximately the maximum speed found to be permissible on present-day highways, although, generally, it is exceeded. The ordinary speed for the Army is fixed at 20 miles per hr, although light tanks, carried on their trucks, are moved at 40 miles per hr when required. At night, it may be necessary to march without lights and naturally under such conditions (even when the cars may use their lights) the speed is considerably reduced. As 50 yd is left free between each company, it will be seen that one company requires 1 mile of road when moving; or at speeds as great as 40 miles per hr, with vehicles maintaining the proper distances, each mile is limited to fifty-four cars.

[42] Cons. Engr., New York, N. Y.

Columns of motor-driven vehicles can be moved safely, day and night (the latter in case of an emergency only) at 40 miles per hr, provided all road crossings and junctions are properly controlled. Cars should only be allowed to enter the road under the direction of a traffic control; therefore, it seems that the approaches to the express highway should be similarly controlled. This would call for as few approaches as possible between terminals, and one for each lane so that there would be no crossing of cars at any time.

Undoubtedly, the perfect highway will be constructed eventually; but the writer believes that the high-speed commercial roadway is a long way from realization.

R. A. MOYER,[43] ASSOC. M. AM. SOC. C. E. (by letter).—Many controversial questions are involved in the proposals offered by the author; however, the most important question that remains unanswered is that of deciding upon the proper speed or speeds for which the highways of the future are to be designed and for which existing highways are to be re-designed and improved.

The writer discussed this subject at some length in 1936 and 1937,[44] including a recital of the more general aspects of the problems involved. In analyzing Mr. Noble's paper, the writer wishes to add further interpretations of the results of his extensive research on the subject of speed *versus* safety, as it applies more specifically in this case to the problem of designing express highways for 100 miles per hr recommended by Mr. Noble as a suitable design speed.

There seems to be general agreement among highway engineers to-day that many highways in the United States are in immediate need of modernization and that the greatest single factor which has been responsible for this situation is speed. Highway engineers are by no means in agreement in regard to the methods to be adopted to solve the many problems created by wide variations in speed and especially by travel at high rates of speed. The author leaves the impression that the best solution to the speed and highway accident problem lies in the design and construction of express highways for speeds of 100 miles per hr. After more than five years of intensive study of the many factors related to speed, the writer is convinced that safety on highways can not possibly be assured by following such a course and that the surest way to increase accidents and fatalities is to encourage high-speed travel by building highways permitting speeds of 100 miles per hr. Not only is travel at such speeds unsafe on the basis of the physical laws which govern motor-vehicle operation and which are inviolate, but the difficulties which confront the driver at such speeds constitute an even greater threat to his safety. Furthermore, the extra costs of providing suitable highways for travel at this speed, and especially the excessively high operating costs, definitely indicate that such travel is uneconomical and impractical.

[43] Assoc. Prof. of Highway Eng., Iowa State Coll., Ames, Iowa.

[44] "Speed *versus* Safety on Straightaways", *Civil Engineering*, November, 1936; and "Speed *versus* Safety on Curves", *Civil Engineering*, February, 1937.

The author may defend his stand on the basis that if the highway is designed for a speed of 100 miles per hr, it will be safe for speeds less than that. Now, it is the writer's opinion, that this attitude is contrary to the first fundamental concept of good design offered by the author when he states that "it is possible to design a highway so that the motorist is led unconsciously to choose the safe act rather than that which is unsafe," and he further points out "the desirability of designing the highway on the basis of a constant rate of vehicle speed between large terminal points." With these concepts or principles of design the writer concurs. However, few persons driving cars at 100 miles per hr on a highway of the type suggested by the author could ever be expected to have the ease of mind or feeling of safeness commonly experienced when driving at the moderate speed of 50 miles per hr on a dual highway or even on a two-lane highway designed to present-day standards to accommodate such a speed. The tenseness and feeling of unsafeness commonly experienced at speeds greater than 60 or 70 miles per hr on the best of present-day highways is born out of the knowledge that there is a certain minimum time limit to any driver's reactions to meet certain emergencies and errors of judgment below which it is impossible to go. In that split second so much can happen over which the driver has no control that only by taking the control of the car almost completely out of his hands (as has been done in the safest rail operations) can safe operation be made possible. Not only is there a fixed limit to reaction time but, what is more important, the forces with which the driver has to contend at a speed of 100 miles per hr have been increased many times, compared to the forces encountered at present-day average speeds of 40 to 50 miles per hr. The time required to bring the car under control has likewise been increased; and the distance traveled during this interval extends far beyond the zone of safety within which control of the car may reasonably be assumed to be possible. Only a revolutionary change in the steering, braking, and driving of cars can correct this situation. Accordingly, even if the driver were led unconsciously to choose the safe act on a highway designed for 100 miles per hr, his chances of following his choice when driving at this speed would all too frequently be very small, indeed, to prevent the accident.

A valuable feature of this paper is that it has directed attention to the most vital factor in modern highway design—the speed factor—and furthermore, it has stimulated discussions on definite design details which the author contends should provide positive safety at a definite speed. However, to establish the design speed arbitrarily at 100 miles per hr, or at the maximum speed at which the cars are now, or may soon be, capable of, is contrary to another basic principle in design mentioned by the author in which he states that to-day emphasis should be based on broad highway economics founded on loss of life and property as well as on operating costs.

In the 1936 report of the National Safety Council on "Accident Facts," statistics are given which indicate that the severity of accidents increases with an increase in speed. Thus, at speeds of less than 20 miles per hr, 1 accident out of 61 is fatal; at speeds between 20 and 29 miles per hr, 1 accident out of 42 is fatal; at speeds between 30 and 39 miles per hr, 1 accident out of 35 is fatal; at speeds between 40 and 49 miles per hr 1 accident out of 25 is fatal; and at speeds greater than 50 miles per hr, 1 accident in 11 is fatal. Statistics of railroad-crossing accidents, involving cars and trains, have consistently shown that one accident in two or three is fatal. Tremendous forces are involved in accidents involving high fatality rates. It should be noted that the forces developed at high rates of speed vary as the square of the speed and that the aforementioned statistics indicate a certain amount of correlation in this respect.

Not only is the severity of accidents increased with an increase in speed, but the chances for accidents increase with an increase in speed. This was revealed in 1936 in a report,[45] by Charles J. Tilden, M. Am. Soc. C. E., in which the accident records of owners of cars observed traveling at high and low speeds were analyzed. It was found that in this instance "the high-speed drivers who have accidents have more of them, so that they account for 45 per cent more accidents than do the low speed drivers."

In regard to the economics of express highways, Mr. R. E. Toms summarized the highway cost phase of it very ably in a paper presented at the 1937 Annual Meeting of the American Association of State Highway Officials.[46] He stated that,

> "* * * however desirable they [express highways] may be, they are not possible except on a very limited mileage of our State Highway Systems. * * * Assuming that it would be desirable to improve 5 per cent [about 16 000 miles] of the State highway mileage with four or more traffic lanes with opposing traffic separated, grades at intersecting highways separated, border roads to eliminate unrestricted access from abutting property, and sidewalks for pedestrians where needed, the expense involved in this undertaking alone would amount to approximately four billion dollars. This is just about the amount that has been devoted to highway improvement in this country during the last 20 years through the program of Federal aid to the States matched with State funds, plus the amounts of Federal funds appropriated for emergency construction which did not require matching by the States. When these figures are considered, we must admit that in so far as we can visualize the future at this time from 95 to 97 per cent of the State highway mileage in this country may never progress in improvement beyond a two-lane highway."

Although Mr. Tom's estimate of the cost of constructing express highways may have been high, since it calls for an average initial cost of about $250 000 per mile, this figure is not unreasonable when stated in terms of the cost per vehicle-mile on a highway carrying 4 000 or more vehicles per day. The annual cost for such a highway, including maintenance costs, snow removal, depreciation, interest charges, and

[46] "Highway Safety Exemplified by Properly Designed and Constructed Highways", by R. E. Toms, *American Highways*, January, 1937.

charges for policing, would probably be about \$15 000 per mile and, for 4 000 vehicles per day, this would represent a tax cost of about 1 ct per vehicle-mile. The present average tax cost for highways in the United States, based on the license fee and gas tax, is about $\frac{1}{3}$ ct to $\frac{1}{2}$ ct per vehicle-mile. It would be quite possible for the Federal Government to undertake such a project and to assume full control of this system of highways. A Federal license would be required to operate on the highway. Tolls might be collected to finance the cost of construction and operation. The highway would be constructed, maintained, operated, and policed by the Federal Government.

Although the highway cost may not be unreasonably high where the traffic volume is sufficiently great to justify the construction of such a highway, the motor-vehicle operating costs are so much higher at 100 miles per hr than at the present-day average speeds of 40 and 50 miles per hr, as to make it very doubtful whether traffic would operate at such speeds for any considerable distance; and, certainly, it would be absurd to build highways for such a speed if only a small percentage of the traffic would travel at the designed speed, or if drivers were to operate at such a speed for only a few minutes at a time. Tests conducted by the writer indicate that fuel costs at 70 miles per hr are almost double the costs at 40 miles per hr, and at 100 miles per hr there is every indication that the costs for the same car are about three times the costs at 40 miles per hr. Oil costs seem to follow a similar trend, or if oil costs are reduced at the higher speeds, the engine costs are increased, due to increased wear on cylinders and pistons. Tire wear follows the square law very closely and the tire costs at 100 miles per hr are most likely to be about six times as great as at 40 miles per hr. Engine breakdowns are still very common in the Indianapolis, Ind., races where an average speed of slightly more than 100 miles per hr is maintained for only 500 miles. One can be quite certain that engine repair costs and car maintenance costs would be greater at 100 miles per hr than at 40 miles per hr. A conservative estimate of the increased operating costs for the same car due to speed is that the cost of operating at 70 miles per hr is 2 cts per mile more than at 40 miles per hr and at 100 miles per hr it may easily be 4 or 5 cts per mile more than at 40 miles per hr. Such a cost of high-speed travel can not be disregarded when proposals are made for spending billions of dollars to build express highways. It would be a sad commentary on engineering judgment to find that after such highways were built, traffic would not be willing to pay the tax to use them—the toll-free State highways with their lower speed limits carrying most of the through traffic.

In his discussion of details of design, the author states that there is great need for research before satisfactory design details can be developed. It has been gratifying to note that this paper has provided the means for bringing together many discussions in which considerable experimental data and many excellent theoretical analyses of the design problems are

presented for the first time. Tests conducted by the writer[47] have provided much basic information that is needed in the solution of this problem. Although present knowledge is far from complete, it is the writer's conviction that the basic facts are now known, and it is not so much additional information that is needed as it is the proper use and interpretation of the information at hand.

The most important element in the design of an important highway to-day is the speed factor. This is not a matter to be decided upon by an individual, from experience based on local conditions, but rather it is an element of design which should be as rigidly controlled as are the weights, lengths, widths, and heights of vehicles. Speed may quite properly be thought of as a "fourth dimension" which controls curvature, superelevation, road width, and sight distance. In fact, practically every detail of design is wholly or in part controlled by the speed factor. For important highways, it is desirable, therefore, to standardize or control speed for the same reason that weights and lengths of vehicles are standardized. The establishment of such a standard is not an easy matter.

In this discussion, the writer has touched on only a few of the more important factors which should be considered before speed standards are decided upon. A complete analysis of the speed problem and of establishing design speed standards for various classes of highways is not within the scope of this discussion.

It is virtually impossible to design highways to permit safe travel on ice-covered surfaces for the high-speed travel, which the author suggests will be a controlling factor in determining the superelevation on curves. Tests clearly indicate that there simply is not sufficient friction available between rubber tires and ice to make it possible to develop a speed of 100 miles per hr on a level surface, not to mention the difficulties of steering or of stopping the car at that speed. The writer recommends that superelevation be used on all curves to permit easy steering and that the maximum rate of superelevation of 0.1 ft per ft be used on the sharpest curves, combined with a maximum value of f equal to 0.1 where this frictional force is necessary to counteract centrifugal force not taken care of by the superelevation. The safe speed on ice is almost never greater than 30 miles per hr on straightaways where traffic is separated and it certainly does not seem possible that curves could be designed to permit higher speeds with safety on ice by any known device commonly used in highway design to-day. The writer wishes also to state most emphatically that spiral curves are necessary and may very properly be used on all curves.

In this paper, the author has aroused the imagination of his readers. The paper has been timely because this country now appears to be approaching the end of what has been aptly called a "highway construction holiday." A new era of road building seems to lie immediately ahead. The modern car is so far ahead of the highways on which it

[47] *Bulletin 120*, Iowa Eng. Experiment Station, Iowa State Coll., Ames, Iowa, August, 1934.

must now travel that mere improvising will not suffice. A new conception of a modern highway is needed. Men of vision and of wisdom are needed, who can weigh all the variables involved, who can foresee the direction in which true progress lies, and who can formulate the broad plans upon which the highway systems of the future are to be built. The magnitude of the improvements under consideration are worthy of the most thorough and painstaking analysis and it is for this reason that this paper should prove to be a really worthwhile contribution to the literature on the subject and a benefit to all the people in this country who, in the last analysis, will profit most by such studies.

CHARLES M. NOBLE,[43] ASSOC. M. AM. SOC. C. E. (by letter).—The response to the paper, and the frank expression of opinion, is gratifying. The discussion has been directed as much along sociological, psychological, and philosophical lines as along a train of thought devoted to technical design. Of the three elements which constitute the broad background of highway safety (namely, the operator and his control, the vehicle, and the highway) the paper treated only the latter, on the theory that the other two were, in a technical sense, out of the province of the designing engineer; but, since the discussion has broken free of the original limits, it may be in order to continue in the spirit of the discussion and begin at once with the non-technical phases before turning to the more technical features.

The writer wishes at once to concur with all that has been said respecting the desirability and advantage to be gained from a rigid restriction of the privilege of driving a motor car on the public streets and highways, as well as the adequate testing and training of the operator. There is no doubt that a very large percentage of accidents can be prevented in this manner.

The deprivation of one's license to drive, from the reckless and unfit, would relieve the highway at once of one of the gravest hazards, while at the same time it would have a sobering effect on the remaining drivers. Nothing in the paper could be construed as advocating looseness or laxness in this direction and, for some years, the writer has been keenly aware of the advisability of rigid control and policing. However, such control is more in the province of the administrator, the police official, the politician, and the engineer, acting in the broad capacity of his profession. Essentially the problem of the designing engineer is to design to comply with conditions as he finds them, or as he can reasonably predict they will be in the future. Perhaps a short review of elementary basic engineering design principles may not be out of order, as there appears to be a tendency to overlook some of the fundamentals which general engineering practice has evolved.

In designing a bridge, for example, the first task of the designer is to discover the magnitude of the loads which the bridge may be required to support, the physical properties of the materials of construction, the

[43] Asst. Engr., Port of New York Authority, New York, N. Y.

proper factor of safety to apply to the materials, the determination of the stresses of all kinds which will occur in all parts of the structure, and, finally, the proper proportioning of each member, based on the transmission of stresses to it. The completed design represents a logical and consistent process of thought, which combines a close attention to detail with a clear picture of the functioning of the structure as a whole. It is axiomatic that success in engineering design is dependent on the correct assumption of the loads to be carried, the proper selection of the materials of construction, and the correct stress to apply to these materials.

Suppose bridge engineers designed structures, using loads less than the actual known loads, because they felt the actual loads were unreasonably high, that loads of such magnitude should be prohibited, and because they hoped legislation might be passed some time in the future to curtail the loading! This seems to be somewhat the attitude of a number of highway designers. There appears to be a reluctance to acknowledge the loads which the highway is called upon to support.

Traffic density and speed are the loads. Alignment, grades, superelevation, sight distance, shoulders, signs, lighting, and a multitude of details which add to vehicle safety, are the materials. Loads have been assumed that were too small, and the materials have been stressed up to and beyond the ultimate strength. This is not in accordance with established engineering practice.

A brief review of recent highway engineering history may be of assistance in clarifying past design measures and in illustrating that design practice is, at present, pausing at the cross-roads, while consideration is being given to the direction it shall pursue. The twenty years since about 1917 represent the pioneering period in highway design as related to the motor car. At the beginning of the period no road system, as at present defined, was in existence, and the motor industry was still in its infancy. The pressing need was to bring into existence, from a standing start, a connected road system embracing the entire United States. The task was colossal. Cheapness of original cost and speed in location and construction were the goal.

At that time, the property owner contributed the bulk of the road money, and he expected a road dollar to go a long way, geographically. The results may be compared in a rough sense with the earlier development of the railways, which, although not of a thoroughly permanent nature, were, nevertheless of vast benefit to the nation. America was "pulled out of the mud" in the incredibly short time of twenty years, thus making possible the almost magical development of the motor car and, even if the exigencies of the period had permitted of more leisurely and permanent construction, engineers had nothing on which to base a forecast of future requirements, for no one really dreamed of a stock car of moderate price which could travel with ease hour after hour at 70 or 80 miles per hr. Engineers were literally pioneering in a new form of transportation, and, consequently, one must not be too critical of their performance.

To-day, the situation is quite different. The pioneering period has definitely closed, and the highway and motor industries are entering upon an era of early maturity. The motor car owner is contributing the major portion of the monies for highway improvement, and consequently his safety is entitled to careful consideration; in addition, there is ample "case history" from which to make an intelligent forecast of future needs. From now on the engineer must produce a finished and polished product, perfected as to detail and equipment, and, in addition to expeditious travel service, an adequate margin of operating safety must be provided.

There has been a misconception on the part of many readers. It has been assumed that the writer is a proponent of speed, and that he advocates an improvement in design for the purpose of providing speedways to encourage the motorist to drive at high speeds. Nothing could have been further from the writer's mind. He does feel, however, that a great number of motorists always have driven at a higher rate of speed than road conditions warranted, and that they will continue to do so until road conditions are improved to a state more in accordance with the speed habits of the nation. As far as the writer personally, is concerned, he would be content never to exceed 50 miles per hr, but the problem the engineer is facing cannot be solved by injecting personal opinion into design practice. Engineers are designing an engineering structure, and engineering principles and methods must be applied—principles and methods which have evolved from the design of other engineering structures.

There has been considerable discussion and adverse criticism by many commentators respecting the writer's suggestion that design be based on a speed of 100 miles per hr. It must be recognized at once, however, that a design for express routes, based on this speed, is a very effective method of assuring a proper factor of operating safety for more moderate speeds, while at the same time providing a reasonably sure form of insurance against obsolescence. As subsequently demontrated the adoption of such a design speed does not involve as much difference in actual design standards as might be supposed in comparison with a design based on a sustained speed of 60 miles per hr. Be this as it may, the embarrassing question may quite reasonably be asked: Is there anything in the past history of the development of the motor car which justifies a confidence that top driving speeds have been reached? It should be remembered that the motor industry is highly competitive and therefore, will continue, in all probability, to strive to give the public the kind of vehicle which it demands.

As far as the speed situation is concerned, present design practice appears to be in a somewhat unfortunate position. If the road was so crooked or so congested that even moderate speed was physically out of the question, it would be reasonably safe as far as serious accidents are concerned; or, if the road was designed uniformly for a speed greater than

any one cared to drive, then it would be safe from a physical standpoint at all the operating speeds to which it might be subjected. Present design, however, is neither the one nor the other. It is open enough to encourage speeding, but not open enough to justify such speeding, and thus highway designers are guilty of encouraging the motorist to operate at speeds not justified by the actual design. It should be emphasized that safe design consists not only of good alignment, superelevation, and grades, but upon a skillful combination of all the components outlined in the paper, so that a consistent and ordered whole is produced. The writer earnestly feels that engineers should face the facts squarely, should make an intelligent effort to forecast the future, and should then proceed in an ordered and logical manner to design along engineering principles, adopting a proper factor of safety.

The key to the widespread advance in sustained road speeds appears to be related more to the general improvement of the vehicle rather than specifically to increased horse-power in the motor. As long ago as 1920 there were a number of makes of American stock cars which were capable of speeds of 75 and 80 miles per hr; but, except for the most reckless and adventurous, there were few that even approached these speeds, because driving one of those cars at such high speeds was distinctly a nerve-wracking experience which only a thrill seeker would endure. The human nervous system could not stand continuous high-speed operation in such cars, and, consequently, continuous operation seldom exceeded 40 miles per hr. Thus, highway engineers had no experience or any other basis for predicting a rapid advance in road speeds. Along in the middle 1920's, when the manufacturers had mastered the production of a fully dependable motor, they turned their attention to other features of the vehicle. Improvements in the body, steering, tires, brakes, reduction in vibration, redistribution of weight, shock absorbers, rubber mountings, etc., pyramided in rapid succession, until to-day the car glides over the highway with swiftness and ease, eradicating all sense of speed values, with complete lack of nerve tension and fatigue for the operator.

In a word, all sense of speed has been destroyed. This, then, is the major cause of the general increase in sustained road speeds, and coupled with greater power plant in the medium priced and cheapest vehicles, it spreads the power of high speed among the great mass, and among all classes of people. The destruction of the sense of speed is the primary reason why many conservative motorists operate at higher speeds than conditions warrant. This is particularly true where conditions require speeds in the lower brackets.

A recent advertisement of a car "priced just above the lowest" listed, among others, the following: "No vibration or road rumble; new ease of steering; no 'wind wander' even in a gale; no 'edging off' in ruts or gravel; new sound-proofing; so silent inside you can talk in a whisper; 'city ride' on any kind of road; * * *" Incidentally, this car is equipped with 93 hp. There can be little doubt that manufacturers will soon

reduce the cost of high speed. In view of the highly competitive nature of the industry, do highway engineers really believe advancement in automotive design will cease abruptly?

Mr. Purcell gives the results of observations in California showing that 94% of all cars traveled at or less than 55 miles per hr. Assuming the observations were taken in 1936, it should be remembered that more than 60% of these cars were three years old, or older. In other words, 60% were not newer than the 1933 model, and many of the most effective improvements in vehicle design which particularly deaden the sense of speed, have occurred since that year.

Since comparisons are inevitable, suppose for a moment, the essential difference between improvement in railway line and improvement in motor ways is examined. The improvement in track is entirely economic, using the definition in the conventional sense. Such improvement is actuated by a desire to lower the cost of hauling freight or to shorten passenger-train time. Safety is not an issue, because enginemen are given a definite speed order to apply to each section of track, and they are perfectly familiar with their runs. Because these operators are employees who may be disciplined for infraction of orders, obedience is quite general. Thus, from a safety standpoint, bad track conditions can be overcome.

The highway situation is quite different. The motorist, by and large, is not an employee, and he purchases a vehicle from an industry which is not responsible for the design, construction, or maintenance of the track upon which it operates. As long as he can escape the vigilance of law enforcement officers he can do, and does, about as he pleases. He usually feels he is clever if he continues to "get away" with breaking the motor laws. Often he is unfamiliar with road conditions, and more often is operating at a greater speed than conditions require. He has no "slow orders," and, therefore, any sudden change in road conditions which requires a slow speed introduces a hazard which, sooner or later, results in an accident. Moreover, the average motorist does not have the skill and judgment which an engineman possesses. Thus, an improvement in highway standards is a step forward in safety, and consistency in design is the very essence of safe design.

What, then, is there in this situation to assure the highway designer that he will ever catch up with automotive design; that obsolescence will not continue its costly toll? As far as the vehicle is concerned, there appears to be no immediate limit; possibly fantastic speeds may be possible, but a limit there must be, and that limit is more likely to be human flesh than steel and rubber. The human nervous system has a limit, and it has been stated that this limit is possibly 100 miles per hr. This, then, is the basis for the suggestion in the paper that 100 miles per hr may not be an unreasonable maximum design speed.

The purpose of the paper was to show that the present standard of first-class road design is inadequate for high speeds. The destructive forces at high speed are so terrific that an entirely new conception of trunk

highways will be necessary to cope with the situation. This thought is expressed very aptly by Professor Moyer. The writer is not sure, given unlimited resources and money, whether engineers could produce, to-day, an inherently safe design. They may not know enough at this moment about safe design. Nevertheless, a sincere and intelligent effort must be made to provide the motorist with as much protection as knowledge and skill will permit, at the same time continuing an intensive attack on the problem in order that the profession may the more surely advance its knowledge and technique.

In general, the discussion by the commentators may be classified into two more or less distinct groups: (1) That the present standards of design are properly and efficiently performing their functions, and that the highway system, as at present constituted, is as perfect as the motorist may reasonably expect; and (2) that further advancement in the art of highway engineering, particularly as related to safety of operation, is distinctly indicated if the motorist is to be provided with the type of service he should reasonably expect.

It may be well to express to proponents in the first group that no engineering art should remain stationary—that none of the various branches of engineering is remaining stationary When an art remains stationary it becomes mere dogma. The writer feels sure no one really wishes to suggest such a fate for highway engineering. Indeed, it is clear that this branch of engineering has just emerged from the pioneering period and there is a vista ahead of mature but vigorous growth and development.

Specifically, the following suggestions have been offered in lieu of improved design standards, or as reasons against raising such standards:

(1) That vigorous control of the driver should be maintained and the unfit and the accident repeater be ruthlessly ruled off the road;

(2) That vehicle speed be arbitrarily controlled by a mechanical device;

(3) That a large class should not be taxed to provide speedways for the few;

(4) That the cost of adequate highways is too large and is not economically justified, and that the percentage of accidents caused by faulty highways is not great enough to justify an improvement in present standards; and,

(5) That it is questionable whether it is the duty of the State to provide expeditious service.

It may "clear the air" somewhat if Suggestions (1) and (5) are discussed in somewhat greater detail.

Control of Driver.—For twenty years the problem of control (Item (1)) has been discussed but very little has been accomplished. A few years ago it was thought that a system of licensing drivers would be a remedy, but such action has been found to be only mildly palliative. The difficulty is that the great mass of public opinion is opposed to rigid control

measures; politicians will not pass statutes, nor will officials ruthlessly enforce legislation, which they know is not solidly supported by the mass of the people. The Eighteenth Amendment is an example.

As a group, highway engineers would welcome the elimination of all unfit and dangerous drivers, particularly those who prove to be accident repeaters. Granted such a procedure is most desirable and that it would be helpful, it would by no means solve the problem under discussion. It would not materially reduce those accidents caused by imperfections in the highway itself. Many careful and competent drivers have serious accidents. Should sober and substantial citizens be required to risk their lives day by day when it is possible to remove many of the hazards connected with motoring by designing safety into the highway?

Unfortunately, a continued discussion on the subject of control is almost academic. Does any one really believe that rigid and drastic laws will be passed and enforced in the near future? Without wishing to appear cynical, the writer believes the answer is definitely, "No!" Only by the slow process of education can real progress be made, and for this reason it is doubtful whether the goal can be reached within the next twenty years. By that time nearly 800 000 human beings will have paid with their lives, if the present death rate continues, and 25 000 000 will have been injured.

Mechanical Control Devices.—During the past twenty years mechanical speed governors (Item (2)) have been seriously proposed several times; but the public would have none of it. It is one thing for a private company operating a number of motor vehicles to apply governors to their cars but quite another to get a law on the statute books requiring all citizens to apply governors. An employee of a company is quite helpless to prevent the use of such a device, but the electorate have a way of showing their disapproval. In addition, there are practical difficulties.

Would such a law be a Federal statute, or would each of the forty-eight States have to pass legislation specifying an identical speed limit? Would motorists from other States be compelled to stop at State lines and purchase a governor in order to pass through States having such laws? The injection of these conditions into the motor problem would undoubtedly disrupt motor transportation. Finally, is there any one who can point to a strong, unified movement among the great mass of citizens for an enactment of mechanical speed legislation?

Taxation.—The writer can recall hearing, twenty years ago, the same complaint from owners of horses and buggies to the effect that the taxpayers were having to spend good money to create speedways for the motorists (see Item (3)), but does not recall hearing any motorists in recent years complaining about roads being constructed too well. Twenty years ago most of the road funds were being contributed by the property owner. To-day, most of the road money is being contributed by the highway user. As Mr. Dennis states, the American highway is, in effect, a toll road, the user paying a sales tax. For instance, in 1935, the State

and Federal oil and gas taxes and license fees amounted to \$958 753 000, the manufacturers' and personal property tax to \$350 000 000, making a total of \$1 308 753 000. If the motorist, who pays the bills, does not object to the expenditure of sufficient money to modernize the highways, there is no valid reason why the engineer should urge him to accept an article which does not provide him with reasonable safety facilities. To the writer's knowledge, there is no unified and concerted movement among the various associations of motorists for the curtailment of highway construction.

Economical Considerations.—It is often argued (see Item (4)) that it costs too much money to do a first-class job in constructing highways. That may have been true during the pioneering period when the vital need was to create a road system; but now that that era of stop-gap construction is past, engineers can proceed to replace their "log cabins" with brick and stone. It must be realized that adequate highways will cost a great deal of money, and it would seem the better policy to design and construct these highways with the thought of their being permanent, rather than to have to repeat the performance twenty years hence, thus wasting the sums now being spent. A cheap article is not always a bargain.

It is somewhat inexplicable that engineers should take the stand that adequate highways should not be designed and constructed because of the large cost involved, when it is remembered that considerable sums are diverted annually from motor vehicle funds to other than highway uses. A more commendable effort would appear to be to educate the public to the fact that the need of highway expenditure is not over, but in reality only begun, and that the highway industry needs every dollar collected from the motorist to remove hazards from the present highway system and to construct new highways in accordance with advanced technique, to the end that the public will receive more expeditious road service, will derive more pleasure from motoring, and will not be subjected to as many chances of being killed or injured. Thus, the engineer would be performing a notable public service, at the same time assuring himself, and his fellow engineers, of a continued opportunity to make use of his technical talents.

It is further contended that the percentage of accidents caused by faulty highway design is not sufficient to justify the expense of safe design. This is quite a cold-blooded argument when the terrific mental and physical suffering occasioned by traffic accidents is remembered. To make matters worse, the argument may not be altogether true. As stated in the paper, accidents occasion an economic loss from a purely financial point of view. The writer is not aware of any accurate appraisal of this loss. The Travelers Insurance Company, of Hartford, Conn., estimates that it amounts to from \$2 000 000 000 to \$2 500 000 000 each year. W. V. Buck, M. Am. Soc. C. E., states[40] that statistics indicate that 30% of all accidents may be traced to some fault in road location and design.

[40] *Engineering News-Record,* October 29, 1936, p. 612, *and Civil Engineering,* January, 1937, p. 1.

If these figures and assumptions are correct, then faulty highway design is costing the American public from \$600 000 000 to \$750 000 000 each year; and to these figures must be added the economic loss due to obsolescence. It is evident that more study is necessary in order that more nearly accurate figures of the economic loss due to accidents may be made available.

In this connection it may be pertinent to mention railway-highway grade-crossing elimination. Acording to Table 1, only 0.6% of all accidents were due to this cause. If the economic loss from this type of accident is assumed to be at the same rate as for all accidents, then, assuming the foregoing estimate, the annual economic loss due to railway grade crossings only amounts to from \$12 000 000 to \$15 000 000 for the entire United States. Yet, as Mr. Ripley states, New York State recently voted \$300 000 000 for grade-crossing elimination, and there is a strong movement all over the country for rapid elimination of all railway grade crossings.

Studied from a cold-blooded standpoint, this work has no economic justification; but is there any considerable body of engineers who condemn grade-crossing elimination? If engineers are willing to support such work, why are they not willing to support the elimination of other road hazards? Mainly, it is because of the subtlety of the problem. The actual causes of other types of accidents are not as evident even to engineers.

The public is supporting grade-crossing elimination heavily because it can readily visualize a railway crossing as a hazard. If the public really understood the mortality due to other highway hazards, they would without doubt approve the expenditure of the necessary funds to provide for their systematic elimination. More people are killed in motor accidents in the United States in one month than have perished in all the floods in the entire country during the past ten years. Therefore, it would appear wise for engineers to advise the public of the relation between highway design and the accident rate, rather than to remain indifferent until stung into action by public censure.

Responsibility.—Mr. Lavis questions whether it is the duty of the State to provide the motorist with expeditious road service (see Item (5)). This is a pertinent question and deserves careful consideration. As practiced in the United States, the State has, in general, assumed as a duty any function for which there is a persistent and widespread demand among the electorate. It may be assumed, therefore, that if the public demands expeditious service, the State will accept the responsibility within the limits of available highway revenues. The continued reconstruction of outmoded highways is an expression of an acceptance of that duty. Frequently, the relief from congestion in urban areas constitutes a provision of expeditious service, and highway engineers are in a position to know to what lengths the State is willing to go to provide such service.

From the foregoing discussion, it is rather evident that designers are facing (and probably will continue to face for some time) operating conditions over which they have little control. Thus, an open mind, continued thought, compilation and analysis of data, and continued technical prog-

ress, based on well-founded principles, is clearly indicated in order that that happy combination of safe design and over-all economy may be achieved.

Rights of Way.—Of all the features under discussion, the alignment and width of the right of way is by far the most pressing and important, not only from a financial point of view, but also because of its vital influence on vehicle safety. The ability of the average citizen to look into and prepare for the future is generally conceded to be rather poor. His thoughts are chiefly concerned with the present, and usually he is not prepared to make any sacrifices or provide monies to care for the future unless he can be shown conclusively the benefits that will accrue. The dissemination of this gospel and education is in the province of the engineer, for he is generally thought to have the ability to look into the future, to forecast the coming needs, and to evaluate, properly, the extent to which the present generation should prepare for the problems of the next. The water supply, flood control, electrical, and sewerage engineer has demonstrated his proficiency in this field, and has educated the public to respect his judgment. The right-of-way situation presents an opportunity to the highway engineer for public service.

Messrs. Lavis and Crosby have indicated the desirability of initially acquiring ample rights of way with proper alignment. The importance of the subject justifies an expansion of the discussion in order to focus attention sharply upon this vital question.

The right of way is the only element of the highway that is permanent. This axiom was current when the writer entered the highway field in 1914, yet it was heeded to so small an extent that to-day the inadequacy of rights of way, which is the most difficult and expensive error to correct, is acute in many States. Road improvement brought an increase in land values and physical improvement adjacent to the right of way which has made widening and straightening prohibitive in many cases. The critical street situation in cities is a manifestation of the ultimate results of inadequate width. As stated previously, lack of vision during the pioneering stage in securing adequate rights of way should not be criticized without a realization of the problems of the time. To-day, the situation is very different.

Because of its very nature, the trunk highway will be located to as large an extent as practicable upon new rights of way as far removed from developed areas as possible, and, in general, it will be purchased by the acre rather than by the square foot. Therefore, its cost will be less at the time of original improvement than at any period in the future. It can be purchased on the basis of the owner retaining (with restrictions), the mineral, timber, and cultivation rights of the unused part, thus reserving to him a large portion of the material benefits for many years, while, at the same time, he would be relieved of paying taxes on such lands. This procedure will reduce the cost of acquisition, and, at the same time, lessen the opposition of the public and the land owner.

In the discussion by the commentators, frequent mention has been made of the excessive cost of wide rights of way. The cost of anything is relative. Bearing in mind that the life of such land is relatively infinite, the yearly cost is consequently very small; but, for fiscal reasons, it may be advisable to liquidate it within a period of 50 yr, or possibly 100 yr. In Europe, there are rights of way in use to-day which have existed for more than 2 000 yr. The right of way is the very foundation of the pyramid of stage construction.

The initial construction (located off center), may cost less than the land, and in undeveloped regions its standards may be quite low (except for the alignment which is determined by the right of way), until traffic justifies further improvement, but the ultimate construction may cost $200 000 per mile. (In the East, highways have already been constructed through open, easy country which cost $600 000 per mile, exclusive of land.) If the right of way proves inadequate, the previous heavy investment in physical construction may be rendered impotent because when a highway is relocated to a new right of way, all improvements in the form of grading, sub-drainage, stabilization of sub-grade and slopes, drainage, bridges, and landscaping are lost. It is a type of financial failure. If the right of way is of proper alignment and of sufficient width, each step in advancing the standards will make full use of all previous effort and expenditure, thus conserving the people's investment and producing, step by step, a more perfect and up-to-date element of transportation.

It is difficult for those who reside in rural or undeveloped regions to visualize the throttling effect of growing population and development upon inadequate rights of way. Many troubles to-day are caused by the failure of previous generations to realize the possibilities of the future. It was difficult for them to visualize the effects of growth. Many wholly undeveloped regions through which right of way may be purchased at cheap prices, may suffer 100 yr from now if a niggardly right-of-way policy is pursued to-day.

An element of cost not sufficiently stressed is the adverse effect upon, and economic loss sustained by, farmers and property owners each time a highway is relocated. Many farms and parcels of property have been cut up into unusable or uneconomic pieces. Areas containing abandoned pavements usually are not reclaimed and put back into any form of production, and an abandoned right of way seldom finds its way back on the tax books. Certainly highway authorities should not subject land owners to this form of inconvenience and loss more than is necessary. Permanent right of way, of adequate width, would solve the difficulty and tend to stabilize land values, particularly when the freeway principle is used.

The present period appears most opportune to advance the cause of wide rights of way, in view of the continued statements from high governmental sources relative to retiring large tracts of land on the theory that more land is in use than is economically justified, and highway

engineers should be quick to seize the opportunity of informing the public of the lasting benefits which will accrue to the nation from an enlightened right-of-way policy.

Classification.—Mr. Diehl brings up the very pertinent question of highway classification. The subject is not only important but pressing. The road must not only be classified according to present and future traffic trends, but it is quite as vital for it to be classified on the basis of safe operating speed. Fortunately, the groundwork[80] on which to base a classification is being laid by forty States in co-operation with the U. S. Bureau of Public Roads. Whether full and proper use will be made of these transport surveys depends on the initiative and unselfish public spirit of officials and engineers. For the first time, it will be possible to make a real and searching analysis of the social and economic structure of the highway system as a whole.

National Highways.—Without doubt, when the local and regional analysis is completed, thinking will be directed toward the possibility of a national system of highways, designed, constructed and maintained by the Federal Government. This is indicated by Mr. Dennis, and such a system may not be as fantastic as would appear at first thought. Undoubtedly, it would prove a real national asset not only for the every-day needs of the nation, but also as a vital unit in the national defense system. As Mr. Dennis intimates, a national system may be likened to the trunk lines of the railways, with the present system acting as the branch or feeder lines.

If it is assumed that 10 000 miles would constitute a reasonably complete system, it could be constructed for approximately \$3 000 000 000, and if, as Mr Diehl suggests, it is developed within a period of 30 yr, the annual appropriation required (\$100 000 000), is only a moderate portion of the taxes which the Federal Government at present imposes on motor-car owners and the motor industry. In view of the \$15 000 000 000 quoted by Colonel Crosby[29] as having been spent on the existing highway system in the United States during the past 36 yr, \$3 000 000 000 does not appear out of proportion.

In connection with the more technical features of the paper, the writer wishes to express his appreciation to those who brought the latest results of research and thinking before the members of the Society. At the time of the preparation of the paper (spring of 1935), the results of certain very illuminating and clarifying tests,[47] by R. A. Moyer, Assoc. M. Am. Soc. C. E., which have since been widely disseminated, had not come to the writer's attention, and he is grateful indeed for the addition of the material.

To simplify matters, and for convenience, it may prove desirable in covering the discussion, to follow the same order as used in the paper.

Dual Highway.—There is further opportunity for service in establishing design standards of the dual highway, because development has reached the interesting stage in which several variations of type are being con-

---

[80] *Civil Engineering*, March, 1937, p. 178.

structed and subjected to the actual test of traffic. Further analysis of the various classes of accidents occurring on each type, and a thoroughgoing scrutiny of the comparative accident data, may clarify the situation and indicate the proper design to be used for certain particular conditions. Since the discussion did not record current design variations, or any analysis of the philosophy behind the use of particular designs, the writer takes the liberty of attempting to analyze the situation in order to define the issue more clearly in the hope that further thinking will be stimulated. The subject is so new, and there is so little supporting data, that the remarks should be considered only as a personal expression of opinion, and, therefore, fallible.

It is granted that a space separating opposing traffic is essential for trunk-line highways carrying any appreciable volume of traffic; but the width and treatment of this space is a very unsettled matter. There are cases when it is physically and financially limited to a width of a few feet, and other cases where it may easily be 150 ft or more. It is obvious that as the width increases, the chances of opposing accidents diminish. For the narrower widths it is clearly necessary to use some kind of curb to prevent impatient drivers from using the space for passing in case of traffic congestion. The treatment in use varies from straight-sided curbs, 6 to 11 in. high, to numerous types of sloping curbs.

When the width is only 3 or 4 ft, the vertical (batter of 6 on 1) curb may be the lesser evil, but it must be recognized that certain "elbow room" has been forfeited. The operator no longer has the chance to dodge sidewise the few feet necessary to avoid a side-swipe accident when he has been crowded or "pinched" by other vehicles. For widths of from 7 to 20 ft, some kind of sloping curb is indicated, the design to be such that it can be mounted at high speed without danger of loss of control. Considerable experimentation is being practiced in New Jersey in an effort to find a solution for this problem, and it is hoped that tests will be made, using different makes of cars operated at various speeds, in order to establish a design which will permit mounting without throwing the car out of control. A curb of improper design may cause a more serious type of accident than one produced by a side-swipe.

Particular attention must be paid to the material between curbs. In wet weather, and during the spring break-up, unstabilized grass plots are very dangerous, the ground being so soft that vehicles are thrown out of control, if by any chance they are forced into the space while traveling at even moderate speeds.

For widths from 20 to 30 ft, a narrow mall or island may be placed in the middle, using smooth stabilized shoulders adjacent to and level with the pavement; and for widths greater than 30 ft, level shoulders with grass and landscaping between is indicated.

It is axiomatic that no form of fixed obstruction, such as poles, light standards, trees, etc., be placed in the dividing safety space. Head-light glare can be eliminated by planting a type of evergreen, the trunk of which

will not exceed 2 or 3 in., and such a screen will also tend to act as a cushion for cars out of control.

As a motorist, the writer cannot but be tremendously impressed with the general design developed in Delaware; the operator has a feeling of tranquillity and utter safety not experienced in any of the narrow center-width and curbed designs. Passing is no problem because the motorist keeps to the right without supervision, and the wide, smooth shoulders provide a factor of safety as well as a space for parked vehicles.

It is the writer's belief that the width separating opposing traffic is a function of safe allowable speed. As the width decreases, the speed should decrease. Where it is necessary to reduce the width for financial reasons, the additional cost to the State of policing to insure reduced speed, as well as an appraisal of time losses, should be added to the financial analysis. (It should be remembered that the predominating reason for the safety record in the Holland Tunnel is the presence of police officers stationed at frequent intervals to enforce the regulations and prevent motorists from crossing from one lane to the other.) Where restricted widths are required, it may be necessary for the designing engineer to arrange with the State Police to provide sufficient officers to enforce compliance, rigidly, at all hours, with the safe speed established by the engineer. The public will not reduce speed unless an adequate number of officers are present to compel obedience.

Thus far there are no available data to support the idea that safe speed is a function of the safety island width or from which to deduce recommendation of the safe speed for particular widths and it is hoped that research will be instituted in order to establish basic principles.

Mr. Carpenter states that adoption of the dual type will not prevent overtaking accidents. That may be true, but it will greatly reduce them. On the ordinary two-way highway the presence of an oncoming car causes many such accidents, because the passing car is often forced to "crowd" the car being passed in an effort to avoid a head-on collision. This condition is entirely absent on a properly designed dual highway, and thus passing accidents should be reduced to a very small percentage.

Mr. Lewis is to be congratulated on his able presentation of the subject as related to urban regions. The discussion of the freeway is most opportune, and highway engineers should read and digest all he has written with great care. The mention of the throttling effect of commercial development on the transportation efficiency of U. S. Route 1 in New Jersey is pertinent, and particular attention is directed to his statement respecting the reasonableness of barring access from property not directly assessed for the cost of highway improvements. The restriction of access should be no more serious than conditions imposed by the private railway lines traversing the United States.

In connection with Fig. 8, the writer wishes to inject a word of caution respecting the planting of trees adjacent to motor ways carrying high-speed traffic. He feels that no trees, other than small (2 in. to 3 in.

in diameter) ornamental trees, should be planted within a line 50 ft from the shoulder of the highway. The car is not forcibly confined to a track, and often gets out of control. Many lives have been sacrificed on trees, and, therefore, these hazards should not be planted within range of the destructive effects of a motor car.

Colonel Crosby raises the interesting question as to the effect of the "blind spot" in rear vision on safely entering the main highway from the acceleration lane. There is no reason why manufacturers cannot solve the "blind spot" problem by the proper use of rear vision mirrors or periscopes, but since they have not, design practice must admit this flaw. The matter at once resolves itself into a choice between two evils.

The right-angle intersection is dangerous because vehicles wishing to turn usually approach at a higher rate of speed than practicable for the turn, thus causing the vehicle to "swing wide," usually across the first lane into the second. The entering car usually appears without warning, swings into the main road, effectively blocking both lanes, and, not having any great velocity in the direction of the main-road traffic, speed differentials are great. The only recourse of the motorist on the main road is to swing out on to the shoulder, but often the condition occurs so quickly that he has crashed into the entering car before he realizes the situation.

In contrast, the acceleration lane places the entering car in full view of the motorist on the main road for a period of several seconds, thus giving him sufficient time to move over into the left-hand lane. There is no temptation for the entering car to crowd over into the left-hand lane, and the speed differential of the two cars will not be great. The angle of approach is shown so small in Fig. 2 that cars on the main road will begin to appear in present-design rear-view mirrors before the entering car actually begins to encroach in the right-hand lane. Access lanes coming in at more of an angle than shown, will exclude rear-view mirror vision and, at the same time, any angle short of 90° will not provide full visibility for the motorist looking back through the side window.

The access road condition shown in Fig. 2 is probably no more hazardous than an ordinary turnout for passing; certainly it is less hazardous than weaving and passing to right and left as practiced on present multiple-lane highways. This short statement is not intended to refute Colonel Crosby's well-warranted criticism, but only to bring out the comparative hazards of the situation.

Mr. Barnett suggests that the truck lanes be placed on the outside, with the high-speed lanes on the inside, in order to eliminate the expense of "fly-under" crossings. The condition is illustrated in Fig. 5 as contrasted with the original suggestion shown in Fig. 2.

The fundamental philosophy of the paper is that the highway should be designed for basic operating safety. The design shown in Fig. 5 requires the passenger vehicle to merge with the right-hand lane of truck traffic, pass across to the second lane, leave the second truck lane, and lastly merge with the passenger vehicles. This doubles the exposure to

accident, particularly in passing across the truck lanes. The public is quite aware of the hazards entailed in maneuvering around trucks because of their speed, length, and size.

Access to inside truck lanes can be provided at an average approximate expense of $100 000 even in flat country (complete with four separate single lanes of traffic). Because the existing system of highways will carry all short-haul traffic and act as feeders to the express routes, truck access need not be spaced at intervals closer than 20 miles. Thus, such "fly-under" (under or over) connections will only add approximately $5 000 per mile to the cost, which does not appear out of proportion when the entire cost per mile of express highways is considered.

Superelevation and Curves.—The friction factor, f, has been added by several commentators in order to complete Equation (1). There is a difference of opinion among the commentators, however, as to the proper value of f to use, the discussion centering on the effect of centrifugal force acting on the driver and passengers. The problem in reality is divided into two parts by climatic conditions. In regions subjected to ice and snow, the low coefficient of tires on ice will govern; in warm climates, the effect of centrifugal force on the driver will govern. Because of the seriousness of side-skid on a curve at high speed, the writer feels that design should be conservative and that some factor of safety be provided in addition to that subsequently treated under the heading, "Factors of Safety."

Tests[47] indicate that skidding on ice occurs at friction factors ranging from 0.05 to 0.13. The writer has side-skidded on a curve at a friction factor of 0.04. It is recommended, therefore, that a friction factor of $f = 0.03$ be adopted for icy conditions up to the limiting speed that a car can operate on ice on a tangent. Superelevating a curve for icy conditions, for a speed greater than that at which a vehicle can operate on ice on a tangent, is unnecessary. Where ice is not a problem, centrifugal force on the driver will govern. Several recommendations have been made by the discussers, but the writer's tests confirm the recommendations of Mr. Wiley, namely, $f = 0.10$. The writer's experience coincides with that of Professor Moyer and Mr. Wiley, that a certain amount of skill not possessed by all drivers, is required to drive around a curve at a speed which develops a friction factor as great as 0.15.

In utilizing the foregoing recommended values, the radii of curves become so large that discomfort and possibly a hazard is experienced driving around them at the lower-speed ranges if the superelevation is a great as 1.25 in. per ft. It is recommended, therefore, that the transverse bank or slope be limited to 5%, provided, of course, the radii are expanded the proper amount based on the foregoing assumption. To illustrate, Fig. 10(a) shows the speed-radius relation for one cross-slope, 5%, and the design curve is based on icy conditions governing only up to a speed of 60 miles per hr, on the theory that operation at greater speeds on ice, on a tangent, is impracticable. For speeds greater than 60 miles per hr, it is based on friction factors varying (approximately) uniformly from a

value of 0.10 to 0.08. The intermediate curve shows the speed-radius relation when the centrifugal force is exactly balanced by the superelevation. The lower curve, showing minimum speeds at which it is comfortable to operate, is based on the observation that it is fairly comfortable to operate for a limited period on a pavement on a tangent which is

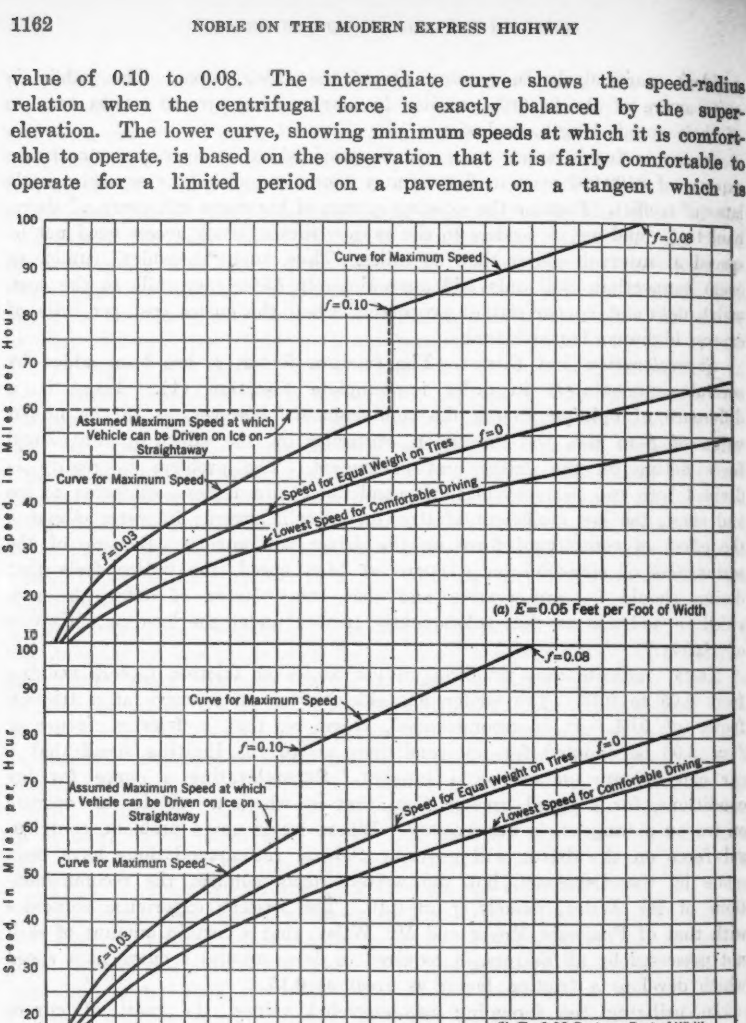

FIG. 10.—RELATION BETWEEN SPEED AND RADIUS OF CURVATURE IN REGIONS SUBJECT TO ICE AND SNOW

crowned 2 in. in 10 ft., and this amount of "unbalance" toward the inside of the curve is assumed as permissible. Fig. 10(*b*) is similar except that it is based on a superelevation of 8%, which is approximately 1 in. per ft. A study of these diagrams is instructive, especially as related to speeds below the "balanced" curve.

Before leaving this phase of curves, it will be illuminating to quote from a paper[51] by Professor Moyer, as follows:

"A significant feature of the slippage tests is the magnitude of the slippage as the speed of the car is increased. The trend indicates that the slippage at speeds of 80 miles an hour or more is so large on curves sharper than 3 deg [$r = 1\,910$ ft] that the most skillful driver will have difficulty in steering the car and holding it within a 10-ft traffic lane."

Transition Spirals.—The writer wishes at once to state that the necessity for transition spirals where high speed is concerned, has been conclusively demonstrated by the discussers. There appears to be no agreement, however, as to the proper length to use. In actual practice the rate of change of centrifugal acceleration ceases to be a criterion because superelevation cancels centrifugal force for a given superelevation-speed-radius combination. The factors affecting length, then, reduce to the time interval required for the operator to turn the wheel and the permissible rate of rotation. No one has commented on the time interval and it is hoped that engineers will continue to study this problem.

The profession is indebted to Mr. Haile for presenting his analysis of the principles of rotation as related to superelevation transitions. Such analyses are a step in the right direction, and it is suggested that investigation be continued to establish well substantiated values for the length, L_v, and the assumption that 0.027 represents a correct value for the expression, $\frac{2\,V^2_s\,(E_2 - E_1)}{L^2_s}$. The correctness of the result is dependent on the proper assumption of these values.

The writer is not so sure that railway-highway conditions are strictly analogous as related to superelevation transitions. The wheel-base of railway coaches is so great that a car will twist if the rate of change of superelevation is too rapid. The wheel-flange striking the outer rail is also a factor. Those conditions are not present in the highway problem. He also wishes to question the general assumption that very long spirals are desirable. It is possible that spirals longer than required to turn the steering wheel properly will require a nicety of "balance" and judgment in steering not possessed by all drivers. Thus, there may be a tendency for the car to "wobble" in the lane, due to the necessity of changing the steering wheel constantly, and developing different slippage angles. It is suggested, therefore, that additional data be accumulated for the purpose of establishing design practice.

Vertical Curves.—It is disappointing that no contribution was submitted on the problem of the influence of the head-light beam on the lengths of vertical curves. Mr. Haile states that the normal length of the head-light beam will not be affected if vertical curves provide a sight distance at summits equal to the distance required to stop the car. This becomes a reality if stopping distance is based on icy conditions. The general problem is divided into two parts, at sags and at summits.

[51] *Civil Engineering*, February, 1937, p. 114.

At sags, the factors are, length of head-light beam, height of the lamp above the pavement, the vertical angle which the upper beam makes with the horizontal axis of the lamp, and the algebraic difference of the grades. With known factors, a graphical solution is simple and may be applied during the process of establishing profile grades. A mathematical solution is simple, but it requires solving simple equations for two cases in order to determine the limiting curve and is not as rapid, therefore, as the graphical method. The vertical curves required for this condition are not particularly long, but some designers may have to revise their ideas of vertical curve lengths somewhat. All motorists are aware of the experience at sags of having the head-light beam cut off by the ascending grade ahead, and seeing the light advancing up the pavement until the car reaches a point on the curve where the normal length of beam is restored.

At summits, the rounding curve intercepts the light rays and the down-curving pavement beyond this tangent point is in darkness, the head-lights piercing only space, giving the impression of a black wall ahead or that the car is about to plunge into an abyss. A mathematical analysis involving the differential calculus produces formulas (two cases), which yield startling figures. For instance, with an algebraic difference in the grades of 8% and a head-light beam of 400 ft, a vertical curve 2 100 ft long is indicated. A vertical curve of more than 3 000 ft is required, if a sight distance (during daylight), of 1 330 ft is desired, which illustrates the correctness of Mr. Haile's observation.

In view of the lack of corroborative evidence, it is hoped that tests and observations will be conducted for the purpose of establishing practical design procedure. Space does not permit, nor is it proper to present at this time, the development of the formulas mentioned. Mr. Haile states that passing would not be permitted at the summits of two-way highways. The writer knows of no positive method of preventing motorists from passing on summits, unless a police officer is stationed on every summit.

Grades.—Many commentators question the value of limiting maximum grades for the purpose of providing reasonable safety in descent on icy pavements. If traffic is so light that not more than two or three cars are present in any mile, safety in descent then affects the individual car and that car only will be involved in a skidding accident, but where the traffic is heavy, with cars immediately adjacent to each other, a skid promptly involves other cars, with the result that from two to seven cars become snarled together, often with disasterous results. For instance, the Operation Department of the Port of New York Authority experiences difficulty as soon as ice forms on the short 4% grade of the New York approach to the George Washington Bridge, in spite of the fact that cinders are applied almost immediately. It has also been found necessary to close the Pulaski Skyway on Route 25, New Jersey, at certain times when ice has formed. The maximum grades on this structure are 3.5 per cent. Ice can form in a few minutes, and a maintenance crew with many miles to

cover will find it difficut to spread cinders promptly. Consideration should also be given to the limiting friction factor of ice, which varies from 0.05 to 0.13.

It is true that, if locating engineers are looking for an "easy way out," the adoption of 8% and 10% grades will lessen their difficulties and shorten the time required for the location. This attitude is somewhat reminiscent of the early days of railway location. However, after the railways had passed from the pioneering period and became engaged in the reconstruction of their lines, the attitude disappeared. There are cases on record of the location work taking a considerably longer period of time to complete than the actual construction. Indeed, studies for some railway lines have extended over a period of ten years. Do highway engineers consider railway location more important than highway location, when the direct relation of alignment and grades upon vehicle safety is considered?

There should be a realization that the location of modern trunk highway routes is a very important matter, and all possibilities should be investigated in order that the best obtainable route and individual location be secured. If the physical conditions of a trunk route are of such a nature as to require 8% grades, that should be sufficient cause for its rejection, if it is in a climate subject to ice and snow.

Sight Distance.—Messrs. Barnett and Haile are quite correct in stating that minimum sight distance should not be computed based on 17.4 ft per sec per sec, because of the high friction developed between tires and road surface in order to decelerate at that rate This point should be particularly emphasized. Both suggest a friction value of 0.40, which is equal to a deceleration of 12.88 ft per sec per sec. This is greatly superior to the value given in the paper, and its use is recommended for climates not subject to ice and snow; consequently, Fig. 4 should be disregarded.

In regions subject to ice formation, the low friction coefficient of tires, on ice, should govern up to the maximum speed possible on such a surface. Because of the comparatively long distances resulting, and because the seriousness of an accident from this cause (within the lengths prescribed), is less than from insufficient superelevation, a friction value of 0.10 has been assumed. A new diagram, Fig. 11, showing stopping distances, has been prepared to be used instead of Fig. 4. The writer realizes that the diagram may be criticized on the basis of showing distances that are too short to care properly for icy conditions in view of tests[77] which show coefficients on ice as low as 0.05.

The question may also be asked whether there is any real justification for designing on the basis of icy conditions in localities where ice may not occur more than a few days during each year. The answer to this question may be found in the well-stablished practice of other branches of engineering. A building, for example, may not have to withstand the wind loads for which it is designed more than once in 10 yr, or flood-control dams, levees, and spillways may not be called upon to withstand full flood height for which these works are designed, more than once in

20 yr; yet engineers feel it is sound policy to design for the maximum condition. In this connection it may be stated that highway engineers apparently are more flood conscious than accident conscious, as it is quite usual to construct highways above the highest recorded flood level.

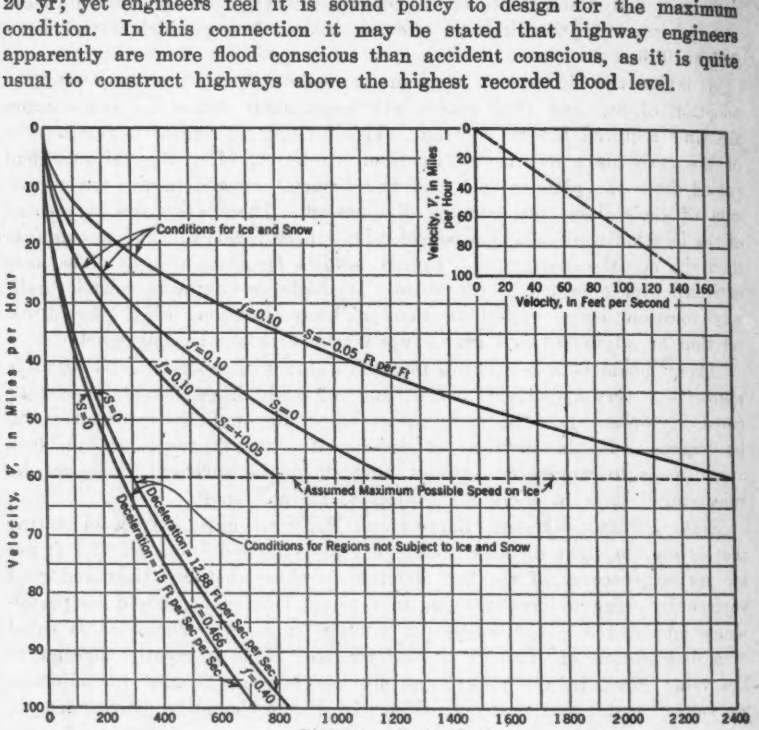

FIG. 11.—DISTANCE REQUIRED TO BRING A MOTOR CAR EQUIPPED WITH FOUR-WHEEL BRAKES TO A STOP AFTER BRAKES ARE APPLIED

It is to be noted from Fig. 11 that a speed of 60 miles per hr under icy conditions, requires a greater stopping distance than a speed of 100 miles per hr, with dry and wet surfaces. For a speed of 60 miles per hr on ice, a sight distance of 1 332 ft (1 200 ft + 132 ft) is required on level grade for a one-way (dual) highway. In order to obtain this sight distance on a curve (with a central angle greater than 14°), and assuming that all obstructions are cleared for a distance of 40 ft from the edge of the pavement, a curve with a radius greater than 5 300 ft, will have to be adopted. In other words, if all trees, cut banks, or other obstructions are kept uniformly 40 ft from the edge of the pavement, it will be necessary to adopt a curve of not less than 5 300-ft radius in order to obtain a sight distance of 1 332 ft.

Thus, in general, it is evident that if the design is based on icy conditions, sight-distance requirements will compel the use of curves of sufficient radii to care for speeds of 100 miles per hr.

Safety on Tangents.—There has been an implied assumption by some discussers that a tangent should be considered as a criterion of safety, merely because it is straight. Straightness alone does not assure safety. The mere fact that there are more miles of tangent than curves is not the only reason that more accidents occur on tangents than on curves. There are sound reasons for these accidents. Often a fairly long tangent is encountered after a series of sharp curves. This is an invitation to the motorist to speed, and frequently other operating conditions not connected with straightness are such that there is no justification for an increase in speed.

A tangent with no separation between opposing traffic, narrow soft shoulders, deep ditches, heavy crown, steep grade, and with poles, trees, head walls, bridge walls, and guard rails near the pavement, is surely more dangerous than a properly designed curve. Such a tangent, however, is in direct contradiction to the spirit of the paper. An analysis of accidents which can occur on a tangent of this nature may be enumerated as follows: Head-on collision; rear-end collision, with car standing on the pavement; side-swipe due to passing; forced off road by passing car and overturning in ditch; car sufficiently out of control due to soft shoulder to collide with tree, utility pole, guard fence, or other obstruction; car skidding with the aforementioned results; and a blow-out or other mechanical failure, resulting in all the foregoing types of accidents.

With separated roadways, wide smooth stabilized shoulders free of all obstructions, adequate sight distance, smooth profiles, and reasonable grades, some types of these accidents would be eliminated entirely, and the seriousness of a large number of accidents would be minimized. Sufficient time, space, and "elbow room" would permit a vehicle to recover from a minor mishap in time to prevent disaster.

It is not contended that a properly designed curve of sufficient radius, adequate superelevation, with well designed spirals, is more dangerous than any other part of the road structure. The philosophy of the paper is that hazards should be removed from the highway whether they occur on a tangent, on a curve, in a tunnel, on a bridge, in urban regions, or in the open countryside.

Statistics.—Several discussers presented detailed accident statistics and have deduced certain conclusions therefrom. Statistics may prove misleading unless thoroughly analyzed by a competent statistician. With no attempt to treat a subject with which the writer is unfamiliar, it may be pertinent, however, to point out certain of the more obvious pitfalls connected with traffic-accident statistics. In analyzing such records, the relative values that must be assigned to certain figures should be borne clearly in mind. For instance, unless it is realized that less vehicle miles are operated at night than during the day, the erroneous conclusion might be reached that it is less hazardous to motor at night than during the day, when it is noted in Table 5 (*f*) that 58% of all accidents occur during daylight, whereas only 42% occur during dusk and darkness. To particularize further, it must be realized that there are less vehicle miles

operated during rain, fog, ice, and snow, that certain regions in the United States have little or no rain, certain sections have no ice, and, furthermore, that there are fewer hours of rain than dry weather, less hours of snow and ice on the pavement, and still less hours of actual snowfall and fog. As previously noted, there are more miles of tangent than curves.

When the statistics are properly adjusted to represent the true relation on a basis of comparison of hours-mileage-volume, a clearer picture of the actual exposure to accident for given conditions will result. There is little doubt that it can be shown that the exposure to accident is increased by rain, fog, snow, and ice, and that these are definite factors which should enter into the formula for safe highway design.

Capacity.—Mr. Diehl states correctly that the safe spacing of cars should be the distance required to bring the vehicle to a stop (braking distance + lag distance). He further states that because of this, the capacity of a highway is unduly reduced at the higher speeds. This is true, but not to the extent which some investigators have assumed, since their assumption does not coincide with the driving habits of most motorists. Without condoning or in any way recommending this dangerous practice, it must be realized that operators usually keep a distance back from the car ahead only sufficient to care for the space covered during the lag period. The motorist relies on being able to decelerate at the same rate as the car in front. If a lag period of 1.5 sec is assumed, this distance approaches the braking distance at the lower speeds, but is only a fraction of the distance at the higher speeds. This becomes very striking if the total stopping distance is computed for icy conditions..

Factors of Safety.—A careful study of Figs. 10 and 11, shows that the factor of safety for sight distances and curves is either zero or very low if the design for the actual expected speed is based on these diagrams. As Professor Hawthorn states, "the driver's control over his vehicle varies, other conditions being equal, with the square of the speed." In a rough sense, this relationshp can be used as a measure of factors of safety. In other words, if Figs. 10 and 11 are used in the sense that values derived therefrom represent the ultimate strength of a material, then established engineering practice requires that some factor of safety be applied. If the "ultimate strength" is assumed as 100 miles per hr, then a factor of safety of 1.5 is provided at a speed of 80 miles per hr, 2 at 70 miles per hr, and somewhat less than 3 at 60 miles per hr. It should be remembered that a factor of safety (against ultimate strength) of 3 is in established use for such a uniform and consistent material as structural steel. Fully realizing that such a method is not strictly scientific as applied to highways, and yet it does form some measurement of safety.

If, then, it is desired really to design a highway for safe operation for a speed of 60 miles per hr, curves, spirals, superelevation, and sight distance (except where icy conditions require greater values), should be designed on the basis of a speed of 100 miles per hr. This will give a measure of safety in a longitudinal direction.

Safety in a lateral direction is less easily measured. It is disappointing that the discussion did not contain any data and suggestions from which a start could be made to appraise factors of safety in a lateral direction. For instance, if the pavement was flanked by smooth, stabilized shoulders of infinite width, with all obstructions removed, complete lateral safety would be provided for many types of "out-of-control" skidding and "driver-asleep" accidents. Conversely, if the shoulder were only 1 ft wide, the accident hazard would be greatly increased. Manifestly, it is utterly impossible to provide shoulders of infinite width, but there must be some measure of the factor of safety for any given speed-shoulder-width combination. This problem is not simple, and, therefore, presents a challenge.

In this connection, certain engineers have assumed that once a vehicle is out of control, the responsibility of the highway designer ceases. If this assumption were logical, then from force of logic the conclusion would be reached that the operator should always drive perfectly, in which case there would be no highway problem. Since it is physically impossible for the motorist to drive perfectly, and since the results of an accident are the same from whatever cause, the designer does have a responsibility and, therefore, should make a reasonable allowance for the case in which the car is out of control.

For example, as Mr. Lavis suggests, somnolence is a factor which should be considered. Any one may be guilty of it, and a certain amount of protection should be provided. One-way roadways, with sufficient width between, furnish a certain degree of protection to the left of the motorist; the shoulder furnishes protection to the right. The slight additional roughness of the shoulder will awaken most drowsy drivers, and if given space and time, the car can regain the pavement without mishap. The same conditions apply to inattentive operators.

The statements of Messrs. Carpenter and Wiley should be emphasized, that the minimum standard often becomes "the" standard, and is used when better standards could be applied with little, if any, addition in cost. Many times the designer is so engrossed in solving structural or mathematical problems that he becomes "blind" to the essential issue of designing for basic operating safety, and, consequently, unwittingly inserts unnecessary hazards to operation. Often it is no more expensive to design safely, but there are many times when safe design requires courage and conviction on the part of the designer. Professor Alvord has performed a service in emphasizing that under-design is unprofessional. It should be repeated that consistency in design is the very soul of safe design.

The highway should be considered as a unit, and uniformity and consistency should be a feature of the results, whether the route be in the city, in a tunnel, on a bridge, or in the open countryside, to the end that it efficiently and safely serves its function as an element of transportation.

Application to Broad Field.—Mr. Carpenter is acute and is quite correct in his assumption that the writer's interest in safety also extends beyond the limits of the express highway. It covers the entire highway field,

including farm roads and city streets, not only as related to new construction, but also to the removal of hazards from the existing system.

Design in this broad field must be approached with new vision, and enlightened standards must be established, based on a definite design speed, to the end that operating safety is the basic philosophy. As stated in the paper, the selection of the design speed for any particular class of road is one of the most important decisions connected with the design. The future possibilities of use and traffic volume must be determined accurately in order that adequate right of way and proper alignment be obtained. With such provisions, the initial design speed for remote roads may be set less than the ultimate as far as profile, graded width, type of pavement, and details are concerned, if economy is paramount. With such a procedure, speed standards may be improved from time to time without appreciable loss of investment. If the speed standard is less than the legal limit, the permissible rate of speed should be posted at frequent intervals.

There is a tremendous opportunity to perform a humanitarian service in the removal of hazards from the existing system of highways. The magnitude of the task is apparent when it is remembered that there are more than 3 000 000 miles of rural roads in the United States. There is crying need for a hazard survey to locate and classify hazards according to some rating; and a program with appropriations in each State and each political sub-division of each State for the continued and consistent removal of hazards. The removal of such death-traps is quite certain to yield greater dividends in lives saved than the complete removal of all railway grade crossings.

In order to provide a criterion of operating safety, it is suggested that the entire existing system be classified on the basis of safe allowable speeds. Thus, for example, it may be established that a given section between towns, or other natural division points, may permit vehicles to operate safely at a speed of, say, 35 miles per hr, except for a few particular locations where the safe speed may drop to a lower figure, say, for illustration, 20 miles per hr. These places, then, are of particular hazard, and every effort should be made to reconstruct them to the 35-mile standard at the earliest possible date. Except as related to the elapsed time of travel, it is inconsequential what the safe speed may be—10 miles per hr, or 60 miles per hr—as long as consistency is maintained. It is the unexpected hazard that will continue to take the lives of many conservative motorists on the existing system. The safe speed should be posted as a speed limit on all roads which are of a lower standard than the legal limit, and a gradual change in operating conditions should be provided when passing from one speed classification to another.

The writer realizes that the foregoing attitude is, in part, somewhat contradictory to the spirit expressed in the paper, but the paper applied to new construction, particularly as related to the trunk system. It is manifestly impossible to reconstruct all roads to high-speed standards. A program such as that outlined herein will do much to relieve the acci-

dent situation within a relatively short period, certainly before any large volume of new construction can be completed. These roads will always be feeders to the trunk lines.

Expensive Highways not Necessarily Safe.—Certain engineers appear rather complacent with respect to present and past highway-design thinking, and seem to feel that further mental and physical effort is not only unnecessary but somewhat puerile. In the interest of safety, and for that purpose only, it may prove educational if a few instances of expensive projects, which fall short of the philosophy of the paper, are given. Their identity is unimportant since no reflection on the designers is due or intended, and the illustrations are given solely to show that the engineer has not yet brought his thinking up to date as related to safety—he is not yet thoroughly safety conscious.

An express highway, several miles long, was constructed, which cost nearly $5 000 000 per mile, without right-of-way cost. It carries a daily traffic of approximately 45 000 passenger automobiles, trucks not being permitted; yet it has center ramps, the light standards are placed in the center safety island, and although the general posted speed is 35 miles per hr, in several places the posted speed is 20 miles per hr, because of sudden sharp curves and center ramps.

An elevated structure several miles long was constructed at a cost of more than $5 500 000 per mile. There is no physical separation of opposing traffic; it has center ramps, and the roadway has an odd lane. The economic justification for this structure, to a great extent, was based on its carrying a large volume of trucks. Present traffic is approximately 85 000 vehicles daily. During the first six months of operation the accident situation became so serious that trucks were excluded from the structure in an effort to reduce the accident toll.

This structure is a small part of a much larger project which cost an average of more than $1 000 000 per mile. The greater part of the route is of multiple-lane type, four to six lanes wide, constructed at grade in the usual manner, except that all railway and important highway crossings are eliminated by grade separation. When completed, it was considered an outstanding example of modern highway design. Within a year after being opened to traffic, the newspapers and public christened it "Death Highway." Three-car and four-car accidents were common, and six-car and seven-car accidents not uncommon. In the last two or three years, a large mileage has been reconstructed and made over into a divided way, with an island separating opposite direction traffic, at an additional cost of approximately $65 000 per mile. It is reported that accidents have decreased where the roadways have been separated.

These projects were designed by some of the most competent and alert highway engineers in the country, who were using the most modern and up-to-date design methods in vogue at the time. When it is considered that the work was performed within the past decade, the swiftness with which highway design thought is developing becomes apparent. It is also apparent from the unfortunate experience noted that the public is awaken-

ing to the situation, and unless the engineer becomes alive to the problem, he is quite likely to find himself in an uncomfortable position from which he may not be able to extricate himself without loss of prestige.

Conclusion.—There has been an assumption on the part of some commentators that the highway engineer is unduly restricted by laymen in the form of commissioners and politicians, and, therefore, of necessity must continue to design "within the money" in accordance with the ideas of other than technical men. This is true to a certain extent, even at the present time, and it indicates that engineers should rise to the occasion and make an intelligent effort to bring the true facts before governing bodies. It is also true that the layman will only value the engineer and his judgment as highly as the engineer values and has confidence in his own competence and judgment. There was a time when engineers designed bridges "within the money" because they were brow-beaten into it against their better judgment. A series of failures convinced the governing bodies that they did not know as much about the forces of Nature as engineers. As a consequence, it is very rare for a bridge to be badly under-designed in this day. The highway is failing to-day, but its failure is not as spectacular and obvious as a bridge failure.

It has been the writer's observation that governing authorities are willing to listen to, and act on, concerted engineering opinion when they are convinced of the hazards involved in disregarding it; but when the engineers are uncertain and not in agreement among themselves as to the proper method of solving a given problem, the governing bodies must not be blamed too much if they take a financially conservative, as well as a politically expedient, attitude.

Consequently, it is of the utmost importance for engineers to bring their ideas more in harmony with each other, and having achieved solidarity, to go forth and spread the gospel of highway safety in relation to design. In the last analysis the engineer will be held responsible by the public for safe highway design. The writer reiterates his conviction that the engineer must have vision and courage.

The paper has been broadened and enriched by the discussion, and, in closing, it is desired to express again appreciation to all the discussers who so generously gave their time and effort to the subject.

In addition to those noted previously, acknowledgment is freely given to the Automobile Manufacturers' Association, and Mr. C. George Krueger, for assistance and courtesy in supplying data and illustrations.

Paper No. 1978

THE ENGINEER, AN EMPLOYEE-EMPLOYER

ADDRESS AT THE ANNUAL CONVENTION, DETROIT, MICHIGAN, JULY 21, 1937

BY LOUIS C. HILL,[1] PRESIDENT, AM. SOC. C. E.

It is not uncommon to-day to read in a newspaper a glowing account of some outstanding engineering work and in the same issue of that paper to be confronted with the news that engineers are organizing into labor unions. Thus, we have public recognition that this is the age of the engineer, that the material progress of the world to-day is dependent upon his achievements; and, yet, engineers are resorting to collective bargaining because of a lack of economic recognition of the individual engineer.

In 1930, John F. Coleman, Hon. M. and Past-President, Am. Soc. C. E., opened his address[2] before the Annual Convention of the American Society of Civil Engineers, with the statement:

"For years there was a constant cry to the effect that the engineer did not receive the recognition which he deserved. Lately, the same cry is heard although less frequently. In the past there was much to justify such complaint, and even now there is some excuse for it.

"It seems probable, however, that the engineer himself is in great degree responsible for such a state of affairs in that he has been until recent times almost inarticulate in the councils of men; * * *."

During the seven years since the Society was so challenged, this country has passed through a period of severe depression out of which arose the most ambitious program of public works the world has ever known. Engineers by the thousands and tens of thousands have been employed in the design and on the construction of such works, all of which have been publicized to the extent that the names of many projects have become household words.

Yet, whenever engineers get together, at meetings of the Society or in other groups, at social gatherings or in their homes, an inevitable subject of conversation is the lack of professional recognition of the engineer by

[1] Cons. Engr. (Quinton, Code & Hill-Leeds & Barnard), Los Angeles, Calif.

[2] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1344.

the public. Do these men mean professional recognition in the sense of public acknowledgment of the importance of engineering work in general, or do they mean something more material which affects them as individuals? I believe that little of the discussion so prevalent to-day has its origin in any failure of the world at large to appreciate the Engineering Profession in the abstract. Rather, I think it is the economic status of the engineer, his material and mundane reward, which is of consuming interest.

The basic reason for this situation was suggested by the late Harrison P. Eddy, Past-President, Am. Soc. C. E., in his address[3] before the Annual Convention of the Society in 1934, when he defined Engineering as a true profession, although of a different character from those of Law and Medicine. In that address he brought out that lawyers and doctors in large measure are independent professional practitioners, whereas engineers are generally employees. The validity of his distinction is evident from the fact that when one is sick the personal services of a doctor of medicine are sought, and the services of a particular lawyer are engaged when one is faced with legal difficulty. On the other hand, the engineer is employed only rarely by another individual. Only a very few persons have any appreciation of the function of the engineer as an individual, even though every citizen of this country, whose reading goes beyond the tabloids and the sport sheets, must be conscious of the tremendous part which the Engineering Profession plays in affairs of the modern world.

The engineer has little more association with those who make daily use of his works than the men who produce the materials which go into his works have with him. Even the engineer in private practice meets professionally only a few laymen. From the nature of his employment, he deals generally with corporations, both public and private; where he has one client, a lawyer may have twenty and a doctor a hundred. Most engineers, therefore, by the very conditions which make their work possible, are substantially barred from individual personal contacts with the public.

To have a basis for action and at the same time to be frank with ourselves, we must accept the condition that engineers comprise fundamentally an employee group in which the world at large has the greatest confidence, but regarding whom the public has little individual concern. Going a little further with our introspective analysis, we must consider the significance of the unique fact that ours is the only profession in modern society which both works for itself and employs itself. It is because of this anomaly that each engineer is in great measure responsible for the status of his profession, both abstractly and concretely.

The current roster reveals that approximately 42% of the entire membership of the Society are in the public employ. Almost half of these are employees of the Federal Government; the others work for various State and county governments, municipalities, and other political subdivisions. About 6% of the members are connected with colleges and universities,

[3] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 1383.

many of which are State institutions. In round numbers, then, one-half the members of the American Society of Civil Engineers in all grades are employed in some capacity by governmental agencies. Probably a greater proportion of the civil engineers not members of this Society are likewise employed.

About two-thirds of the other half of the membership are employees of private corporations, a few in high executive positions, the great mass in subordinate or employee positions. Little more than 10% of the total membership are evidently in private practice as consulting engineers or as principals and associates of engineering firms. The unclassified remainder includes those retired, or temporarily unemployed, and those engaged in special pursuits.

This predominance of the employee status in Society membership is even more significant when the occupational distribution of the members in the various grades is considered. Substantially 34% of those in the grade of Member and 42% of the Associate Members are employed by some governmental agency; nearly 60% of the young men in the Society, that is, those in the grade of Junior, are likewise governmental employees. If to these be added the hundreds who are on the faculties of institutions supported by taxation, it is apparent that many more than one-third of the Members, almost one-half of the Associate Members, and nearly two-thirds of the Juniors are public employees.

This greater proportion of young engineers who are employees of governmental agencies may be due in part to the fact that private practice is largely closed to them, but more likely it is due to changing conditions. Comparable statistics of twenty years ago probably would have shown that more than one-half the younger engineers in the Society were in the employ of private firms and corporations. Such a conclusion follows from analysis of the membership distribution of those now in the employ of private corporations: in that, roughly one-third the Corporate Members of the Society are corporation employees, as compared to only about one-quarter of the Juniors. It is evident, therefore, that any consideration of the economic status of the engineer must take into account the evident trend toward governmental employment.

Anomalous as it may seem, a large proportion of the engineers who are employees are at the same time employers of engineers. Particularly is this true of those in responsible charge of work, even though few engineers may be employers in the sense that they have authority to engage, to retain, or to dismiss subordinates according to their individual ideas of policy. In a very large measure, however, all of us who are Corporate Members of the Society are responsible for the work done by our subordinates and their assistants, and rarely will changes in their positions or salaries be made by our superiors or employers except on our recommendation.

In general, therefore, the engineer in responsible charge of work occupies the dual position of an employer of engineers while he himself is an employee of a public or a private corporation. To the same extent that he is responsible

to his superiors for the execution of engineering work done by his subordinates, the engineer in charge is responsible to his subordinates for any recognition or lack of recognition given them by his superiors.

Much of this is not new to us. Other Presidents of the Society have pointed out that the responsibility is our own, and in papers read at the Annual Convention at Portland, Ore., in 1936, attention was called to conditions affecting the status of the engineer. Thus, it may well be asked: What has been done to advance the Engineering Profession in the eyes of the public and what has been done to improve the social and economic status of the individual members of the profession?

As to the former question, great progress has been made: Engineering works are news to-day and, in the abstract, the world at large has conceded to our profession the recognition we deserve. In all this the American Society of Civil Engineers has played a major part. Also, as a Society, we aided many engineers in obtaining employment during the depression, and we were effective in establishing salary scales for engineers on emergency relief works which were at least as high as the wages paid to skilled labor. Again, as a Society, we are seeking to establish standards for the proper compensation of engineers in the employ of public and private corporations.

However, so definite have become the demands for more effective action and more tangible results that quasi-technical organizations have been formed which have as their primary objective the improvement of the economic status of the engineer. Guilds and other associations are in existence for similar purposes, which make no pretense of being technical in character, and in some localities the younger engineers and engineering aides have gone so far as to join militant labor organizations.

It should be obvious that this trend toward trade unionism, if permitted to continue, will destroy whatever standing the engineer has obtained as a member of an acknowledged profession. Hence, it is imperative that we consider what line of action is available to us other than the direct action of collective bargaining.

It is evident to me that the answer lies in recognition of the responsibility of each engineer to his subordinates. I wish to emphasize that point: It means that most of the members of this Society must assume, actively and individually, the obligations of the dual function of employee-employer. Such a duty goes far beyond the administration of the work of engineers subordinate to him; it involves real concern for the working conditions of those subordinates and for the monetary and other rewards they receive for the work which they do.

With full appreciation of the altruism, ideals, and ethics of our profession, we must admit that the desire for money, with the power and security that money gives, is the controlling motive of modern civilization. Rightly or wrongly, the world to-day measures its recognition of the work of the individual by a money standard. Such being the situation, it is desirable and proper that each engineer should further the interests of every engineer subordinate to him by emphasizing to his superior or employer the importance of the engineering problem, the accuracy of execu-

tion, the responsibility, and the integrity of purpose that characterize the work of his subordinates. Just as often as he does so, he will take a positive step toward improvement of the status of his profession and at the same time promote his own well-being. On the contrary, each time such an engineer understates the worth of engineering services, he does positive injury to the profession and to himself.

In this latter category falls the consulting engineer who obtains work on the basis of its cheapness, and thus is required to hold down the rates of pay to his subordinates. The engineering executive of a governmental agency who promotes the use of his personnel by political subdivisions at costs to them which cannot be met by engineers in private practice likewise does a direct injury to the Engineering Profession. Similarly, each time that the chief engineer of a corporation reports to the executive officer that he has saved money by employing engineering talent at the market price for skilled labor, he belittles his profession, and he brings nearer the day when he himself becomes only the foreman of such labor, an honorable but not a professional position.

Such practices were challenged seven years ago by Past-President Coleman when he told the Society that the standing of the engineer was his own responsibility and that advancement must come from within the profession.[3] Instead of accepting this responsibility as an individual, the engineer generally has shifted it to some organization with the hope that something would be done. When he did so, and failed to sell to his superiors the value of the services of his subordinates, he failed also in his obligation to the profession. Improvement in the social and economic status of the members of the Engineering Profession can come as a result of our own individual efforts, if every engineer will acknowledge the responsibility of the employee-employer relation which is peculiar to the Engineering Profession, if also he will accept the obligation of this relationship, and, finally, if he will make that obligation the basis of his own professional action.

Failure to accept that obligation will jeopardize the professional standing of engineers and engineering, because any further trend toward trade unionism among engineers will destroy public confidence in us as members of a true profession. By our own efforts we can correct the conditions which already have forced many engineers to put aside the standards of the profession and accept those of a trade instead; but effective action may not be postponed and the responsibility rests directly upon the individual members of the American Society of Civil Engineers.

STRUCTURAL APPLICATION OF STEEL AND LIGHT-WEIGHT ALLOYS
A SYMPOSIUM

PAGE

Note.—Presented at the meeting of the Structural Division, Pittsburgh, Pa., October 14-15, 1936, and published in October, 1936, *Proceedings*.

With Discussion by Messrs. E. Mirabelli, R. W. Vose, Raymond H. Hobrock, William F. Clapp, J. C. Hunsaker, Horace C. Knerr, F. T. Sisco, J. Charles Rathbun and D. M. MacAlpine, Fred L. Plummer, C. F. Goodrich, G. K. Herzog, John H. Meursinge, P. G. Lang, Jr., W. L. Warner, Elmer K. Timby, Werner Lehman, Otis E. Hovey, R. G. Sturm, E. Robert de Luccia, O. J. Horger, A. W. Demmler, Theodore Belzner, J. P. Growdon, Karl Arnstein, A. Christianson, Robert E. Glover, Arthur C. Ruge, Alexander Klemin, Paul E. Gisiger, Russell C. Brinker, Arshag G. Solakian, H. D. Hussey, Ralph Freeman, A. V. Karpov, Leon S. Moisseiff, A. V. Karpov, R. L. Templin, J. H. A. Brahtz, M. J. R. Morris, Zay Jeffries, C. F. Nagel, Jr., and R. T. Wood, James Aston and E. C. Hartmann.

FOREWORD

By Jonathan Jones[1], M. Am. Soc. C. E.

The automobile of to-day has been made possible—not merely made cheap, but actually made possible—by new types of steels, new treatments of steels, new knowledge regarding the properties of steels and how to control them, and, also, in some degree, by a corresponding development of the light structural metals. To-day's airplane also is the product of this research into, and development of, new metallic alloys. Where can be seen to-day, the airplane cloth so essential to the aviation of the World War? In the last few years, a new development has begun toward light-weight railway rolling stock based, again, on the newest metallic alloys.

In view of such rapid developments in various industries, of which the writer has mentioned three, it is incumbent upon any metal-using industry (upon none more than upon the fabricators of bridge and building frameworks and similar structures) to inquire what new economies, what new possibilities, may be anticipated in the structural field from the newer knowledge and the newer structural materials.

For the first quarter of the Twentieth Century this field was substantially stationary. Almost without exception the framed structures of that period were constructed of open-hearth steels of virtually a single simple class. The designers of a few monumental structures turned to nickel, manganese, or silicon for help, but these exceptional incidents made no difference in the average, or even in fairly impressive, bridge spans, and meant literally nothing to thousands of structural designers.

It would seem to-day as if that stationary condition is broken not to be resumed, or certainly not until after a long period of experimentation and development. New structural steels and light structural alloys are being pressed upon the structural engineer, not always, perhaps, with a very clear understanding of what he needs. Any survey of the situation, therefore, can be as of to-day only, but nevertheless it is unfortunate that neither as of yesterday nor of to-day has any such survey been undertaken, and the results arranged so that the average structural engineer may appreciate what is, and what is not, being done with new structural metals, and what may, and what may not, be "around the corner."

To fill this gap, and to perform this service, is the function of this Symposium. The specialists who have contributed papers are known to be both informed and informative; and they discuss questions such as the following:

(1) What does the newest laboratory knowledge reveal as to the important qualities of materials, of how to distinguish the best from the less suitable, of how to define, and attain in modern designs, that elusive function, the factor of safety?

---

[1] Chf. Engr., Fabr. Steel Constr., Bethlehem Steel Co., Bethlehem, Pa.; Chairman, Executive Committee, Structural Division, Am. Soc. C. E.

(2) What new tools for examination of stress conditions should structural engineers take seriously into account?

(3) What will variations in alloy additions, or in manufacturing practice, do to produce desirable qualities in structural steels, and at what cost?

(4) What degree of corrosion resistance is obtainable in materials subject to structural use, and can the price be paid?

(5) What alloys lighter than steel have properties that interest the structural engineer, and what seem to be the economic possibilities of their use?

(6) What has been done thus far, and what promises to-day to be done, in the actual utilization of these special structural metals?

(7) What is the objective in further development of new structural alloys, and for what can a premium be justifiably paid?

These several questions embrace one topic, that of the special structural metals of to-day and their structural use.

Note.—In order that the information imparted in the papers of this Symposium may be of the greatest possible usefulness to Civil Engineers it has been necessary to identify several of the alloys under the trade designations by which they are most commonly known. A consistent effort has been made, however, to avoid advocating special interests, with the understanding that the discussers, likewise, will confine their comments to the intended scope defined in each paper, as bearing on general classes of alloys rather than on individual proprietary types within those groups.

The term, "kips", to denote "kilo-pounds" or "thousands of pounds", has been used by each author because of the opportunity of thus arranging the tables in a more compact and convenient form; and an effort has been made to avoid conflicts in the introduction of the few algebraic symbols involved. The papers are not mathematical as a rule and only a few algebraic symbols have been required. These conform essentially to the American Standard Symbols for Mechanics, Structural Engineering and Testing Materials[2].

STRUCTURAL APPLICATION OF STEEL AND LIGHT-WEIGHT ALLOYS

A SYMPOSIUM

MODERN STRESS THEORIES

By A. V. Karpov[3], M. Am. Soc. C. E.

Synopsis

Structural design is a field that has not been strictly defined. Commonly, it is assumed to include only stationary structures of a fundamental character. A broader definition would be more in line with the present scientific engineering attitude. The same basic principles that are used in the design of non-moving structures—as, for instance, bridge trusses—are applied in the design of railroad rolling stock, automobile frames, trusses of the lighter-than-air ships, or structural members of airplanes, etc. The inter-relation and reciprocal dependence of these widely different fields of engineering endeavor is growing in importance, extending structural design into fields that commonly are assigned to mechanical engineering.

Due to the experimental and theoretical investigation made during the last few decades and prompted mostly by the needs of automobile and airplane designers, engineering science has undergone a considerable change, not unlike the spectacular changes in physical and chemical sciences. These changes are influencing mechanical designs profoundly, but in so far as structural designers are concerned, there are diverging views concerning the necessity of changes in design conceptions and practice.

For quite some time the structural engineer avoided the issue by assuming that the new developments were confined to problems in mechanical engineering, and, in particular, to its most modern branches, aeronautical and automobile engineering. The rapid advance in other engineering branches necessarily must be reflected in structural engineering.

Engineering Designs as Probability Problems

Every proposed engineering structure presents a probability problem that can be stated as follows: What is the probability that the design decided upon will result in a most suitable structure during the entire period of its assumed useful life?

In its broad sense, an engineering design is an attempt to solve this probability problem by determining the future suitability of an engineering structure, considering the many governing viewpoints. In a structural design the safety of the structure is the most important consideration; economy, utility, and durability are the other viewpoints that are most often considered.

[3] Designing Engr., Hydr. Dept., Aluminum Co. of America, Pittsburgh, Pa.

The determination of its suitability is based on the prediction of the probable future behavior of an engineering design. The difference between the predicted and actual behavior is an indication of the state of engineering knowledge at the time the design was made. This indication is of a very general nature since it encompasses not only the assumption on which the purely engineering aspects of the design were based, but also the general assumptions made, before the structure was built, concerning the future service conditions.

That every engineering structure must function during a certain period of time was always realized. The structures of ancient times in which only materials were used as they occurred in their natural state—as, for instance, natural stones—were very little influenced by aging. Such structures stood for indefinite periods of time.

At present, radically different materials are used which are much more effectively utilized and which have the tendency to change their properties either with time or with stress application or with both. As a general rule, the fact that a structure is adequate and safe under initial service conditions does not assure its future adequacy and safety. Fast-running engines in which numerous and rapid variations of stress are taking part were probably the first that called the attention of engineers, to the fact that a design that was entirely satisfactory during the initial load application may fail after a comparatively short service, due entirely to the changes in the stress-bearing capacity of the material.

The ultimate purpose of every engineering structure is to receive external and gravitational forces that must be distributed, transformed, and transmitted to some outside medium. The purpose of an engineering design is to predict these forces and the influence they will have on the structure during the entire period of its life.

Changes in Engineering Attitude as to Materials and Design Methods and Assumptions

Present and, probably still more, future engineering progress depends very largely upon the changed engineering attitude as to the materials to be used in engineering designs. Instead of simply utilizing the existing easily obtainable materials, new materials are being developed which are not so easily obtainable and, consequently, are more expensive, but which, for one or a number of reasons, are preferable, or may be even more economical, notwithstanding their higher cost.

In most applications the advantageous and economical use of such materials requires a better utilization than is customary with less expensive materials. The improvement in utilization is attained by a better understanding of the properties of the materials and closer evaluation of the future behavior of the structure.

In the past, for instance, it was considered good engineering to build machinery that was able to carry a much higher load than was specified, reflecting the insufficient engineering knowledge with respect to the requirements

and actual performances. With reference to bridges, even at present, the claim is often made that a particular bridge is well designed because it carries loads that are much heavier than were originally specified.

The structural designer realizes only gradually the up-to-date viewpoint of the aeronautical, mechanical, or electrical engineer, that good engineering requires a design that fits the conditions. That an over-ample design is poor engineering as well as an inadequate one. In that connection one of the interesting recent changes in engineering ideas is the attitude toward weight. A few years ago the weight was considered not only as a favorable factor in engineering designs, but as a criterion of quality—the heavier the better. Consequently, no particular efforts were made to reduce the weight. At present, the attempts can be followed through all fields of engineering development to create more economical or better suitable design by the elimination of useless weight: The use, if possible, of arch dams instead of gravity dams; the substitution of artificial materials in housing, which are either lighter or which can be used in less quantities; the substitution of high strength or light-weight alloys in metal structures; the introduction of welding; the lightening of bridge floors; the reduction of weight of automobiles and airplanes; and the use of weightless agencies in the numerous applications of electric energy.

The Extent of Present Theoretical Knowledge

The present electronic theory is based on the assumption that the electric and magnetic forces of the electrons are ultimately responsible for the continuity of each physical body. The different orientation of these forces is responsible for the properties of the different materials and in particular for their stress-carrying capacities. The fundamental approach to the stress problems would be to consider these electric and magnetic forces. At the present inadequate state of knowledge that approach is impractical. Even the less fundamental relations between the individual particles or crystals of the material have not been sufficiently studied and rationalized to be practically applicable.

The present engineering approach necessarily must be simplified, which is done by the introduction of the theory of stress. This theory should make it possible to determine the distribution of forces applied to the structure and their transformation into strains and stresses. It should provide a method by which the behavior of the structure may be predicted if the applied external forces or loading are known or can be assumed with sufficient accuracy. In the engineering sense of the word, stresses are changes in the internal forces that are holding these particles together. Stresses introduced in any physical body are manifested in strains and resulting deformations and deflections. The mathematical expression of the engineering theory of stress is given in a set of differential equations. The mathematical solution of these equations should result in a set of functions that can be solved for each point of the body, giving, for each set of conditions, the corresponding position of each point and the stress in each desired direction. As a general rule, the

mathematical functions are applicable only within the range of continuity and cannot be extended beyond a discontinuity.

The surface of each structural element will be a discontinuity, regardless of whether it is exposed to the atmosphere or to a liquid, or is a jointing or connection area of two structural elements or the border area between materials differing in their properties. In the engineering sense that would mean that each set of functions will determine the conditions within the body of a continuous structural element, and also at its surfaces or discontinuity areas, the latter being of particular importance. The conditions at such surfaces are referred to as "boundary conditions".

Present mathematical knowledge is limited and no general solution is available of the differential equations set up by introducing the theory of stress. Consequently, the solution of each structural problem resolves itself into finding the partial or approximate solutions of the general equations which will solve, with more or less accuracy, the particular stress problem.

All the approximate methods are based on a number of more or less reliable assumptions. Besides the traditional assumption that the material follows Hooke's law nearly all methods are based on the assumption of linear stress distribution throughout the thickness of the body. In many cases, such an assumption may be reasonable at a certain distance from the boundaries, but as a general rule it violates, grossly, the actual conditions at close proximity to the boundaries. As a consequence these methods, in general, do not satisfy the boundary conditions, although they may permit a reasonably close determination of conditions within the thickness of a uniform body.

At the boundaries, however, the difference between the theoretically determined, and the actual, conditions may be appreciable, particularly at places where a sharp change in the boundary conditions occurs. Such change may be due either to an abrupt change of cross-section or to local application of concentrated forces.

The theory of stress gives two major criteria for the determination of the suitability of a design—the deflection and the stress. The deflection is an integration of the differential strains over the entire structure or over an entire structural element. Consequently, if the average conditions determined by the use of an approximate method are close to the actual average conditions, there may be a very satisfactory agreement between the deflections determined by the use of such a method and the actual deflections, notwithstanding the discrepancies at the boundaries.

In so far as the stress is concerned, the suitability of a structure should not be judged by the average but by the maximum stress that may occur at any point, and that maximum, as a general rule, will occur at the boundary. The value of such governing maximum stress cannot be determined with reasonable accuracy by the use of the traditional approximate methods.

Properties of Metals and Alloys of Importance in Structural Designs

The ideal material, which is the basis of conventional designs, not only has perfect elastic properties, obeying Hooke's law through the entire range of stress, and exhibiting a linear stress distribution through the thickness of

the body, but it is also unaffected by time, retaining the same properties after an indefinite length of service. No actual material has such properties and in up-to-date structural design the behavior of the material must be considered during the first, as well as the intermediate and last, load application for the entire expected life of the structure. The possible deterioration of the material with time, the creep, and the fatigue properties, must be investigated before an engineering judgment can be formed as to the suitability of the particular material for a particular application.

The stress-resisting capacity of a metal or alloy is the fundamental property that makes possible its use in any engineering structure. The suitability of different metals and alloys is judged by comparing their ultimate strength, elastic limit and elongation, fatigue, creep, impact properties, weight, and price.

Metals and Alloys Used.—The pure metals are very unsatisfactory in so far as their stress-resisting capacity is concerned. No pure metals are used in structural designs; the carbon steels are the oldest and most important alloys. The modern steel alloys, the aluminum and magnesium alloys, are recent additions to the structural field.

From the seructural designer's viewpoint an ideal alloy should possess high stress-carrying capacity at light weight and low cost and, at the same time, should have a high degree of permanence or a high degree of corrosion resistance. A series of alloys having these qualities and of different moduli of elasticity would make it possible to use the most suitable alloy for each design.

No alloy or alloys are available at present that would meet all the requirements satisfactorily. The ultimate goal of metallurgical research is to find compositions and fabrication methods that will improve the stress-resisting as well as the other desirable properties. Such an ideal alloy is not even in sight, and structural engineers will be compelled, for a long time to come, to use numerous alloys, each one satisfying a part of the requirements among which the cost will always be important.

In so far as the modulus of elasticity is concerned, it seems that, at present, metallurgical science does not propose any methods by which that important property can be varied sufficiently.

Ultimate Strength.—Ultimate strength is measured by the stress at which the material fails during a single gradually increasing load application, based on the original cross-section of the specimen and using an arbitrary size and shape of specimen. One of the complications in the application of present stress theories, lies in the fact that the ultimate strength depends not only on the kind of material, but also on the kind of stress. The same material will show a different ultimate strength in tension, compression, bending, or shear.

Considering the simplest case, the theoretical maximum tensile strength of a material reflects the degree of adhesion between its molecules.

The general assumption is that this adhesion is due to the molecular or internal forces that hold the molecules of the material together. If the modern

electronic theories are accepted, it is only logical to assume that there is a particular arrangement of all electrical and magnetic forces that will result in the maximum internal force holding the particles together and, consequently, will represent the conditions of the absolute ultimate tensile strength that cannot be exceeded by any material under any conditions. Then the ultimate tensile strength obtained in any material under a particular set of conditions could be expressed as a percentage of the absolute tensile strength. This percentage will be low for unsatisfactory arrangements of the internal forces and will increase if the internal forces are better orientated with reference to the tensile stress applied. No information is available as to what such absolute ultimate strength may be, but it is reasonable to assume that it is not even approached in any of the commercially used structural materials.

The present state of knowledge is insufficient to determine how a better orientation of the internal forces may be obtained, but practical experience shows that such improvements are possible even if an explanation for them is not apparent. It is not even clear whether the increase in the specific gravity of the material has any favorable influence on the orientation of the internal forces.

The most important improvement in the orientation of the internal forces, resulting in the increase of ultimate strength, is obtained by cold working suitable alloys. At the same time such cold working not only does not increase, but very often decreases, the density of the material. This fact could be taken as an important indication that the proper orientation of internal forces has no direct relation to the specific gravity, but depends on some factors unknown.

The general speculation permissible under these assumptions is that it should be possible by the use of means, unknown at present, to produce alloys of the same degree of orientation of internal forces irrespective of their specific gravities. Practically, that would mean that it should be possible to produce light alloys of very high ultimate tensile strength.

Materials identical in so far as the orientation of the electric and magnetic forces is concerned, should be identical in all other respects. There are numerous ways in which the orientation of these forces can be changed in metals, resulting in an unlimited variety of metals and alloys; but practically nothing is known as to the character of these re-orientations. The following classification of the known methods of re-orientation of the internal forces may be made:

I.—Re-orientation involving change in chemical composition:

(*A*) Changes brought about by the addition or substitution of different alloying elements, resulting in alloys of a different chemical composition.

(*B*) Changes in composition of the integral parts of the alloys, resulting in alloys of the same general chemical composition, but of different properties.

(*C*) Changes in surface conditions, known as chemical corrosion.

II.—Re-orientation not involving any change in chemical composition:

(*A*) Changes in grain structure caused by cold working or heat treatment.

(*B*) Changes in the internal equilibrium conditions caused by the introduction of internal stresses.

(*C*) Changes in surface conditions caused by mechanical erosion.

(*D*) Changes in surface conditions caused by repeated application of stress.

Factors that do not influence the stress-resisting capacity directly, but are customarily included, may be classified as follows:

III.—Factors reflecting insufficient theoretical knowledge:

(*A*) Stress concentrations that cannot be determined exactly.

(*B*) Unknown distribution of stress throughout the thickness of the specimen resulting in the introduction of a new variable—the size of the specimen.

IV.—Factors reflecting inadequate manufacturing procedure:

(*A*) Non-uniformity of material.

(*B*) Unsatisfactory surface conditions.

The chemical composition is naturally the major factor. Nothing is known concerning the fundamental relation between chemical composition and strength of the various materials and in particular metals. Much has been learned during the last few decades about the influence of comparatively small quantities of some alloying elements on the strength of commercial alloys. Nevertheless, the development of new alloys is very much a "cut and try" proposition. The present metallurgical knowledge of the fundamental factors influencing the strength of metals is rather limited. In general, every commercially used metal can be made stronger by adding proper alloying ingredients. Even the impurities that are unavoidable in any commercial process may change the strength of metals to a large extent.

On the other hand, in most cases, the increase of strength indicated by increased ultimate strength that is due to alloying, is obtained with a simultaneous decrease in ductility, indicated by decreased elongation. Since, for practical purposes, a metal of high strength and high ductility is desirable, it is necessary to arrive at some compromise as to the most favorable combination of strength and ductility. For alloys to be used as castings it is possible to utilize materials of very low ductility; metals that must be changed to a prescribed shape by forging , stamping, extrusion, or rolling necessarily must have a much higher ductility, at least at the working temperature.

Some of the alloys are susceptible to heat treatment and change their properties if heated to a certain temperature and cooled in a definite way. The wide influence that changes in chemical composition may have on alloys with different percentages of alloying elements is demonstrated in Fig. 1, which shows the total percentage of alloying elements and the ultimate tensile strength of a number of non-commercial and commercial aluminum alloys. It embraces the highest values of the ultimate tensile strength obtained.

In drawing this diagram, no attention was paid to the method by which the highest ultimate strength was obtained, such as heat treatment, cold working, etc. The greatest tensile strength obtained for each alloy was the

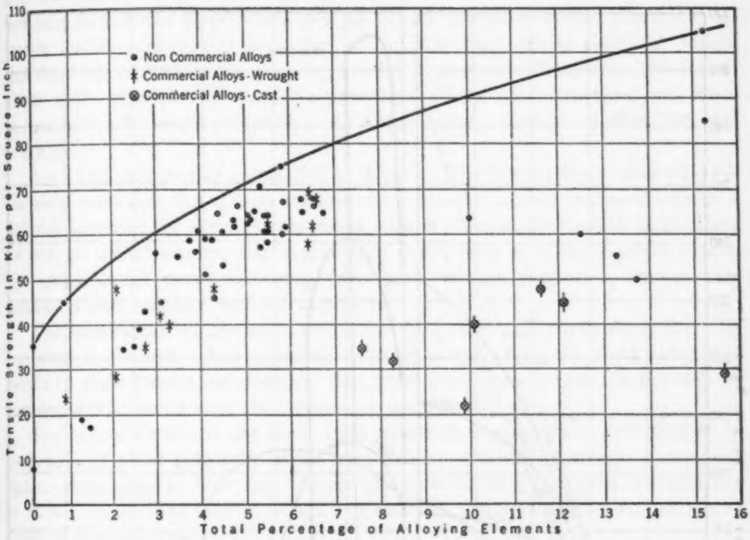

FIG. 1.—ULTIMATE TENSILE STRENGTH OF ALUMINUM ALLOYS.

information included in Fig. 1. It is reasonable to assume that every point of the enveloping curve can be filled in, with future progress in the study of the different possible alloys.

The increase in the percentage of alloying elements increases the ultimate tensile strength, but may decrease the ductility, and in many cases the corrosion resistance, to such an extent that the resulting alloys often have no commercial use. Increasing the number of alloying elements may improve these conditions, resulting in increased stress-resisting capacity without a detrimental influence on other desired properties, resulting in commercial alloys.

The large number of points representing non-commercial alloys indicates that a large number of factors needs to be considered in order to find whether a particular alloy will prove to be useful.

No information is available that would indicate the maximum strength that may be reached by the alloying of different base metals.

Stress-Strain Curves, Modulus of Elasticity, Yield Point.—Although very little is known about the ways in which the different chemical ingredients act in the alloy, the final results are reflected in stress-strain curves, particularly if these curves are obtained by the use of sufficiently sensitive instruments.

A number of such curves are shown in Fig. 2, which is drawn in such way that for the first part of the stress-strain curves, up to 0.01 in. per in., or 1% of strain, a large scale of strains is used, the remainder of the diagram is

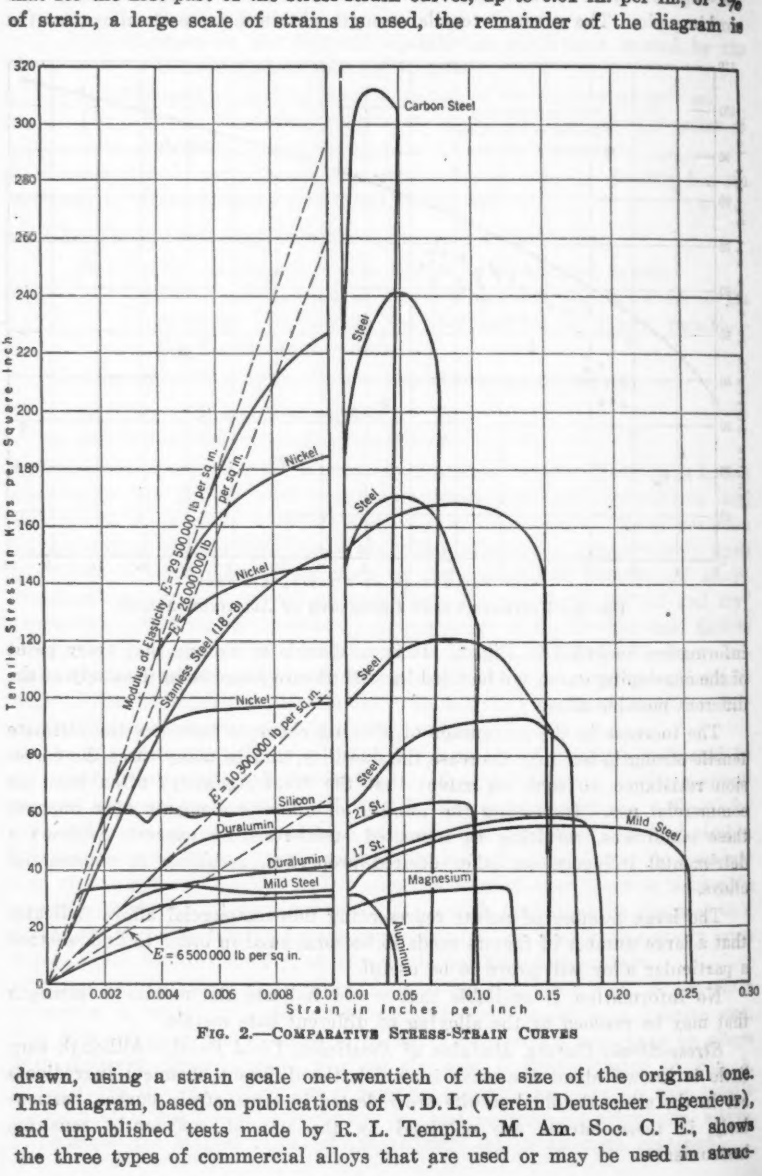

FIG. 2.—COMPARATIVE STRESS-STRAIN CURVES

drawn, using a strain scale one-twentieth of the size of the original one. This diagram, based on publications of V. D. I. (Verein Deutscher Ingenieur), and unpublished tests made by R. L. Templin, M. Am. Soc. C. E., shows the three types of commercial alloys that are used or may be used in struc-

tural designs, the steel, aluminum, and magnesium alloys. A study of Fig. 2 reveals a few interesting facts:

1.—Notwithstanding the very large variation of the ultimate strength and elongation, only four different moduli of elasticity are available, one between 29 000 and 30 000 kips per sq in. for low alloy steels, the other between 25 000 and 26 000 kips per sq in. for high alloy, stainless, steels, the third about 10 300 kips per sq in. for aluminum alloys, and the fourth about 6 500 kips per sq in. for magnesium alloys. In structural materials as commercially used at present, no intermediate moduli of elasticity are available.

2.—Yield points may be studied in Fig. 2. The low-strength steel alloys—the mild steel and the silicon steel—have pronounced yield points at which a definite break of the strain-stress curve occurs. The high-strength steel alloys as well as the aluminum and magnesium alloys have no definite yield points, the stress-strain curve changing from the straight part to a curved part gradually and steadily without any break.

The importance of the yield point for mild steel and particularly for silicon steel is obvious. Any stressing of these alloys above the yield point will result in considerable deformation that must take place before the increase of resistance will occur that may stop such deformation.

For alloys which do not have yield points it is customary nevertheless to designate as yield point the stress at which an arbitrarily chosen permanent deformation occurs. For non-ferrous alloys, 0.2% of permanent deformation is widely used. For ferrous alloys a permanent deformation between 0.1% to 0.5% is usually chosen.

Considering the properties of the alloy and its applications, these arbitrary yield-point values are rather meaningless, but they have some practical significance in limiting the acceptable design deformations.

3.—Fig. 2 makes clear the justification of the application of Hooke's law to low-strength steels if they are not stressed above the yield point; also, it demonstrates the much lesser justification for the application of this law to high-strength steels and light-weight alloys and the non-applicability of Hooke's law to low-strength steels stressed above the yield point.

4.—It shows: (*a*) The uncertain nature of the definition of the modulus of elasticity; and (*b*) the difference between the initial and the actual moduli of elasticity for the different types of alloys.

Boundary Conditions.—The surfaces of any structural element are boundaries which represent the most abrupt change in the conditions. In structural engineering, as well as in many other engineering fields, the boundary conditions may become of considerable importance. They must be considered in any investigation of the stress-carrying capacity of alloys and should be reflected in the mathematical treatment of the stress problems. The present progress in engineering design, as well as in the utilization of alloys, depends to a large extent on the increased attention paid to the boundary problems.

That corrosion, or the disintegration, of metals and alloys starts at the boundary or surface and gradually penetrates the body of the material was

realized, of course, a long time ago, and the metallic surfaces were protected by the use of different paints, or, more recently, by facing the less stable base metal with a more stable alloy or alloying element.

Even now the influence of the boundaries on the distribution of stress within the body of the metal is not always realized. For instance, the traditionally assumed linear distribution of stress does not represent the conditions close to the boundaries. During the last few decades considerable advance has been made in realizing the importance of the boundary or surface conditions in the fatigue phenomena. Without attempting to go into the complicated stress relation among the individual crystals or even more

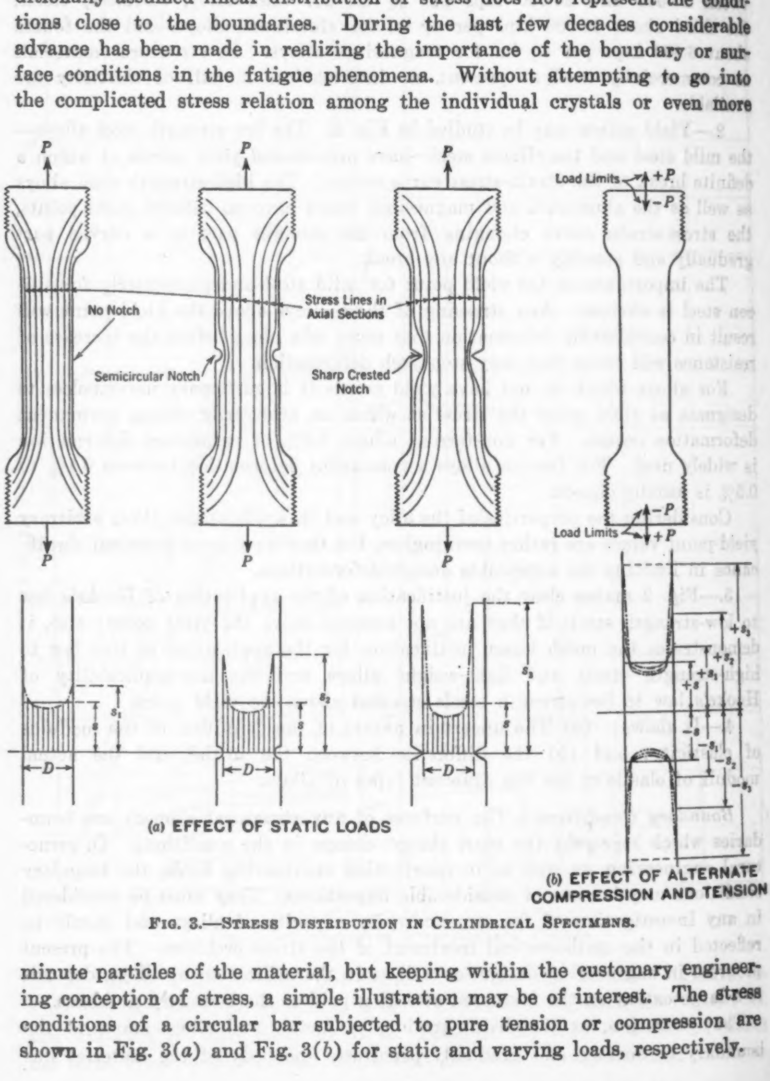

Fig. 3.—Stress Distribution in Cylindrical Specimens.

minute particles of the material, but keeping within the customary engineering conception of stress, a simple illustration may be of interest. The stress conditions of a circular bar subjected to pure tension or compression are shown in Fig. 3(*a*) and Fig. 3(*b*) for static and varying loads, respectively.

The two plain bars have the same diameter, D, and the notched bars have the same diameter, D, as the plain bars, at the bottom of the notch. The static load, P, to which the bars in Fig. 3(a) are subjected, is the same. The varying load, P, to which the bar in Fig. 3(b) is subjected, alternates between $\pm P$, the numerical value of P being the same as in the case of the bars subjected to static loads.

Under the traditional assumption of linear distribution of stress, a tensile stress, s, will be developed at the middle section of the plain bar (Fig. 3(a)) and at the section taken at the bottom of the notches at the bars. This stress will be equal for each of these three bars and will be distributed uniformly over the entire available cross-section, as shown by solid lines in Fig. 3.

The actual stress in the plain bar (Fig. 3(a)) under static load probably will be greater at the surface and less at the middle as shown by the broken-line curve, the ratio between the maximum actual stress, s_1, and the traditionally assumed stress, s, being usually referred to as the stress concentration factor. The actual stress in the bar with the circular notch will be greater at the bottom of the notch and somewhat less at the middle, as compared with the plain bar, and as shown by the broken-line curve, the maximum stress being s_2. Finally, the actual stress in the bar with the sharp notch will be still greater at the bottom of the notch and somewhat less at the middle, and as shown by the broken-line curve, the maximum stress being s_3.

A much better visualization of the conditions may be obtained by the use of the stress fields or stress lines analogous to the fields and lines used in the study of electrical phenomena. Instead of visualizing the stress at one cross-section only, it is possible to visualize the flow of stress. In Fig. 3(a) such stress lines are drawn for an axial section of each cylinder. At each point the direction of the stress is a tangent to the stress line. The intensity of the stress is shown by the distance between the stress lines. The influence of the differently shaped notches may be visualized by the study of these diagrams.

Introducing the stress concentration factors, c_1, c_2, and c_3, the maximum stresses, s_1, s_2, and s_3, may be expressed as $s_1 = c_1 s$; $s_2 = c_2 s$; and $s_3 = c_3 s$. The values of c_1, c_2, and c_3, and, consequently, the values of the maximum stresses, s_1, s_2, and s_3, depend on the properties of the material, particularly on the shape of its strain-stress curve. As long as the material follows Hooke's law at the low range of stress, the strain-stress relation is expressed by the straight part of the curve. Under these conditions the concentration factors reach their highest value. When the material deviates from the straight part of the curve, increased deformation or plastic flow takes place. This tends to redistribute the material, tending to decrease the peak value of the stress and, consequently, to decrease the concentration factor.

Alloys having straight-line stress-strain curves and definite yield points will develop the maximum stress concentrations with increase of load until the maximum stress reaches the yield point, after which the stress concentration factor will decrease rapidly.

Alloys that gradually diverge from the straight part of the stress-strain curve will develop lower stress concentration factors at the lower range of stress.

Assuming, again, linear stress distribution, the traditionally evaluated stress in Fig. 3(*b*), under the varying load, will fluctuate between plus and minus s; the numerical value of s again being the same as in the bars subjected to static load, and being uniform over the entire cross-section. The actual stress in the bar will depend on a number of conditions. If the force, P, and, consequently, the actual maximum stress, s_1, is small, the stress in the bar will fluctuate between the limits shown by broken-line curves, corresponding to the actual stress of the bar in Fig. 3(*a*), without producing any changes in the material. Consequently, the reversing load may be applied an indefinite number of times, without producing a failure. If the stress, s_1, is great enough, the actual stress of the plain circular bar (Fig. 3(*b*)) will fluctuate between limits that will change gradually. At the first load application, the stress limits will be the same as before. If the reversing load is applied a number of times, incipient cracks will be formed at the surface of the bar, an increase of the surface stress will follow, and the stress limits will be approximately the limits of the bar with the circular notch (Fig. 3(*a*)), shown by the broken-line curve, with the maximum stress, s_2.

In this case, again, the phenomenon may stop if s_2 is low enough and the reversing load may be applied an indefinite number of times without producing a failure; but if s_2 is great enough the repeated application of the reversing load will cause the incipient cracks to change their shapes, increasing the surface stress until it corresponds to the conditions of the bar with the sharp notch in Fig 3(*a*), with the maximum stress, s_3, the notch being chosen so as to produce the highest possible value of c_3.

These conditions will be somewhat complicated due to the fact that the circular bar will contract or expand, not only parallel to the axis or in the direction in which the forces are applied, but also along the diameter or at right angles to the direction of the forces. This complication, however, in the simple case assumed, will only be of secondary importance.

If the stress, s_3, developed under such conditions is low enough, no more changes in the conditions of the incipient cracks will occur, and the specimen may be subjected to an indefinite number of load reversals without failure.

If the stress, s_3, is high enough, a permanent and continuous change in the crack conditions will be produced and the failure will occur after a number of load reversals during which the incipient crack will grow and attain larger dimensions, causing an increase of stress due to the reduction of the effective cross-section. It may take a considerable number of load reversals before the incipient cracks will come to such a condition that they start to grow; but after that the final growth is usually accomplished during a small number of load applications, and the failure takes place rapidly.

Finally, the reversing load, P, applied to the specimen may be so great that although the stress, s_1, will be lower than the ultimate strength, the stress, s_3, exceeds it. Under such conditions the failure will occur after a limited number of load applications as soon as the growing maximum stress approaches the ultimate strength of the material.

This description of the fatigue phenomena may not be exact in every case, but should give an understanding of the underlying conditions as known at present.

The properties of metals and alloys of importance in engineering structures may be divided into two classes: The first are the properties that depend mainly on the internal deep-seated conditions; and the second those that depend upon the surface conditions. Modulus of elasticity, shape of the stress-strain curve, ultimate strength under static load, creep, and single impact properties, all depend on the internal conditions and are affected very little by the surface conditions. Corrosion resistance, fatigue strength, and fatigue strength under repeated impact, are properties that depend fundamentally on the internal conditions, but may be influenced to a very large degree by the surface or boundary conditions.

Fatigue Properties.—Fatigue strength is determined by the formation of incipient cracks on the surface and by the extension of such cracks. If the formation and extension of these cracks can be retarded, the fatigue strength will be increased, and *vice versa.* The stresses developed at the surfaces are the major factors in the formation of the cracks. It is not the mean stress or the assumed stress that is of importance, but the actual maximum stress that may occur.

The extension of cracks depends on the load or stress fluctuation. A static load may develop minute cracks, but unless the maximum stress is close to the ultimate strength of the material such cracks will not grow. The variation in stress will change the conditions of the cracks. Small variations of stress from a constant mean value will make the cracks spread only if the mean value is high. Larger stress variations will make the cracks spread even at a smaller mean value until the complete reversal of stress may result in their extension and spread, although the mean value is zero.

These conditions may be summarized on a diagram with a base line of 45°, such as that shown in Fig. 4, in which the mean value of the stress is plotted on the 45° base line, using either the scale on the ordinate or the abscissa axes. The stress variations are plotted vertically as ordinates using the mean stress value as the zero point. This diagram, based on the publications of V. D. I., extends from the zero mean value which will be the origin of the co-ordinate system and to the value of the ultimate strength plotted at the 45° base line.

To draw such a diagram the fatigue strengths must be determined on a large number of identical specimens of a particular alloy under different conditions of load variations, but for a stress of the same kind, either tension or compression.

For practical purposes a diagram such as Fig. 4 should not be used above the true or assumed yield-point value, resulting in that part of the diagram shown by solid lines.

Number of Load Applications.—The fatigue strength of a material is determined by the testing of a sufficiently large number of identical specimens. Each specimen is tested in a similar manner but at a different stress range.

If, for instance, the fatigue strength at the complete reversal of stress is to be determined, the specimens are tested under conditions of complete stress reversal, starting with a number of specimens that are tested at high stress.

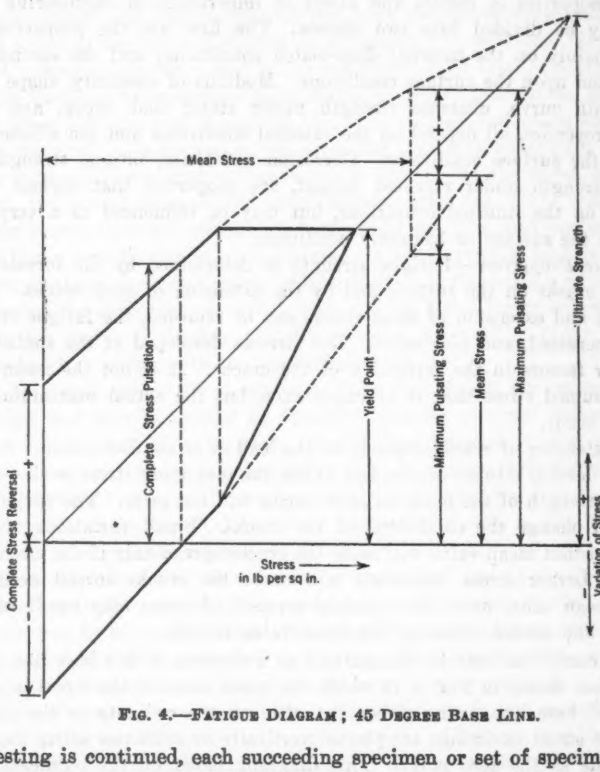

FIG. 4.—FATIGUE DIAGRAM; 45 DEGREE BASE LINE.

The testing is continued, each succeeding specimen or set of specimens being tested at a lower stress, so that the result represents a series of gradually decreasing values of stress to which the specimens were subjected. For each specimen two values are obtained, the stress at which the specimen was tested and the number of stress reversals at which it failed. The stress is determined by the use of traditional methods, disregarding any possible stress concentration.

In order to obtain complete fatigue data, tests must be made and diagrams plotted for complete and partial stress reversals and for complete and partial stress pulsations.

The accepted term, "endurance limit", can be defined as the fatigue stress under complete stress reversal below which metal will withstand, without failure, an indefinitely large number of cycles of stress. It may also be defined as the stress value at which the stress-cycle curve changes to a line, straight and parallel to the abscissas. For partial stress reversals and for pulsating stress the term, "fatigue strength", would seem more applicable.

There is a wide difference in the shape of the stress-cycle curve for different materials. For some materials the curve has a very pronouncd "knee" and the endurance limit is a very definite term, but for other materials the curves have no definite "knee" and, for some materials, the stress-cycle curve does not change to a line straight and parallel to the abscissas.

To determine the properties of the different alloys it is necessary to run the fatigue tests either until a definite endurance limit or fatigue strength is established or until the proof is obtained that no definite value can be obtained.

The term "endurance limit", is often misused. For practical purposes, particularly in structural problems, data may be utilized which represent results of tests obtained at a lower number of load applications; such data should not be referred to as "endurance limit", but as "fatigue strength", and it would seem necessary in each case to supply a clear indication of the limiting number of load applications at which the data were obtained. The term, "endurance limit", should not be applied to cases of partial stress reversals or stress pulsations.

Surface Conditions.—Fatigue strength may be influenced to a large extent by changes in the surface conditions. The methods by which such changes may be obtained can be divided into a number of groups. The most radical is the group involving the change in the chemical composition of the boundary layer of the metal or alloy. If such a change results in a surface which prevents the development of cracks, or which prevents the minute cracks from spreading, an increase in fatigue strength may be obtained. The nitriding of steel changes the chemical composition of the surface, resulting in a considerable increase in the fatigue strength.

Changing the surface conditions without changing the chemical composition covers a group of methods of primary importance. First in this group is the case in which changes occur automatically during the repeated application of the fluctuating load. The changes produce what is known as the "strain-hardening effect." It seems that if, during the load application, stress concentrations occur, that bring the peak of the stress above the yield point for materials that have a yield point, plastic deformations are caused, thus changing the properties of the material that may retard or even stop the growth of the incipient cracks. For materials that do not have a yield point, the same condition occurs if the stress is high enough to produce a sufficient deformation.

Similar results may be produced by cold working the surface by use of rollers or by similar means. The increase in the fatigue strength in this case may be attributed partly to the compacting of the surface particles and partly to the pre-stressing of the surface which, if properly applied, may reduce the stress peaks.

The next group of methods involves the finish of the surfaces. Machined and highly polished specimens have the highest fatigue strength in this group. The elimination or reduction in size of the incipient minute cracks is the probable explanation. Fatigue strength is reduced if the surfaces are only

machined but not polished, and it is still more reduced for rough, non-machined surfaces. The notching of the surface, or injury by sharp cuts, and, finally (for mill-rolled shapes), using the material with the mill scale left on, will result in the lowest fatigue strength. The presence of cracks and high stress concentrations are the most probable explanations.

The final and lowest in fatigue strength is the group in which the surfaces are covered with liquids. It would seem that if liquids of high viscosity are pressed into the incipient cracks, or liquids of low viscosity flow freely into them, they act as wedges during the closing of the crack, increasing considerably the stress concentrations and reducing the fatigue strength. The chemical reactions of some of the liquids cause a further lowering of the fatigue strength by increasing the sizes of the incipient cracks or deepening them.

Finally, a very considerable lowering of the fatigue strength and the destruction of the metal, submerged for instance in water, may occur due to cavitation and resulting corrosion, when the material is subjected to a very large number of very rapid blows due to the continuous and rapid forming and collapse of vacuum bubbles in the surface layer of the water adjoining the metal.

If similar metals or alloys are compared, those that have a lower ultimate strength can be improved as a general rule to a larger degree; and, on the contrary, high-strength alloys are more sensitive in so far as the lowering of the fatigue strength is concerned. Thus, the fatigue strength of a low-strength carbon steel can be improved by nitriding to a larger degree than the fatigue strength of high-strength steel; but if compared with machined and

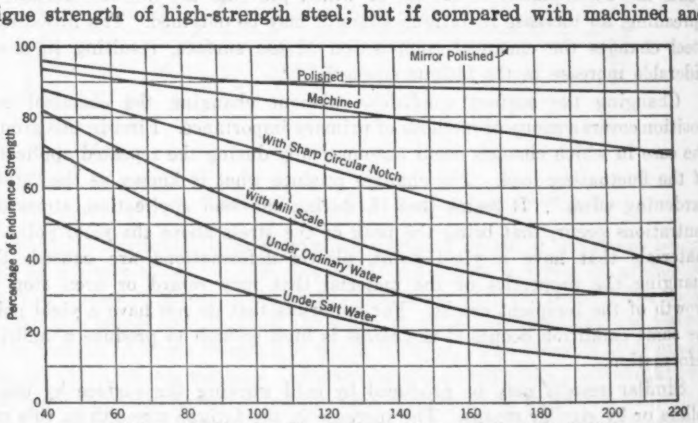

FIG. 5.—REDUCTION OF ENDURANCE STRENGTH OF STEEL ALLOYS DUE TO SURFACE CONDITIONS.

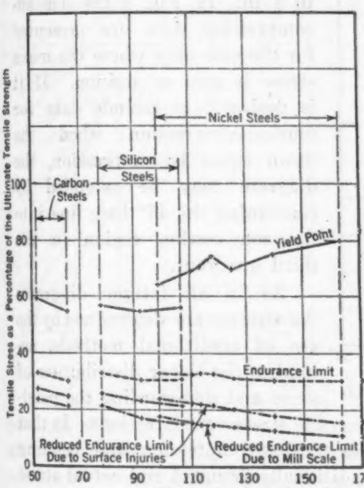
polished surfaces, a notch or surface injury will lower the fatigue strength of high-strength alloys to a larger degree as compared with similar low-strength alloys.

In so far as steel alloys are concerned, Fig. 5, based on V. D. I. publications, illustrates this conditions. The diagram is based on fatigue strength obtained

on specimens in tension-compression and bending. The highly polished or mirror-polished specimens are given the 100% rating.

Reduction factors are to be applied, depending on the ultimate strength of the particular steel alloy and its surface conditions. They must be applied not to the mean value of stress but to the plus-minus stress fluctuation. If a combination of factors is involved the lowest values shown on Fig. 5 should be used. As usual, the values for sharp circular notches do not take into consideration the stress concentrations and give a good idea as to what the reduction in fatigue strength may be if the surface is injured by a blow leaving a sharp indentation.

The influence which that reduction of fatigue strength may have under conditions of complete stress reversal is demonstrated in Fig. 6, based on the data



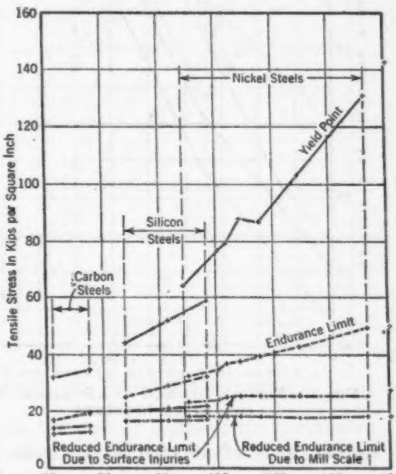


FIG. 6. FIG. 7.

shown in Fig. 5, for different steel alloys. This diagram shows the yield point, the endurance limit for highly polished specimens, the reduced endurance limit due to surface injuries using the data for sharp circular notches, and the reduced endurance limit that is obtained if rolled material is tested with the mill scale left on. All these data are expressed in percentages of the ultimate tensile strength. Finally, the diagram, Fig. 7, shows that under the same conditions of a complete load reversal the high-grade steels have endurance limits somewhat proportional to their higher ultimate strength, only for highly polished specimens. For specimens with injured surfaces or with the mill scale left on, there is only a very slight increase of the endurance limit.

Complete Fatigue Diagrams.—The fatigue strength of a material, tested under identical conditions in so far as the properties of the alloy and its surface conditions are concerned, depends on the kind of applied stress.

Therefore, it becomes necessary to test the materials separately for three kinds of stresses—tension-compression, bending, and shear. Fig. 8, based on V. D. I. publications, shows a complete fatigue diagram of a silicon steel alloy on which the fatigue strength for all three kinds of stresses are shown. The characteristics of this alloy were: Carbon, 0.25%; silicon, 0.2%; manganese, 0.6%; ultimate strength in tension, 64 kips per sq in.; and, elongation, 0.20% in 4 in. In Fig. 8 the tension-compression data are presented for the case only where the mean stress is zero or tension. If it is desirable to include data for tension-compression when the mean stress is compression, the diagram may be extended by continuing the 45° base line into the compression region in the third quadrant.

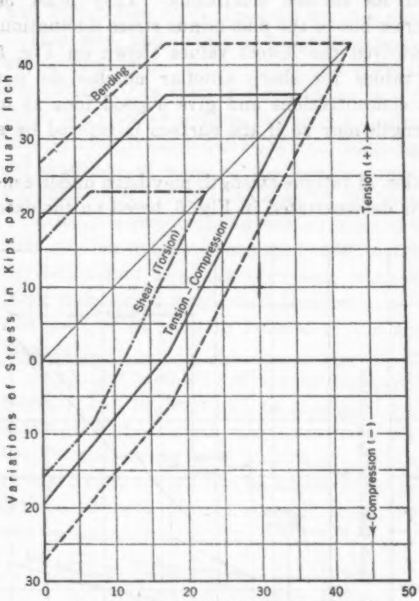

FIG. 8.—FATIGUE DIAGRAM OF A POLISHED SILICON STEEL SPECIMEN

As in all fatigue diagrams the stresses are determined by the use of traditional methods, assuming the linear distribution of stress and disregarding the possible stress concentrations. In that respect it is of interest to compare the tension-compression and bending stresses. The comparison between the traditionally assumed and actual stress distribution is shown on Fig. 3(*a*) and Fig. 9 for the tension-compression and bending, respectively. By comparing these two diagrams it can be seen that in the case of tension-compression the actual stress is higher, and in that of bending lower, than the assumed stress. If corrections due to non-linear distribution of stress were applied to the data in Fig. 8, the fatigue strength in bending would be lowered and that in tension-compression would be raised, bringing both of them together. The large difference between the shear and tension-compression fatigue would be made still larger.

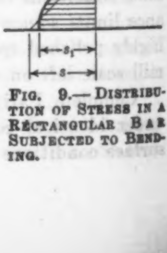

FIG. 9.—DISTRIBUTION OF STRESS IN A RECTANGULAR BAR SUBJECTED TO BENDING.

Comparative Fatigue Diagrams of Different Alloys.—The fatigue strengths of a number of alloys, determined on highly polished specimens under tension-compression stress, are shown in Fig. 10(*a*), based on unpublished tests by R. L. Templin, M. Am. Soc. C. E., and on V. D. I.

publications. The alloys were chosen to represent high-strength alloys of their respective classes.

The ultimate tensile strength and elongation of these alloys are given in Table 1. Although it gives the absolute fatigue strength values, Fig. 10(*a*)

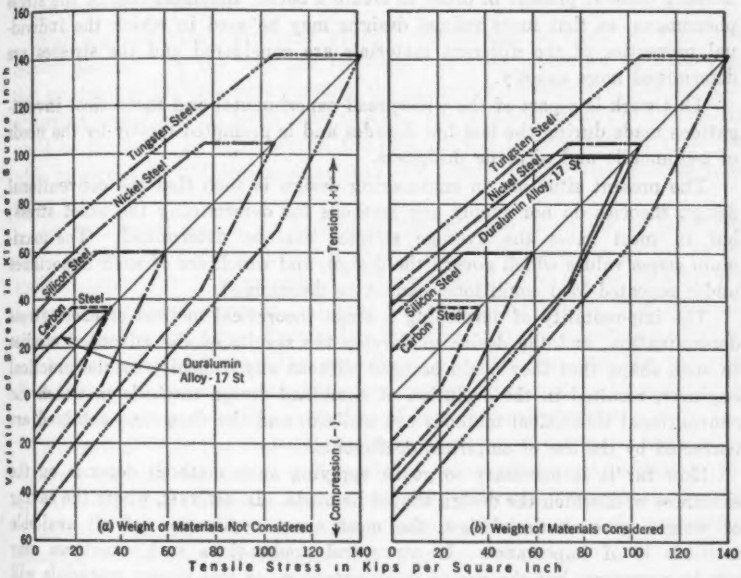

FIG. 10.—COMPARATIVE FATIGUE DIAGRAMS FOR POLISHED SPECIMENS.

does not offer a proper basis for comparison, since the weights of the materials are not considered. Fig. 10(*b*) is based on the same data, but the weight is considered by assuming the steel as the material of unit weight, and multiplying the fatigue stress for duralumin by the steel-duralumin weight ratio, which makes possible a direct comparison of the different alloys on the strength-weight basis.

TABLE 1.—CHARACTERISTICS OF ALLOYS IN FIG. 10.

Alloy	Ultimate tensile strength, in kips per square inch	Percentage elongation, in 4 inches
Duralumin	59	19
Carbon	64	20
Silicon	107	10
Nickel	139	10
Tungsten	170	10

IMPROVED DESIGN METHODS

Determination of Stress.—The assumption that the materials follow Hooke's law does not take care of the individual properties of the different materials,

but bases all designs on the use of non-existing ideal materials, with perfect elastic properties. The assumption of linear stress distribution in many cases precludes the proper determination of stress, particularly at the boundaries.

Considerable experimental and theoretical work was done in the past and is being done at present in order to create a better understanding of the stress phenomena, so that more refined designs may be used in which the individual properties of the different materials are considered and the stresses are determined more exactly.

This work is a part of the widespread experimental and theoretical investigations made during the last few decades and is prompted mostly by the needs of automobile and airplane designers.

The present situation in engineering design is such that the conventional design theories do not supply any methods for determining the exact stress; but in most cases the average stresses can be determined. The maximum stress values which govern the design, and which are of such importance under repeated load conditions, cannot be determined.

The impossibility of developing a strict theoretical method of exact stress determination, and the desire to develop the results of the advanced studies in such shape that they could be used without any difficulty by the practical engineer, resulted in the evolution of combined design methods in which the conventional theoretical methods are utilized, and the data thus obtained are corrected by the use of empirical coefficients.

How far it is necessary to go in applying such methods depends on the exactness with which the design should be made. In aircraft, where the saving of weight governs the design, the most exact application of all available methods is of importance. In structural applications such exactness may not be necessary, but the use of more expensive or less known materials will make advisable the application of methods of greater exactness than the customary methods.

The exact methods that can be applied at present may be divided briefly in four steps:

First.—Assuming that the structure or its elements are built of an ideal material (which is practically non-existent), the stresses are determined by the use of conventional design methods;

Second.—The conventional stresses thus determined, are corrected to bring about close agreement between the design and correct stresses in the ideal material;

Third.—Stresses determined for the ideal material are corrected again, to take care of the substitution of materials actually used for the ideal material, so that a close agreement is assured between the design and actual stresses; and,

Fourth.—The finally determined stresses for the materials that are actually used are compared with the stress-resisting capacity of these materials under the expected loading conditions.

The traditional structural designs are based on the use of the first step only. The fourth step is seldom fulfilled; since the stress-resisting capacity

of the materials is not correlated with the expected loading conditions, in particular, the fatigue properties are usually neglected.

The inclusion of the second and fourth steps in the design will insure much greater precision. All four steps probably represent the most exact design possible at present.

Stability.—Stability problems are of considerable interest in the more refined designs. In the past the tendency has been to design structures so that no stability failures were possible, the failure by overstressing the material occurring under smaller loads than those at which the condition of instability could be reached. In other words, the attempt was to keep the safety factor with reference to stability greater than the safety factor with reference to stress failures.

An economical design not only must be balanced in so far as the stress safety factors are concerned, but it should also be balanced in so far as the stability safety factor is concerned. Theoretically, there are no reasons why a structure or its elements should have different safety factors with reference to stress and to stability. Practically, the stress-carrying capacities of alloys are better understood than the conditions of instability, and the tendency of the designer is to use higher safety factors with respect to stability as compared to stress, with the exception of some aircraft designs.

No matter what the material, and how stiff the structure or each of its elements may be, the strains and resulting deformations and deflections will appear every time forces are applied, the only difference being in the amount of deformations and deflections. These factors will depend on the modulus of elasticity of the material used and the stresses developed.

The mathematical treatment of the stability problem is even less definite than that of other stress problems. The fact that the change from stable to unstable conditions in most cases occurs during a very small change in the loading conditions, makes the exact mathematical solution a problem of such refinement that it cannot be obtained exactly by the use of present mathematical methods.

Practically nothing is known about the question as to whether, and, if so, how, the local stress concentrations and repeated load applications influence the stability. In comparing the application of different alloys, the stability may become an important factor.

If higher stressed, stronger alloys of the same specific gravity and modulus of elasticity are substituted for low-strength alloys, the thickness of the members is reduced, the deformations and deflections are increased, and, consequently, the stability safety factor is lowered.

If alloys, equally stressed and of the same strength but of lower specific gravity and lower moduli of elasticity, are substituted, no direct conclusion may be drawn. The comparative stability will depend on the details of design with respect to the distribution of the additional volume of the alloy of lower specific gravity.

Application to Actual Designs

Necessarily, the refinements of engineering design must start with a more exact prediction of the future loading conditions. Not only should the maximum force to be applied be known but, for varying forces, the amount of variation and the probable frequency of different load application must also be known. All these conditions have an important bearing on the behavior of the structure.

The relation between the shop and field labor costs and between the cost of material and labor are changing factors the importance of which is considerably accentuated since more expensive materials and different jointing methods are put at the disposal of the structural engineer.

Considering the different designs, the fatigue and stress concentration phenomena are of particular interest. The load that a metal structure carries produces stresses that may vary from a perfectly static to a completely reversing stress. There are very few metal structures the members of which are subject to perfectly static stress. Even the steel skeletons of buildings are subjected to a constantly varying stress, due not only to the wind action but also to temperature variations. As a general rule, these stress variations are small as compared with the mean stress. On the other hand, the number of structural elements that are subject to complete stress reversal is also comparatively small. The vast number of structural elements are subjected to varying stresses of different degrees of pulsation or reversal.

The number of stress pulsations or reversals may be considerable. The most outstanding instances are structures that are subject to vibrations in which the number of stress pulsations or reversals may be comparable to the number of stress reversals to which parts of fast running engines are subjected. Most of the structures are subjected to fewer stress pulsations or reversal.

These considerations would indicate that stress concentration and fatigue phenomena must be taken into account in structural design.

Joints.—The necessity to develop expensive high-speed internal combustion engines forced the mechanical engineer to take into consideration and to begin a study of stress concentration and fatigue phenomena. Joints, being the most expensive and most sensitive part of a structural design, are at present forcing the structural engineer to follow the same path.

Riveted joints are necessarily producing stress concentrations. If two similar riveted joints are compared, the traditionally assumed strength of which is the same, it would seem that the joint in which a small number of large rivets is used will have higher stress concentration than one in which there is a larger number of small rivets. All other conditions being equal the joint with a larger number of smaller rivets should have the higher fatigue strength.

The next conclusion would be that a continuous welded joint should have a greater fatigue strength than a riveted joint, which may not always be the case. The local heat application will result in residual stresses that may

increase the peak stress. The different properties of the base material and of the welded material, and the possible changes in the properties of the base material adoining the weld may produce internal boundaries, resulting in high stress concentration similar to those produced by abrupt changes in shape. The stress concentrations thus produced, and the changes in the properties of the base material, may result in a considerably lower fatigue strength of the joint.

Safety Factors and Working Stress.—The adequacy of an engineering structure is expressed in terms of the safety factor, which is supposed to represent the ratio between the actual and the ultimate conditions, under which the structure will fail. The safety of a design is not determined by an average safety factor, but by the lowest safety factor at the danger spot of the weakest element. It may be influenced by the fact that in any redundant construction, the members can partly unload this burden upon other parts of the structure, thus making the actual safety factor higher than the minimum safety factor of a single element. The factor is to be considered first in strength, represented by the stress safety factor, and second in stability, represented by the load safety factor. In the consideration of any given safety factor of a structure the most important item is the reliability of its determination. If crude design methods are used, the actual safety factor in many places or instances may be much lower than the theoretical safety factor. If more refined design methods are used, the actual and theoretical safety factors will be in closer accord.

In practically all cases a structure designed by the use of conventional methods, with a high safety factor, will be less safe than one designed by the use of more refined methods and using a smaller safety factor. The conventional safety factor idea is that the safety factor for a particular design under given loading conditions is a constant coefficient; but actually the safety factor varies.

In all engineering structures the factor of safety decreases as time goes on. In some instances it may initially increase for some time, if the stress-bearing capacity of the material increases, until it reaches its maximum, and it will then decrease. Some of the alloys as well as concrete are typical in that respect. In most structures the initial safety factor is the largest and after the structure goes into service the safety factor decreases gradually. Taking into consideration only the decreasing stress-carrying capacity with repeated loadings, the initial or maximum safety factor in many cases may be twice as high as that which will obtain after a definite time period. The difference will be still greater if the changes in material—its corrosion or deterioration—are considered.

If these conditions are realized it should be clear that a simple statement that the structure is designed with a certain safety factor is not sufficient. The safety factor should be qualified. In structural designs in which the fatigue properties and the stress concentrations are neglected, the design safety factor represents a theoretical initial safety factor, which actually is not attained even at the initial period.

The safety factor specified in modern aviation designs in which the fatigue properties and stress concentrations are considered, represents the actual safety factor which the structure will have at the end of its useful life, the initial safety factor being higher. The selection of the proper safety factor requires considerable engineering judgment. Too high a factor will result not only in an uneconomical structure, but will make it difficult (as, for instance, in long span bridges) or even impossible (as in aviation), to design a structure that could fulfill its functions. The danger of too low a safety factor is obvious. In practical applications the safety factors vary between 1.25 and 4.0 and often are even higher. It seems only reasonable to accept lower safety factors for more refined designs and to accept high factors for less refined designs in which only the initial theoretical safety factor is considered.

Region of Permissible Stress Variations.—The data given in a 45° diagram may be applied to a design if the proper reductions are applied. Fig. 11 shows the method of applying reductions. It is based on data given in the previous diagrams on tests made on highly polished small-sized specimens.

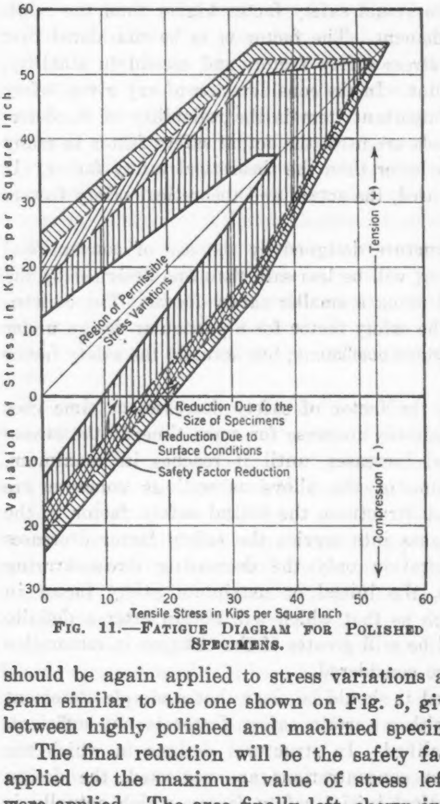

FIG. 11.—FATIGUE DIAGRAM FOR POLISHED SPECIMENS.

Part of the reductions must be applied to the stress variations. The first reduction applied takes care of the difference between the size of the testing specimen and the actual structural elements, and the possible difference in their properties. A small reduction in stress variations should take care of the usual difference in sizes. An increased reduction would be necessary if there is a difference in properties of the test specimens and the material actually used.

The next reduction shown in Fig. 11 should take care of the difference in surface conditions of the test specimens and the actual element. This reduction should be again applied to stress variations and should be taken from a diagram similar to the one shown on Fig. 5, giving, for instance, the reduction between highly polished and machined specimens.

The final reduction will be the safety factor reduction, which should be applied to the maximum value of stress left after the previous reductions were applied. The area finally left, shown in Fig. 11, will give the region of permissible stress variations, which should govern the design.

Conclusion

During the last few decades the theoretical bases of Structural Engineering have been very much standardized and have changed slowly. Structural engineers used ordinary mild steel and there was no particular need of refinement in material or in methods of design. At present, there seems to be a gradual change in conditions, making advisable a more critical attitude.

Conventional designs neglect stress concentrations, fatigue, and creep phenomena, and assume perfectly elastic properties of the materials. Such designs are idealized, presuming a mode of load application and jointing (which in the majority of cases may not be approached), and the use of non-existing ideal materials.

It is only natural that the development of engineering science should have started with the simplified, idealized conditions, and that at present the trend is toward evaluating the adjustments that are necessary in order to force the idealized and the actual conditions into a better agreement.

A clear visualization of these conditions will make possible the determination of the degree of refinement in the theoretical design that is practical and reasonable. There is a widespread belief that better designs are obtained if the conventional theories are applied and extended to cover a number of possible secondary influences.

Considerable time may be spent and very elaborate theoretical values obtained, which may represent a very refined extension of the conventional theories, but in most cases such efforts do not disclose the behavior of the actual structure that is not subjected to idealized loadings and is not made of an idealized material.

The conventional theories being only an approximation, the further extension of such approximate theories will result, in many cases, in larger discrepancies between the evaluated and actual behavior of the structure. More refined designs will involve additional engineering work, and it is desirable at least to indicate the methods by use of which the additional time invested in a design will bring returns in assuring a closer agreement between the evaluated and actual conditions. This purpose may be stated as the designing of structures in which the evaluated and the actual safety factors are identical.

The paper records an attempt to outline broadly the factors that should be taken into account. In the following papers of the Symposium some of the points mentioned in this paper are developed more authoritatively and in more detail. It is believed that at present the developments are too fluid to be stated in terms of definite rules and recommendations, although there is a possibility that the static conditions of the past will not return for many years. In that event, the structural engineer must change his attitude in line with that of the more advanced branches of engineering.

TESTS OF ENGINEERING STRUCTURES AND THEIR MODELS

BY R. L. TEMPLIN[4], M. AM. SOC. C. E.

SYNOPSIS

The scope of this paper is limited to tests of structural members, involving the determination of deflections, stresses, and general behavior under given loads, of engineering structures and their models. Following mention of the purposes and types of the tests made, is a discussion of the details of the methods used. Consideration is given to similarity conditions, model materials, testing apparatus, and testing technique. Reference is made to specific examples of tests of actual structures, and of small-sized and over-sized models. The results from an over-sized model example are given, illustrating the various purposes mentioned.

From consideration of the factors affecting structural tests of engineering structures and their models, and the results obtained from such tests, it is concluded that the purposes enumerated can be fulfilled if proper consideration is given to actual departures from strict similarity conditions.

TYPES OF ENGINEERING STRUCTURES AND TESTS TO BE CONSIDERED

Within recent years there is evidence of an increase in the number of engineering structures that are tested, either during or after construction, or both, under definitely imposed conditions of loading. Although these tests have been made with some differences in purpose, in general, they have been conducted with the intention of checking the design assumptions, postulates, and calculations. Examples of such tests may be found in the publications of the Society, particularly in the *Transactions* for the past seventeen years (1919–1936). Tests of the kind referred to, frequently afford a very satisfactory accelerated method for revealing the adequacy or inadequacy of the structures in lieu of the more generally used tests of time and service.

The types of structures that may be tested include essentially all those made of engineering materials with apparently no serious limitations being imposed by size, use, or location. The scope of this paper, however, will be restricted to structural tests involving determination of deflections, stresses, and general behavior under given loads.

The designs of most modern engineering structures are based on: (1) Some given over-all dimensions; (2) certain physical properties of the materials involved; (3) assumed conditions of loading; (4) analyses of stresses, deflections, and stability; (5) empirical rules; (6) "engineering judgment" with

[4] Chf. Engr. of Tests, Aluminum Co. of America, New Kensington, Pa.

"suitable" allowances for safety; and usually with (7) consideration of the economics involved.

When an engineering structure performs the expected duties throughout or beyond its estimated life, it is generally considered a successful engineering project. Most engineering structures have successfully fulfilled their designers' intentions, but this does not mean, necessarily, that the actual behavior of the structures under service conditions, or the magnitude of the stresses throughout the various parts of the structures, have been in close agreement with the assumed or calculated values. Although many engineers are familiar with the assumptions involved in the design of a given structure, there seems to be a lack of data to show quantitatively the discrepancies between the actual behavior either of the structure as a whole or of its various parts and the predetermined theoretical values. The quantitative effects of the errors involved in the usual assumptions made concerning isotropy and homogeneity of materials, Hooke's law, continuity, and fixity are often difficult to evaluate.

In order that a better understanding of these factors, as well as of many other factors involved in the behavior of some engineering structures, either under arbitrarily imposed or actual service conditions, may be had, tests have been made on actual structures or on their models. In the majority of cases the results obtained from such tests have indicated quite definitely that this field of endeavor might be considerably enlarged with consequent advantages to all concerned Among the various advantages that might be anticipated, would be more efficient, safer, and, probably, more economical structures.

Purpose of Tests.—Tests of actual structures are usually made for any or all of the following purposes: (1) Checking the analysis against the actual behavior of the structure under known load conditions; (2) checking the actual behavior of the structure under service conditions; (3) providing data to be used as a basis for changes in design rules; and (4) checking the efficacy of any alterations made in an existing structure.

Tests of models of engineering structures may be made for any or all of the following purposes: (5) To check analysis by actual measurement of the behavior of the model under known load conditions; (6) to provide data to be used as a basis for changes in design rules; (7) to check the efficacy of any proposed alterations in a given construction; (8) to supplement theoretical analysis by experimental analysis; (9) to avoid theoretical analysis by experimental analysis; (10) to provide an easier, quicker, and usually a less expensive means of obtaining the desired information, than would be the case if the actual structure were tested; and (11) to provide a means for studying the behavior of a design under loading conditions not possible with a full-sized structure.

Types of Tests.—Types of mechanical tests which may be conducted with the foregoing purposes in mind, may be subdivided into two general classes: (*a*) Static; and (*b*) dynamic.

Under static tests may be included the determination of strains (and, from these, stresses) and deflections, at critical points or throughout the structure, resulting from known conditions of loading.

Dynamic tests include those involving the measurement of strains (and, hence, stresses) and deflections resulting from the impact of moving loads, as well as the determination of the natural vibration frequencies of various parts of the structure, or of the structure as a whole.

In both types of tests it should be emphasized that the stress and deflection values obtained, represent changes resulting from the conditions imposed, and although corrected for "no-load" or "dead-load" or "at-rest" conditions, should not be designated as "true" or "absolute" stress or deflection. Even a limited understanding of the strains induced in materials, especially metals, during production, and in the actual structure by fabrication and erection, would mitigate seriously against the use of such appellations unless heterodox definitions of their meaning are to be accepted.

Test Methods

Size of Models and Materials Required.—Considerable discussion has appeared in technical literature concerning the laws of similarity to be followed when using models to analyze the behavior of engineering structures. The papers by B. F. Groat[5], M. Am. Soc. C. E., and the discussions pertaining to them, have emphasized the theoretical requirements for models which are intended to comply with strict similarity conditions. In these same discussions it has been shown that one may make some departures from the ideal conditions and yet obtain worth while results. The writer is quite in agreement with the latter idea after a number of years of experience in the use of models to assist in analyzing engineering structures. Although it is recognized that extensive tests of actual-sized structures are preferable in many instances, for obvious reasons, they are often impracticable and, in some instances, impossible. Supplementary partial tests on actual structures frequently afford a satisfactory final check on both theoretical and experimental analytical studies, as, for example, those made on the towers of the George Washington Bridge[6].

Models of engineering structures are generally thought of as being smaller than their prototypes. This need not always be the case, however. In some instances over-sized models can be, and have been, used to advantage. An example of tests on an over-sized model will be cited subsequently. Irrespective of whether the model size chosen is larger or smaller than the prototype, conditions of testing, in most cases, can be controlled to better advantage than in the case of tests of actual structures.

Models Made of the Same Material as the Prototype.—As indicated by Mr. Groat[5] an engineering model should be one which is scaled down, or up, in such a way that the dimensional and time requirements explained in his paper are fulfilled. These are theoretically ideal conditions which are very difficult to comply with in actual practice. Consider, for instance, a model of a truss in which structural members are fastened together by means of

[5] "Ice Diversion, Hydraulic Models, and Hydraulic Similarity", *Transactions* Am. Soc. C. E., Vol. LXXXII (1918), p. 1138, and "Theory of Similarity and Models", *Loc. cit.*, Vol. 96 (1932), p. 273.

[6] *Transactions*, Am. Soc. C. E., Vol. 97 (1933), p. 181.

gusset-plates. If the model is a photographic reproduction of the prototype, the cross-sectional areas of all the members will be changed in the proportion of the square of the scale ratio, but the moments of inertia of the members will be changed in a different proportion. The stiffness factors of the members—that is, the moment-of-inertia-to-length ratios of the various members—however, will be changed to still another scale. The stiffness of the gusset-plates will be changed to a scale different from that of the cross-sectional areas. Consequently, when the various members are considered individually, the degree of end restraint will not be the same as in the prototype, and the behavior of the various members of the model, under combined axial loads and bending, will be different from that of the corresponding members of the prototype.

In the laboratories of the Aluminum Company of America, at New Kensington, Pa., the procedure of testing models of structures has been to consider the model itself as a structure and to make a combined analytical and experimental study of it as such, to determine its behavior under various types of loading. By so doing, all the factors introduced are treated automatically in the light of their proper magnitude, so that when the prototype is being studied, the various elements entering into the behavior of the structure are not considered by simply applying a scale factor to the results of the model tests, but the various factors and considerations are included in a detailed analysis. In joining various members to make an assembled structure, it is impossible to reproduce, in a small or in a large model, the same conditions that are normally obtained in the actual construction of its prototype. Therefore, the effect of connections cannot be determined reliably from small or large models unless all the factors entering into the determination are known. This is especially true in connection with loads which normally will produce fairly high stresses in the prototype and may cause a local yielding of the material, whereas, in a small model of the structure, in which the stresses are scaled down automatically, this local yielding does not occur.

In many models which depend for load upon their own dead weight, or on the weight contained within them, it follows inevitably that if a direct scale reproduction of the prototype is made, the resultant stresses in the various parts of the model structure will be changed also, to the same scale ratio. This procedure makes any measure of strength obtained from models of this type very ineffective, unless analytical work involving all the variable factors is carried on and used as a basis for interpreting test data.

In many structures the ultimate safe load that can be supported depends upon the stability of the structure as a whole, or of some of its parts. In general, the stress at which a particular member becomes unstable, is a function of the proportions of its parts; as, for instance, the stress at which a thin outstanding plate buckles is directly proportional to the modulus times the square of the ratio of thickness to the outstanding width. Thus, the stress at which an outstanding flange would become unstable would be the same for a prototype or a model, with the result that if the stresses in the model are changed as the scale ratio, a false sense of stability is obtained.

Models Made of Materials Different from Those of the Prototype.—It may be desirable to make models of an engineering structure from a material different from that of the prototype, so as to:

(1) Correct for the stresses that actually occur in the model; that is, the ultimate strength of the material for the model should be changed to the same proportion of the actual stress under test as the ultimate strength of the prototype bears to its actual stress in service.

(2) Correct for the stability; that is, to have a material with a modulus sufficiently low, so that the stress at which the various component parts will become unstable bears the same relationship to the stresses in the model, as the stress at which the prototype becomes unstable bears to the actual stresses in it.

(3) Correct for the different relative distribution of direct stresses, bending, and shear, by having either auxiliary loads or a composite model made up of two materials so that resistance to shear and bending of the model will be the same as that in the prototype.

(4) Correct for the relative proportion of dead and live weight in the model and in the prototype. In this event the specific gravity of the model should be comparable to the specific gravity of the prototype.

(5) Provide the same distribution of stress in two-dimensional or three-dimensional models. This requires the Poisson ratios for the materials in the model and the prototype to be equal.

In order to interpret model studies, Factors (1) to (5) must be considered in connection with the theoretical similarity studies indicated in Mr. Groat's papers previously cited, because, if any one of the conditions enumerated is violated, it may be that a direct comparison cannot be made between the model and the structure. Since it is practically impossible to fulfill all these conditions simultaneously, it becomes necessary to supplement model studies with adequate theoretical analyses in order to take into account the effects of the various factors.

In selecting the size of model to be used, consideration should be given to the size of the testing apparatus available and the magnitude of the strains and deformations to be measured. Even if specially designed apparatus must be used, for any given tests, limitations will be imposed, which must be recognized if the desired results are anticipated.

Testing Apparatus.—In the testing of actual structures or models it is customary to apply either static or dynamic loads, or both. In the case of static loads applied to actual structures, dead weight of one form or another is frequently used. Almost any form of available material, of suitable density, may be used for such loading, but care should always be taken to insure that the load is applied to the structure in as close agreement as possible with the assumed conditions of application, or in accordance with service conditions (preferably both), if close agreement between calculated and actual values is anticipated. The method sometimes used for loading both actual structures and models, is a cause of a considerable number of the discrepancies observed. There are numerous methods, other than dead

weight, for applying loads to the structure being tested; for example, calibrated hydraulic jacks or springs can often be used to advantage. In the case of laboratory tests, some arrangement such as that used in the Materials Testing Laboratory of the University of Illinois[7] is worthy of comment. A part ($23\frac{1}{2}$ ft by 120 ft), of the concrete floor of the laboratory is heavily reinforced and provided with suitable inserts at regular intervals, into which may be screwed tension bolts that furnish the necessary reactions for any structure to be tested. When the structure is restrained by this method it may be loaded with dead weights and levers, or hydraulic jacks or springs with load-indicating devices.

When the structure to be tested can be put in a testing machine, the loading problems are usually very much simplified, although under such condition restraints may be applied to the structure under test, that are not in strict accordance with the assumed or desired loading conditions. The torsional and bending resistances offered by testing machines in the test of columns, using any type of heads except those substantially free from friction, is an example. The spherical heads usually provided with commercial testing machines are not substantially free from friction while under load. Furthermore, considerable lateral restraint is imparted to beams by testing machines when using the testing procedure generally followed, and this lateral restraint may appreciably affect the test values obtained.

Changes in the strains occurring in the various parts of a structure may be determined by using any one or more of a variety of strain-gages. Although a number of such instruments of different sizes and types are available commercially, special designs are evolved, occasionally, to meet particular requirements. The types used may be classified as mechanical, electrical, optical, acoustical, or some combination of the four. Some of the instruments are intended to be applied manually to the structure while making an observation, and then removed. Others are attached permanently for the duration of the test. Both indicating and recording (intermittent and continuous) types are available. Some can be read locally only, whereas others permit of distant observation.

The instruments to be selected for field use, in most instances, should be more rugged than those which may be used in the laboratory. Increased ruggedness of design, unfortunately is frequently accomplished at a sacrifice of sensitivity or accuracy, or both. Temperature effects are often negligible under laboratory conditions of test, but must be considered carefully in the field; thus, certain parts of the better field types of strain-gages are made of invar. Even so, such types of instruments should be checked with suitable standard bars to correct for residual temperature effects as well as for incidental maladjustments. An example of the consideration which should be given to a selection of strain-gages may be found in the report of the Committee on Arch Dam Investigation[8].

[7] Described in pamphlet issued by Univ. of Illinois for distribution at the dedication of the Laboratory, May 2, 1930.

[8] *Proceedings*, Am. Soc. C. E., Vol. LIV, Pt. 3, May, 1928, p. 64.

Regardless of the type of strain-gages selected, considerable attention should be given to the details of the methods of applying the instruments to the gage lines, throughout which the changes in strain are to be measured. For those strain-gages which require holes at the ends of the gage length, variations in the size and condition of the edges of the holes used affect both the accuracy and the sensitivity of certain instruments more than others, depending on the mechanical design of the instrument. When clamps or machine screws are used for attaching the instruments, appreciable errors may occur because of an indeterminate degree of restraint in the apparatus. The method of attachment sometimes used with some types of tensometers, or strain-gages, are examples.

The sensitivity, accuracy, and total range of available strain-gages vary appreciably, and, therefore, deserve careful consideration from the viewpoint of what is desired in any given test. Just because a strain-gage is sensitive to $\pm$ 0.00001 in. per in., it should not be inferred that the instrument is accurate to the same degree. Quite frequently the limit of accuracy will be found to range from three to thirty times this value. The total range of an instrument may become a limiting factor when attempting to measure large strains. Some of the instruments, notably those of the optical type, have very limited total ranges or give values for large deformations which may include appreciable errors that would be negligible in the case of small deformations. There are a number of other details which should be given consideration in the application of strain-gages to a structure, which will be dependent on the particular instrument used, as well as on the test conditions. Only a few of the more important factors involved have been mentioned, for the purpose of emphasizing the need for attention to such details if the best results are desired.

Measurements of the deflections of structures, or of their component parts, require first a definition of the desired quantities with respect to some given datum planes or bench-marks. Under test conditions, the reference planes or marks should remain fixed or, if they do move, both the magnitude and direction of such movement should be known. Deflections of a beam, for example, are best determined by reference to points on the neutral axis directly over the centers of the supports, and deflections of a pin-connected truss by reference to centers of the end pins at the supports. Deflections of a concrete arch dam, however, might be construed as including deflections of the arch proper, the movement of abutments and of that part of the canyon affected by the load on the structure, with reference to fixed points beyond the influence of the structure and its load. There are excellent opportunities for both confusion and errors, in attempting to interpret given deflection values for structures, where there is evidence of lack of appreciation of the requirements for proper reference planes or points

The instruments for deflection measurements are so varied in character and type as to preclude any discussion other than mere mention of a few of those more commonly used: Scales, micrometer screws, dial-gages, tapes, plumb-lines, levels, theodolites, and combinations of some of these devices. Likewise, their sensitivity and accuracy vary over wide ranges. It will

suffice for the purposes of this paper, to emphasize the necessity for selecting suitable deflection-measuring apparatus with regard to the character of the values to be determined and the desired accuracy, rather than let the choice depend entirely on availability of equipment. Deflection measurements, when properly made and correlated with known loading conditions, may, and generally do, give reliable data on the behavior of a structure and serve as a valuable check on the theoretical or experimental analysis.

All the measuring devices used in testing structures should be calibrated by comparison with acceptable standards, preferably those furnished by the National Bureau of Standards, U. S. Department of Commerce, Washington, D. C. Many types of measuring instruments, such as strain-gages, change with use because of wear in the moving parts or accidental misuse. In such instances, additional calibrations should be made at intervals, depending on the specific instrument and the usage it has received. Calibration devices suitable for checking load, strain, and deflection-measuring apparatus, are available, and can be certified as to accuracy by the Bureau of Standards, and then used by any one possessing them, for calibrating the instruments for which they are suited. The degree of accuracy of measurements, suggested by so much attention to calibration of apparatus, may not be in harmony with some of the tests of structures heretofore made; but in conformance with the idea of attempting to enhance, materially, the value of experimental analyses of structures, it is believed that more attention should be given to details of calibration of the instruments used.

Testing Technique.—In the testing of structures, the errors arising from the personal equations involved in the manipulation of the instruments used, must be considered, in addition to those already mentioned. The magnitudes of these errors usually become less, at a diminishing rate, as the experience of the observer increases. Some data exemplifying the magnitude of the personal errors, involved in strain-gage measurements, are shown in Fig. 12. The ordinates of these curves represent the differences in the lengths of the gage lines determined from two readings, and the abscissas represent the percentage of the total number of gage lines on which differences in readings did not exceed values indicated by ordinates. The data were selected at random from a large mass of similar data available. Fig. 12(*a*) shows a comparison of data obtained by two different observers using the same 2-in. strain-gage, on gage lines located on horizontal, vertical, and oblique surfaces. The data shown represent measurements on 536 gage lines by Observer *A* and on 569 gage lines by Observer *B*. In Fig. 12(*b*), the group of readings by Observer *B* has been broken down with respect to position in order to show how that factor affects the personal equation involved. Fig. 12(*c*) shows a comparison of results obtained by two different observers, one using a 2-in. strain-gage and the other a 10-in. strain-gage of a different type. The data given are from measurements taken on 1 050 gage lines by Observer *C* and on 310 gage lines by Observer *D*.

Observed values obtained during the tests of structures, must be corrected frequently or adjusted to compensate for changes occurring in the test conditions, such as rise or fall in temperature. Just how to make corrections

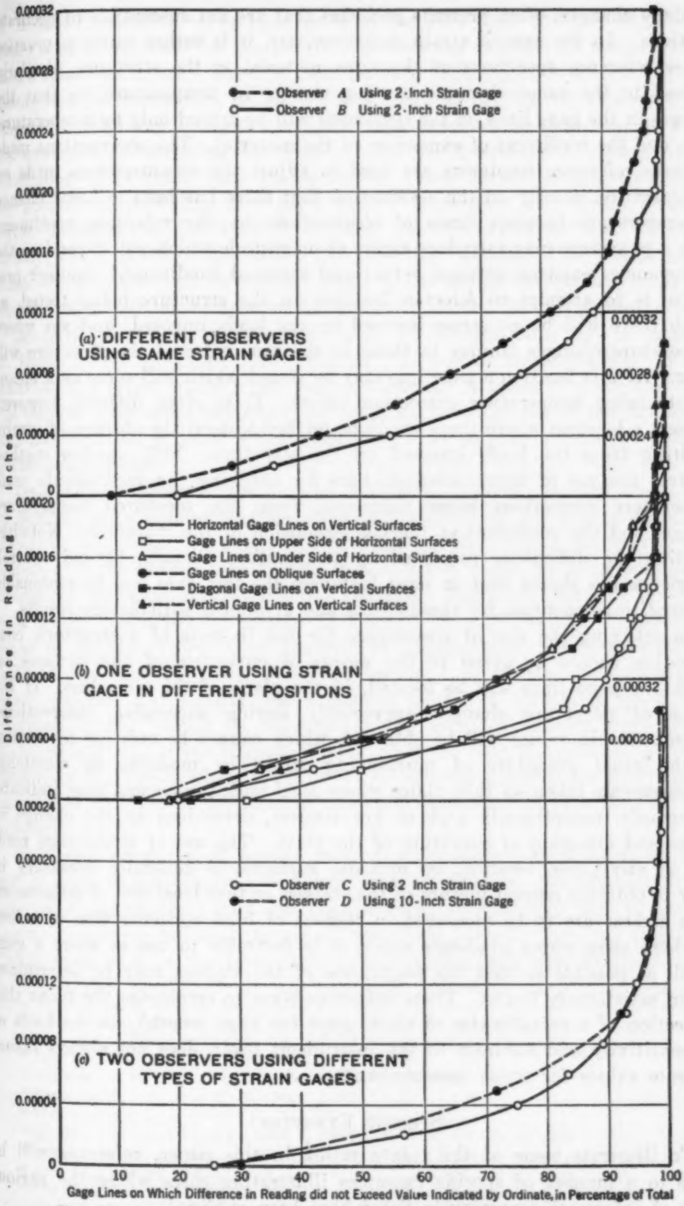

FIG. 12.—MAGNITUDE OF PERSONAL ERRORS INVOLVED IN STRAIN-GAGE MEASUREMENTS.

for these changes, often presents problems that are not susceptible of accurate solutions. In the case of strain measurements, it is rather common practice to use reference specimens of the same material as the structure, similarly exposed to the same elements causing change in temperature, so that the changes in the gage lines on the specimens will be caused only by temperature, time, and the coefficient of expansion of the material. The observations made on these reference specimens are used to adjust the measurements made on the structure, usually on the assumption that there has been a linear change in temperature between times of observations on the reference specimens. Such a procedure may introduce errors of magnitude which will depend on the discrepancies existing between actual and assumed conditions. Another procedure is to attempt to select a location on the structure being tested, at which there will be no stress induced by the loads imposed, and yet where temperature changes similar to those in the remainder of the structure will occur. At this location a gage line may be placed which will serve as a means for obtaining temperature correction values. It is often difficult, however, to select a location where there would be no doubt about the absence of strain, resulting from the loads imposed on the structure. Still another method involves the use of invar reference bars for checking the instruments used, temperature corrections being calculated from the measured temperature changes and the coefficient of thermal expansion of the materials. Notwithstanding the difficulties presented by temperature changes beyond control, experience has shown that in most instances the test data can be reasonably adjusted to compensate for these effects and give quite satisfactory results.

In selecting the size of strain-gage for use in tests of a structure, consideration should be given to the radius of curvature of the surfaces on which the gage lines will be located, in the plane of the gage line. If the radius of curvature changes appreciably during successive observations, apparent strain values will be obtained, which cannot be reduced to stresses by the usual procedure of multiplying strain by modulus of elasticity. Measurements taken on thin plates where local buckling occurs, may indicate, erroneously, exceptionally high or low stresses, depending on the change in radius and direction of curvature of the plate. The use of strain-gage readings at any given location, on opposite surfaces, is generally necessary in order to obtain a correct picture of the stresses at that location. Furthermore, when strains are to be measured in regions of high concentration of stress, or where steep stress gradients occur, it is desirable to use as short a gage length as possible so that the magnitude of the stresses may be determined within satisfactory limits. These instances serve to emphasize the point that a selection of a suitable size of strain-gage (or gage length), on the basis of the sensitivity and accuracy of the instrument itself, does not always insure accurate values for stress measurements.

Specific Examples

To illustrate some of the points raised in this paper, reference will be made to a number of specific examples illustrating cases where the various types of information previously listed have been obtained.

Actual Structures.—The tests made on the Hell Gate Bridge[9] comprise an example of those made for the purpose of checking analysis by measurements on the actual structure. The field tests referred to in the reports of the Special Committee on Stresses in Railroad Track[10] and of the Special Committee on Impact in Highway Bridges[11]; and the tests made on steel railway bridges[12] are examples of checking the actual behavior of structures under service conditions. The tests made on Stevenson Creek Dam[13] were instituted for the purpose of providing new experimental knowledge that would assist in better design rules for such structures. Extensive strain and deflection measurements, made on the Santeetlah pipe line[14] afforded a very satisfactory check on the efficacy of alterations made in the design of stiffener rings and supports after partial collapse of the structure during its initial use.

Model Tests.—Tests made on the model of Boulder Dam[15] are an example of those made to check the analysis by actual measurements of the behavior of a model under given load conditions. A series of models of pipe-line designs were made in connection with the investigation of the Santeetlah pipe line[14] for the purpose of providing data to be used as a basis for changes in the design rules.

One of the purposes of the tests by Wilbur M. Wilson[16], M. Am. Soc. C. E., on multiple-span concrete arches with and without decks, was to check the efficacy of variations in a given type of construction. The model tests in connection with the George Washington Bridge towers[17], were made to supplement theoretical analysis by experimental analysis. The model tests of multiple-span arches conducted by George E. Beggs[18], M. Am. Soc. C. E., offered a means of avoiding theoretical analysis by experimental analysis. Substantially all the tests on model dams are examples of efforts made to provide easier, quicker, and usually less expensive means of obtaining the desired information than would be the case if the actual structures were tested. Model tests made for the purpose of predicting the behavior of a falling dam[19] afford a good example wherein the use of models was a means for studying the behavior of a design under loading conditions not possible with the full-sized structure.

Numerous examples of models made from materials different from those used in their prototypes, may be found upon reference to the technical literature. A single example only, has been selected to exemplify each of the five reasons for using different materials, previously cited. Because aluminum models were used in the tests made in connection with the investigation of the Santeetlah pipe line[14], it was necessary to correct for the stresses that

actually occurred in the model. The series of model tests conducted by H. E. Saunders and D. F. Windenburg for determining the strength of thin-walled structures[20] included corrections in the loads applied in order to give the same effective stability in the models as in the prototype. The model tests[21] by the late A. H. Beyer, M. Am. Soc. C. E., and Mr. A. G. Solakian, wherein photo-elastic methods were used to analyze stresses in composite materials, involved a choice of materials to correct for the different relative distributions of stresses, by using composite models of aluminum and bakelite. A special material was developed and used in the model tests of Calderwood Dam[22] for the purpose of correcting for the relative proportion of dead and live load weight in the model and in the prototype. The material used for a model of Boulder Dam[23] was selected, among other reasons, because it had a Poisson's ratio substantially the same as the concrete which would be used in the prototype.

Over-Sized Models Tests.—In each of the foregoing examples of model tests the size of the model was smaller than its prototype. In certain instances, however, more satisfactory results can be obtained by the use of over-sized models. The results from such experimental tests, made on what may be considered an over-sized model of a filleted, re-entrant, 90° corner, will be given as an example of such tests. The reason for using an over-sized model in this particular case was that with such device it was physically possible to obtain the stress distribution with available strain-measuring equipment, whereas, the usual full-sized re-entrant corners are so small as to make strain measurements quite difficult and unsatisfactory. Fig. 13 is a view showing the method used in testing a series of specimens cut from a plate $1\frac{1}{16}$ in. thick. The material used for these specimens was a high-strength aluminum alloy (17S-T)[24] plate (Young's modulus = 10 300 000 lb per sq in.; and the proportional limit = 20 000 lb per sq in.). The specimens were loaded in a testing machine having seven different capacity ranges, vary-

ing from 400 to 40 000 lb, but in this particular series of tests the range chosen was the lowest that would give the desired load. In all cases the load could be determined within ± 1 per cent. The machine was previously calibrated in accordance with Tentative Methods of Verification of Testing Machines of the American Society for Testing Materials[25].

Two tensometers, having 0.5-in. gage lengths and magnification ratios of 2000:1, were used to determine the strains. The instruments were placed in corresponding positions on opposite faces of the specimen, and the readings were averaged to take care of any variations that occurred throughout the thickness of the specimen. The magnitude of the load applied, in any instance, was that which would give a readily observable maximum strain value but was insufficient to distort the specimen permanently. To insure against permanent distortion and partly to provide measurements of the actual distortion under load, the distance from the line of action of the force to the center of the face of the fillet was measured in each test, using the taut wire shown in Fig. 13, and a suitable scale. In addition, the spread of the angle was measured by means of a 10-in. strain-gage, on a gage line parallel

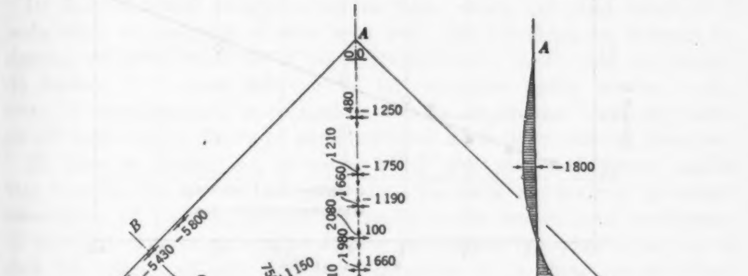

FIG. 14.—DISTRIBUTION AND MAGNITUDE OF STRESSES IN RE-ENTRANT 90-DEGREE ANGLE SPECIMEN HAVING 3-INCH RADIUS FILLET

to the direction of load application. The tensometers and the 10-in. strain-gages were previously calibrated, using a device described elsewhere[26], and found to be correct within ± 0.000015 in. per in.

Observations were made under no-load and full-load conditions throughout most of the tests. Special tests, however, were made for the purpose of

[25] *Proceedings*, A. S. T. M., Vol. 35, 1935, Pt. I, p. 1303.
[26] *Loc. cit.*, Vol. 28, 1928, Pt. II, p. 714.

demonstrating that the load-strain relationship on any given gage line, throughout the range of loads used, remained a linear one, thus making it necessary to determine two points only (no-load and full-load), to define the complete load and strain relationship at any point. The special tests also showed that the distortions of the specimens varied directly with the load.

Fig. 14 shows the magnitude and direction of the stresses obtained from one of the test runs made. The small arrows are on the locations of the various gage lines, with diverging arrow-heads indicating tension along the gage lines and converging arrow-heads indicating compression. Stresses, in pounds per square inch, along the gage lines, are indicated by the numbers directly adjacent to each line. The directions and magnitudes of the stresses at points away from the edges of the specimen were obtained by measuring strains on rosettes[27]. The magnitudes and directions of the stresses at such points were determined by the dyadic circle method.[27]

With these data available on a series of angles of different proportions, a stress concentration factor was determined, as shown in Fig. 15. This

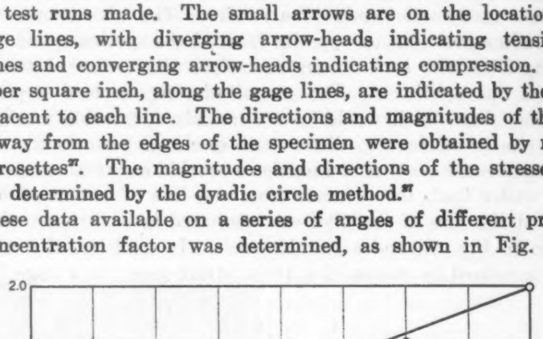

FIG. 15.

stress concentration factor, denoted by K, has been defined as the ratio of the actual measured maximum stress in the fillet, to a nominal stress which may be computed readily. This nominal stress, S_1, is that computed for the inner edge of one leg of the angle at its intersection with the other leg, assuming no fillet and no stress concentration. When values of K were plotted against the ratios of width of specimen to radius of fillet, $\left(\frac{b}{r}\right)$, a straight-line relationship was obtained from which it was found that for the specimens tested, the stress concentration factor could be expressed by the equation,

$$K = 0.5 + 0.37\left(\frac{b}{r}\right) \quad \text{.......................(1)}$$

For other loading conditions different stress concentration factors would be obtained.

[27] *Journal of Research*, National Bureau of Standards, Vol. 10, May, 1933, Paper No. 559, and Vol. 15, December, 1933, Paper RP851.

An experimental study of this same type of problem has been made by means of photo-elastic methods[28]. In this connection, it is interesting to note that with a slight modification of the procedure and technique of strain measurement on over-sized models, it would be possible to extend the stress concentration studies to the case of local bending in the outstanding legs of structural shapes, whereas the photo-elastic methods are definitely limited, at present, to studies in a single plane.

Over-sized model tests were also found very useful in evaluating the strains occurring in multi-stranded cables under conditions of vibration[29]. In this particular instance the experimental analysis was supplemented by theoretical analysis and the two correlated very closely indeed.

Conclusions

From a consideration of the factors affecting structural tests of engineering structures and their models and the results obtained in many instances, from such tests, it may be concluded that:

(1) Tests of actual structures can be made, which will yield satisfactory results when the purposes of such tests are: (*a*) Checking an analysis by observing the actual behavior of the structure under known load conditions; (*b*) checking the actual behavior of the structure under service conditions; (*c*) providing data to be used as a basis for changes in design rules; and (*d*) checking the efficacy of any alterations made in an existing structure.

(2) Tests of models can be made which will give satisfactory results when the purposes of the tests are: (*a*) To check an analysis by actual measurement of the behavior of the model under known load conditions; (*b*) to provide data to be used as a basis for changes in design rules; (*c*) to check the efficacy of any proposed alterations in a given construction; (*d*) to supplement theoretical analysis by experimental analysis; (*e*) to avoid theoretical analysis by resorting to experimental analysis; (*f*) to provide an easier, quicker, and usually less expensive means of obtaining the desired information, than would be the case if the actual structure were tested; and (*g*) to provide a means for studying the behavior of a design under loading conditions not possible with a full-sized structure.

In the case of tests of models the results mentioned in Conclusion (2) may be anticipated in most instances, provided the actual departures from strict similarity conditions are suitably taken into consideration when interpreting test observations

PHOTO-ELASTIC DETERMINATION OF STRESS

BY J. H. A. BRAHTZ,[30] ESQ.

SYNOPSIS

The purpose of this paper is to present an up-to-date picture of photo-elastic analysis, to discuss its applications and limitations, to show the relationship that it bears to other methods of stress investigations, and particularly to bring out the relationship that it should, and must, bear to the mechanical and structural designer and his problems. This is a timely subject, since the ever-growing acceptance of indeterminate structures, and the more expensive alloys makes it imperative to the designer that he avail himself of every possible means of refined stress analysis. Since this paper deals with the subject of photo-elasticity, there is naturally considerable space devoted to standard methods, model materials, and technique.

BRIEF HISTORY AND NATURE OF PHOTO-ELASTIC EXPERIMENTATION

Photo-elasticity had its inception more than a century ago, when Sir David Brewster, in 1816, demonstrated that plane-polarized light, on traversing a flat stressed transparent specimen, underwent some peculiar change in its optical properties, such that when viewed through another polarizing unit, colored bands appeared. These bands—isochromatic fringes—he assumed to be a measure of the internal strains. It is now known that these fringes are directly related to the state of stress in the model. The fringe order is, in fact, proportional to the maximum shears throughout the model without regard to their directions, which is equivalent to stating that these fringes (identified as Order 0, 1, 2, 3, etc.), are directly proportional to the difference of the principal stresses.

Just as engineers in the past have generally been slow in applying new mathematical tools, it was not until the beginning of the Twentieth Century that practical application was made of this physical phenomenon. An excellent treatise on this subject, covering a large number of recurrent practical problems, has been written by Messrs. E. G. Coker and L. N. G. Filon[31] who, following closely the pioneer work of Mr. S. P. Thompson[32], have advanced the art and science of photo-elasticity probably more than any other experimenters, and have co-ordinated their results with parallel mathematical analyses based on the mathematical theory of elasticity.

Theoretical Quantitative Limitations and Practical Qualitative Extensions of the Method

Undoubtedly there are a large number of engineers who are only slightly acquainted with the subject of photo-elasticity, some of whom have very little faith in it as a useful tool. Probably there are others, on the other hand, who believe that it is a scientific achievement representing the last word in stress analysis, and that any problem, regardless of its nature and difficulty, can be put through this seemingly magic process and the answer will appear for them in black and white on a photographic plate. These concepts represent the extremes, and a little clarification of some of its limitations might be in order so as to establish a clear idea of just what the method can do and what it cannot do.

First, the photo-elastic method is a two-dimensional analysis, and the scope of problems must come within the classification of either plane stress or plane strain. For example, a buttress in a dam of the Ambursen type, or the multiple arch, represents a case of plane stress, whereas an imaginary 1-ft slice taken from the center of a long gravity dam is a case of plane strain.

Being an experimental method, coming from the laboratory, the reliability of photo-elasticity analysis is affected by experimental errors and the personal element of the experimenter, the degree to which the operator simulates model conditions to those in the prototype, and the care with which he manipulates his apparatus, will govern the probable error of his results. It is not always a simple matter to simulate conditions directly, or to keep the probable error as low as, say, 10 per cent. For instance, the maximum fringe order may be only four. The experimenter cannot read the fringe order in a photograph closer than one-fourth of a fringe and he may be in error as much as one-half a fringe, which is equivalent to an error of 12.5 per cent. Naturally, this error will be reduced to a minimum when the model is constructed of a highly sensitive material and is loaded close to its elastic limit. Nevertheless, to obtain proper similarity of model to prototype, the physical properties of the model material must be considered carefully. For example, if certain types of experiment are being conducted to simulate a steel structure, the model material should have an elastic modulus that is constant below the yield point. Now, it so happens that the materials that fit this requirement best are not the most sensitive, and those that are extremely sensitive do not behave elastically in a manner similar to steel; therefore, a compromise must be made in choosing a model material that strikes a mean in satisfying the requirements.

Another difficulty is the uncertainty as to just what forces, reactions, and effects are acting on a structure. The same difficulties arise in a mathematical analysis, in which case unknowns are assumed. It would be nice if these factors were always known, but they are not; for example, consider the restraint of the fixed ends of a beam. The fixation is probably never perfect, and no one knows the exact conditions. Numerous examples of this kind can be cited, but they are too well known. However, although these are uncertain conditions, the photo-elastic method can nearly always simulate conditions with more accuracy than any arbitrary assumption.

Corresponding to this indeterminacy of many boundary conditions, there is the difficulty of applying the true loads to models even when they are known exactly. Generally speaking, a concentrated load is much easier to apply than a distributed load, and a uniformly distributed normal load is easier to apply than a uniformly varying normal load or a loading involving shear forces. Furthermore, straight boundaries are easier to load than curved boundaries. These are mechanical difficulties, and the technique is constantly being improved to overcome them. Some new developments along these lines are cited subsequently.

There are some possibilities of expanding the scope of the photo-elastic method in order to deal with certain three-dimensional or composite structures (that is, structures containing materials of varying elastic properties), at least qualitatively. Some progress has already been made along these lines. In this connection mention should be made of some experiments by the late A. H. Beyer, M. Am. Soc. C. E., and Mr. A. G. Solakian, in which they tested simple bakelite beams that contained integral cast-aluminum rods to simulate concrete with steel reinforcement[33].

An experiment has been conducted by Howard G. Smits, Jun. Am. Soc. C. E., in which he attempted to measure the shrinkage stresses in a model of a concrete dam by stretching the base[34]. Although there may be some doubt as to the strict legitimacy of this experiment in simulating shrinkage stresses, nevertheless, as he suggests, it emphasizes the necessity of developing a cement that can be used to combine models of different elastic properties. For instance, in this experiment, the base could be compressed, the dam glued to the base, and then the compression removed. Then tensile stresses would develop in the dam and corresponding compressive stresses in the base. Furthermore, if such a glue were developed, it would open an entire new field of possibilities, such as testing the stresses in a dam resting on a base that is either softer or more rigid than the dam itself; it would also permit the analysis of such problems as a hole in a plate, with a rim of thicker material at the edge of the hole.

Methods, Apparatus, and Model Materials

There is little variation in the optical apparatus used by experimenters in obtaining isochromatic pictures. Essentially, the instrument consists of a monochromatic light source, a nicol polarizing prism, a large lens or concave reflector to create a field of parallel rays in which to place the model, another lens or reflector to focus the rays on another nicol prism, or analyzer, and a camera with a ground-glass back. The reflector type has the advantage of requiring a comparatively smaller space; it produces a large field of parallel rays at relatively low cost, and allows the experimenter to view the ground glass and operate the loading mechanism simultaneously. It is of interest to note that the reflectors are coated with aluminum, in place of the less durable silver, deposited by the method developed by Dr. John Strong, of the

California Institute of Technology, at Pasadena, Calif., in connection with the 200-in. telescope[35].

In addition to giving the value of the difference of the principal stresses or maximum shear, at all points in a model, the polariscope (as it is commonly called) also readily adapts itself to giving the directions of principal stresses at all points, the observer utilizing the black isoclinic lines or lines of constant direction of principal stresses[36]. In many structures the only stresses that are required are those at the boundaries, more commonly referred to by engineers as the extreme fiber stresses. These stresses can be obtained directly from an isochromatic picture, if at a boundary the principal stress required is parallel to the surface, and the other is perpendicular to it; these boundary stresses are equal to zero if the structure is not loaded, or equal to the intensity of normal pressure when loaded normally. Since the normal stress and the magnitude of the difference given by the isochromatic picture are known, the extreme fiber stress is obtained in those cases either by adding or by subtracting the normal load from the measured difference of principal stresses. When the boundaries are loaded with inclined forces, the isoclinic lines must be used to evaluate the boundary stresses, but this is not difficult.

In order to use the photo-elastic method to determine the complete state of stress at interior points an auxiliary step is required in order to obtain the individual principal stresses. Since the difference of the principal stresses has already been found by means of the isochromatics, they could readily be separated by applying a little algebra at any point if one could, somehow, determine the sum of the principal stresses. This auxiliary step can be accomplished by several experimental methods. It is known that in a stressed model, the sum of the principal stresses is proportional to the change in thickness. This change is of an extremely small magnitude, but it can be measured. Coker has developed a very sensitive mechanical extensometer for this purpose, and R. W. Vose, Jun. Am. Soc. C. E., of the Massachusetts Institute of Technology, at Cambridge, Mass., has been successful in constructing a similar extensometer which measures the change in thickness by means of a small auxiliary interferometer[36], which is, of course, the most powerful method of measuring small dimensions. An interesting academic point in this connection is revealed by some experiments conducted by Professor M. M. Frocht, of the Carnegie Institute of Technology, at Pittsburgh, Pa., in which he constructed a test model from a plane-parallel optical flat, and used the two faces of the test pieces for an interferometer. In this manner he obtained interference fringes directly in the model, which again are a measure of the sum of the principal stresses. These bands he calls isopags or isopachic lines[37]. Experiments of this type require a knowledge of Young's elastic modulus and Poisson's ratio of the model material.

[36] "An Application of the Interferometer Strain-Gage in Photo-Elasticity", *Journal of Applied Mechanics*, A. S. M. E., September, 1935, pp. A-99, A-102.

[37] "On the Application of Interference Fringes to Stress Analysis", *Journal*, Franklin Inst., July, 1933, pp. 73–89.

A very practical method of obtaining the sum of the principal stresses is by means of the stretched rubber membrane (see Fig. 16)[illegible]. A horizontal rigid frame is constructed to the shape of the model and the vertical ordinates of the frame are proportional to the sum of the principal stresses of the boun-

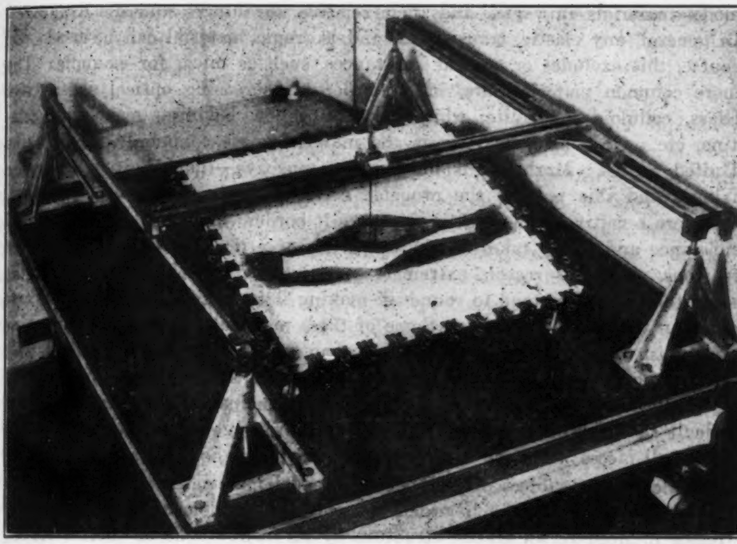

FIG. 16.—MEMBRANE PROFILOMETER (NOTE NEON GLOW LIGHT AND SWITCH IN BACKGROUND.)

daries, which are determined from the isochromatic photographs. A thin rubber sheet is then stretched uniformly over the frame forming a warped surface, every ordinate of which is proportional to the sum of the principal stresses, and these can be measured with an ordinary depth gage.

Although all these methods will accomplish the desired results in completing the photo-elastic analysis at interior points, it is obvious that they have their respective advantages and disadvantages. The two extensometers require a quantitative knowledge of the elastic constants of the model material and depend on very accurate manipulation to reduce experimental errors. Furthermore, only one point on the model can be examined for a given position of the extensometer and each reading requires loading and unloading of the model; with a complicated loading mechanism this involves considerable labor. The only real objection to obtaining the isopachic lines is the cost of constructing the model from a relatively large plane-parallel optical flat. Perhaps the fastest method is the rubber membrane or soap film, but it fails wherever the slopes of the membrane become excessive, and the method

[illegible] Description of membrane analogy, by J. P. Den Hartog, *Zeitschrift Ange. Math. und Mech.*, Vol. II, 1931, p. 156, and *Journal*, Franklin Inst., July, 1933, p. 5.

depends on very accurate determination of the fringe orders at the boundaries of the isochromatic photographs, which is often very difficult due to edge effects.

Having briefly reviewed the standard methods of obtaining stresses in a loaded transparent model, it is interesting, next, to consider the various model materials in vogue, and their relative advantages and disadvantages. In general, any elastic, transparent, and isotropic material can be used. Of course, this excludes crystalline substances, such as mica, for example. The more common materials are, in the order of increasing optical sensitivity: Glass, celluloid, phenolite, white bakelite, yellow bakelite, marblette, gelatine, etc. Of course, bakelite is the material most commonly used in the United States. Marblette is much more sensitive—that is, it yields more fringes and this reduces the probable error in reading stresses. However, the more sensitive a material is the more it borders upon being a semi-liquid substance and partly takes on the properties of a liquid, particularly surface tensions. For this reason, extremely sensitive materials age rapidly in the sense that the edges tend to round off making it impossible to read the fringe order on the very boundaries. Some of these materials are easier to machine and polish into awkward model shapes than others. Marblette and gelatine, for instance, can be cast. Glass, which is frequently used for obtaining the isoclinic lines that give the directions of principal stresses, is the most difficult to machine and has the added disadvantage of cracking or flying into small pieces while the experimenter is applying the loads.

While on the subject of methods and model materials, a brief digression into body forces might be in order, covering the problem of determining the stresses induced in an elastic structure by its own weight or inertia forces. Naturally these forces cannot be used throughout the model by direct application of exterior forces, but must be accomplished by some other means. None of the materials mentioned previously, with the exception of gelatine, is sensitive enough to produce isochromatics from their own weight with the size and thickness of models ordinarily used. However, gravity forces can be magnified if the model is set in a centrifuge and rotated at a high angular velocity. Some interesting studies using this method have been made by Messrs. Philip B. Bucky, A. G. Solakian, and L. S. Baldin, of Columbia University[39], and independently by Fred L. Plummer, M. Am. Soc. C. E.[40]. A more satisfactory method has been suggested by Dr. M. A. Biot[41], in which he applies certain force distributions to the boundaries of the model, obtains the corresponding stresses, and then superposes these stresses to another system of theoretical stresses obtained from a simple gravitational stress function. The net result is the determination of stresses in the model due to gravity alone. This method has been used at the Laboratory of the United States Bureau of Reclamation, in Denver, Colo., and applied to

[39] "Centrifugal Method of Model Testing", *Civil Engineering*, May, 1935, p. 287.

the gravity stresses in the Grand Coulee Dam. The results have been very gratifying and there is no doubt that this method is more practical than the centrifugal method.

There is another possibility of accomplishing this result by using thick gelatine models. A step in this direction has been made by R. R. Philippe, of the United States War Department, and Professor Plummer in connection with stresses in the foundations of earth dams[42].

From Model to Prototype

Without entering into too much detail, a brief explanation is included herein on the method of converting observed fringes into stresses in the structure. First, it is necessary to determine what the stresses are in the model. This is done with a simple test specimen cut from the same piece of stock as that from which the model is made. It is customary to make this test piece in the form of a simple beam subjected to pure bending, photograph it, and count the fringe order at the extreme fibers[43]. This same beam is analyzed mathematically and the stress computed at the same point. The stress is divided by the corresponding fringe order, resulting in the stress (the difference of principal stresses) in, say, pounds per square inch in the model per fringe. The two experiments of course, must be made under identical optical circumstances. Now, the law of similitude may be stated, as follows: The stresses in the model at all points will be to the stresses in the prototype at corresponding points as the normal boundary pressure on the model is to the normal boundary pressure at a corresponding point in the prototype.

Consider a simple example: A beam loaded uniformly with a pressure of 50 lb per sq in. on the edge. A bakelite model is constructed to any scale and loaded with, say, 5 lb per sq in., to obtain the isochromatic pattern. The material is calibrated and, perhaps, it is found that each fringe corresponds to a stress of 200 lb per sq in. in the model. Then, wherever there is a fringe order, 1, in the model, there will be a difference of principal stresses in the structure of 200 × 10 (the load factor), or 2 kips per sq in. If, for example, the fringe order at the center of the beam at the bottom fiber is Order 5, then the stress is 10 kips per sq in. in the prototype.

Comparison with Other Methods of Stress Measurements

It will be valuable to draw some comparisons between the photo-elastic method of stress analysis and two other experimental methods, namely, direct strain measurements on two-dimensional and three-dimensional models and the slab analogy. No mention will be made of the standard practice of testing models to failure, since this is in a class by itself, yielding no stresses, and is based on internal stresses beyond the yield point. In comparing the strain-measurement method with the photo-elastic method, several points should be mentioned. First, the strain-measurement method readily adapts

[42] "Soil Mechanics Applied to Design of Dams", *Civil Engineering*, January, 1936, p. 25; see, also, p. 9.

[43] See, for example, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1269, Fig. 9.

itself also to three-dimensional models even with varying elastic properties. Because of its adaptability into three dimensions, the method stands alone; it dominates this field completely, and is the only known experimental method suitable for analyzing such a structure as a thick arch dam. Necessarily, it is a tedious expensive method both in execution and evaluation and calls for great skill. It allows elastic relationships between model and prototype to be simulated very closely because of the wide latitude of available materials. Quite often the applied loads produce strains that are scarcely detectable in certain regions and in every case the stresses obtained can represent only average stresses in the segment between gage points. Photo-elasticity yields the stress at a point.

Another method of obtaining experimentally the stresses in a two-dimensional structure is by the "slab analogy." This method is well adapted to obtaining the stress distribution, for example, in a gravity dam. A flat elastic slab made of rubber, for instance, is cut to the dimensions of the structure and warped by displacing and twisting the boundaries. The curvatures and twists can then be measured at any point within the boundaries of the model, and it can be shown that these curvatures are always proportional to the normal stresses in the structure in a direction perpendicular to that at which the curvature was measured, and that the shear stresses are proportional to the twists in the slab. Naturally, the slab must be set up in such a manner that the twists and curvatures at the boundaries are equivalent to the forces acting on the boundaries. The basis of this experiment lies in the fact that the differential equation of a warped elastic slab has the same form as the differential equation of compatibility of the Airy stress function. This is another one of those analogies that are being adopted by the Engineering Profession, and is in the class with the soap film analogy used in measuring torsional resistance of odd shapes, such as propeller blades and built-up sections. Other well known members of this family are the electric analogy and the aforementioned rubber membrane analogy also used to measure temperatures in the steady state, pressures, and equi-potential lines in highly viscous hydraulic flow that recurs in soil problems[44].

It may be said of the slab analogy that it is an excellent and reliable method because of the directness of the results; but, like the strain-gage method, it is costly and tedious, requiring a well developed technique. In its present state of development it is justified only in analyzing an expensive major structure.

Returning now to the photo-elastic method and without attempting in any way to depreciate the importance and value of the other methods, it can be said of photo-elasticity that it is an inexpensive method of analyzing difficult structures or elements of machines, discounting, of course, the high initial investment in optical equipment. Furthermore, it is a rapid method, especially when one is interested only in extreme fiber stresses. Moreover, it supplies, immediately, a rough picture of stress distribution in a structure and reveals concentrations wherever fringes are grouped close together. To

[44] "The Flow Net and the Electric Analogy", by E. W. Lane, M. Am. Soc. C. E., F. B. Campbell, Jun. Am. Soc. C. E., and W. H. Price, *Civil Engineering*, October, 1934, p. 510.

emphasize these advantages further: Since the investigator immediately obtains a picture of the stress distribution in the model of a structure that is subject, say, to a number of different loading systems, he can, very rapidly, single out the critical cases. Furthermore, the shape of the model can be altered, reduced, or enlarged at weak points that are revealed in the photographs, and the process repeated. In other words, it furnishes a rapidly converging method of design, even when dealing with a structure that borders in the class which, off-hand, one might say is analyzed readily by the Begg's deformeter method, or the Cross method of moment distribution and column analogy. Naturally, the mathematical analysis should be made wherever possible, but now by photo-elasticity a good starting design and the critical loading are quite well isolated.

Practical Relation to Structural Problems

The true value that photo-elasticity must bear to structural and machine design is readily shown to those unfamiliar with the method by a few examples. It will be apparent that photo-elasticity has its own field, and completely dominates this field from a practical standpoint. Conversely, it is foolish to attempt to use it in those fields that are readily treated mathematically, such as standard beams, columns, tension members, etc., of lengths at least five or six times their lateral dimensions, except for academic purpose or as a check analysis. This includes all standard structural members. Where these ratios are shortened, where a structure is composed of short, thick, integral members, where it is otherwise complicated by holes, notches, reinforcements, etc.—in short, wherever it is obvious from the shape of the structure that it is indeterminate in the sense that the stress distribution is non-linear in character, and the principal stress trajectories assume a complicated curvilinear form—then the structural designer finds that his ordinary tools will not suffice and he must depend either upon his structural sense and previous experience, or perform a test to failure, or carry out a photo-elastic analysis. This type of problem is encountered continually in machine design. This does not mean that the photo-elastic method cannot, or should not, be extended to include fields susceptible to mathematical analysis for check or verification. As a matter of fact, the two overlap and, as has already been indicated, it is a rapid tool for finding critical loads and design sections for use in mathematical analyses. Furthermore, a check between the two goes a long way in removing that feeling of uncertainty which can hang like a nightmare over a designer who entertains a feeling, and rightly so, that perhaps he has made a few too many assumptions in dealing with a statically indeterminate problem without knowing whether or not they are on the side of safety.

Consider, for example, the subject of fillets, such as occur in elements of structures and machines. No one doubts their value, and yet an exact mathematical analysis would be extremely difficult. By testing a small bakelite model, however, a picture of the stress concentrations in the fillet can be obtained. It is possible also to see how they compare with stresses in the web, and the operator can begin with a large radius, cut back, and quickly

try any number. Photo-elastic investigations have shown that a spiral fillet in some cases is more efficient than a circular one[45].

As a second example, consider the problem of the chain link of the type with two holes machined from a flat plate (see Fig. 17 and Fig. 18). A photo-

FIG. 17.—ISOCHROMATIC VIEW OF BAKELITE CHAIN LINK.

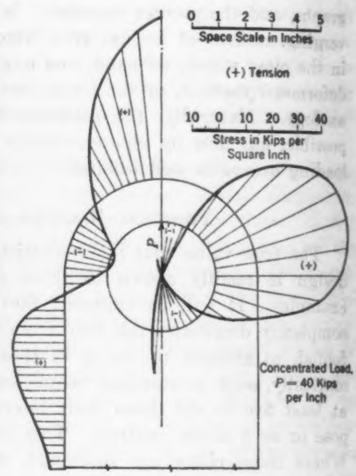

FIG. 18.—BOUNDARY STRESSES IN CHAIN LINK DERIVED FROM FIG. 17.

elastic analysis can readily be used to compare a wide variety of conditions, such as various pin clearances, different ratios of hole to width of link, and various shapes of links. In this type of problem only the boundary stresses are important, and the designer can soon choose an economical and safe shape.

Fig. 19 illustrates an example in which the photo-elastic and mathematical fields overlap. and this experiment was conducted to find critical loading conditions and to check the mathematical analyses made for the critical cases. In this experiment two new loading devices were used[46]. The water pressure in the tunnels was simulated by air pressure applied through rubber inner tubes, restrained on the sides but bearing directly on the walls of the tunnels. The earth pressures were applied through a thick rubber sheet that fitted snugly over the model, and the loads were applied to the outside edges of the rubber.

Other interesting applications of the method are apparent if one side of a bakelite test piece is silvered, and if the light is sent through to the silvered face and back along the same path. For example, a piece of bakelite may be

cemented on the surface of an actual structure, either two-dimensional or three-dimensional, and the changes observed in the induced isochromatics as the structure undergoes changes in loading; or the investigator may wish to

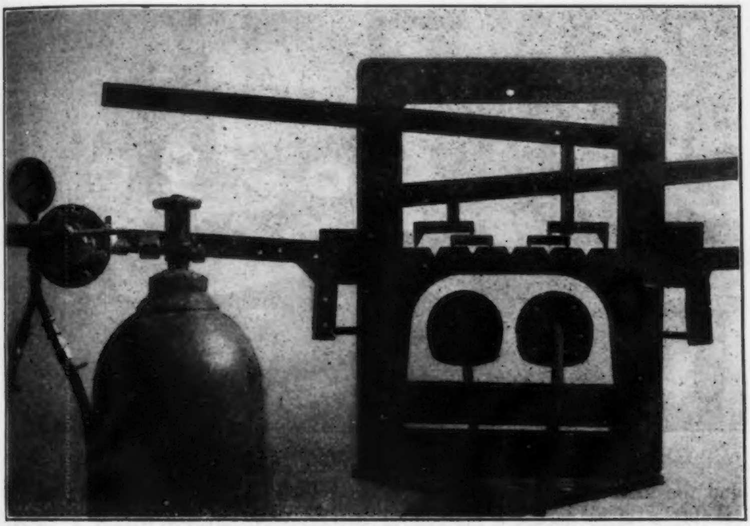

FIG. 19.—LOADING APPARATUS UTILIZED IN PHOTO-ELASTIC ANALYSIS OF DOUBLE-BARRELED CONDUIT FOR BULL LAKE DAM. (NOTE THAT PNEUMATIC PRESSURE IS USED TO SIMULATE INTERNAL HYDROSTATIC PRESSURE.)

measure the stresses in overlapping plates, such as occur in riveted connections. By silvering he can isolate the stress conditions in the two plates. Furthermore, he can study the behavior of viscous fluids under flow, by photographing the isochromatics that develop as ordinary salad oil is subjected to flow around obstacles set between parallel glass plates. Experiments of this type have been conducted successfully by Dr. Sadron, of the California Institute of Technology.

THE INTERFEROMETER

Before concluding, a word should be said about the interferometer as a means of measuring individual principal stresses in a transparent model directly, thus eliminating the necessity of the auxiliary step of finding the sum of the principal stresses. It has been known for some time that this method can be applied, but in so far as the writer is aware it has never been utilized in the United States. One of these instruments has been designed and built at the Laboratory of the Reclamation Bureau, by J. E. Soehrens, Jun. Am. Soc. C. E. (see Fig. 20). Essentially, the method consists of splitting a pencil of light, one part of which traverses a loaded model at a point, vibrating in the plane of one of the principal stresses, and the other goes around the model. The two pencils are brought together again and interfer-

ence fringes develop. The stress at the point in the model will be proportional to the relative displacement of these fringes as the load is applied. Next, the ray is made to vibrate in the plane of the other principal stress

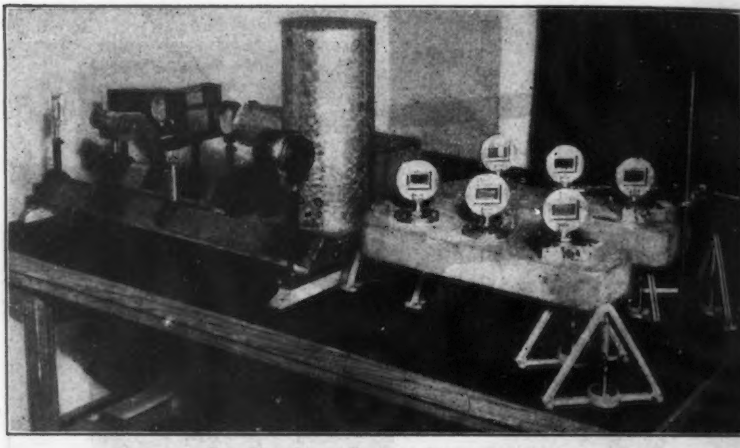

FIG. 20.—PHOTO-ELASTIC INTERFEROMETER.

and the measurements are repeated. It is believed that this apparatus will provide a more accurate method of determining stresses within a model; that is, stresses other than those at the boundaries particularly in cases in which the accuracy of a rubber membrane breaks down, as, for example, at a sharp corner or near the point of application of a load. This machine s much more delicate in its operation than the polariscope and must be designed in such a way that it is insensible to vibrations.

FUTURE POSSIBILITIES

At present, photo-elasticity has demonstrated its value and firmly established itself as an invaluable tool to the Engineering Profession. Its development has been somewhat erratic but positive, and has by no means reached its limit. New model materials and technique are being developed and will continue to be developed. The method is not a simple mechanical one, but a procedure that requires trained technicians. Some universities are now (1936) offering introductory courses in the subject to their undergraduates. As lighter, stronger, but more expensive, alloys assume their natural functions in construction, it will be more important than heretofore to have a complete knowledge of stresses. As these demands become more acute emphasis will be more and more toward photo-elasticity as a means of designing economical structures.

STRUCTURAL APPLICATION OF STEEL AND LIGHT-WEIGHT ALLOYS

A SYMPOSIUM

PAGE

II.—METALLURGICAL AND MANUFACTURING ASPECTS OF FERROUS AND LIGHT-WEIGHT ALLOYS OF INTEREST IN STRUCTURAL DESIGN AND FABRICATION:

LOW-ALLOY STRUCTURAL STEELS

BY E. C. BAIN,[47] ESQ., AND F. T. LLEWELLYN,[48] M. AM. SOC. C. E.

SYNOPSIS

In view of the fact that this Symposium is sponsored by a civil engineering society, the word, structural, in the title of this paper is to be construed as pointing with strong emphasis to framed static structures, such as bridges and buildings, almost to the exclusion of small moving structures and machinery. The other papers in Section II enumerate adequately the more restricted opportunities for over-all economy which are offered to the special high-strength steels in this restricted field of application. Information has been presented to show how the economical expenditure of the steel dollar may still call for the purchase of special steels that differ from common structural steel by having enhanced mechanical properties secured through the incorporation of alloying elements.

INTRODUCTION

In this inquiry, the writers begin with the assumption that the background of their subject has already been well drawn; that every one is aware that alloy steels may have a higher elastic range and a higher breaking load than the ordinary structural steels, but that the elastic modulus is the same. The consequences of these circumstances, as they affect design, are presented elsewhere in the Symposium, where the applications of those low-priced alloy steels are discussed. In this paper, the writers discuss the common alloying elements with respect to the direct and indirect influence their presence, both individually and concurrently, may have upon the properties of structural steels.

The writers first approached their task with a plan for a categorical enumeration or classification of the many so-called "grades" of low-alloy, structural steel that are now (1936) on the market, with their compositions and ordinary mechanical properties, as set forth by their makers. Since, however, such information has been given in a number of excellent compilations[49], the writers conclude that it may be more useful to treat the principles involved in designing alloy steels. Accordingly, two types of these steels have been chosen to illustrate these principles, and, as far as possible, the subject has been developed as a functional study. For convenience, however, a table of some of the current compositions offered to the trade and their reported mechanical properties is included.

[47] Asst. to Vice-Pres., U. S. Steel Corporation, New York, N. Y.
[48] Research Engr., U. S. Steel Corporation, New York, N. Y.
[49] See, for example, *Proceedings*, Am. Soc. C. E., March, 1936, p. 361.

Although it will be convenient for subsequent reference to compare alloy compositions with the regular structural steel, designated "carbon steel", it may be well to forestall a false premise at the start. The vast majority of the structures within the scope of the present consideration are built of a steel which is by no means the pure metal iron or an alloy of iron and carbon alone; structural carbon steels carry about 0.5% of manganese, one of the important alloying elements. An inspection of hundreds of analyses indicates a probable most frequent composition about as shown in Table 2. Steel of such composition, as rolled, for example, in sections 0.50 in. to 0.75 in. thick, develops mechanical properties such as correspond, on the average, to approximately the tensile test data indicated in this table.

TABLE 2.—COMPARISON OF ORDINARY STRUCTURAL CARBON STEEL WITH PURE IRON

Description (1)	Ordinary, structural carbon steel (2)	Pure iron* (3)
Composition, in Percentages:		
Carbon	0.22	....
Manganese	0.45	....
Sulfur	0.035	....
Phosphorus	0.018	....
Silicon	0.05 or 0.20	....
Ultimate strength, in kips per square inch	60	39
Yield point stress, in kips per square inch	38	19
Percentage elongation in 2 in	45	48
Percentage elongation in 8 in	28	30
Percentage reduction in area	58	75

* Commercial purity.

It is interesting to compare the properties of the usual structural carbon steel with those of nearly pure iron (that is, iron of commercial purity) as indicated by Column (3) of Table 2. It is clear that the ubiquity of carbon in the metallurgy of iron and the availability and use of manganese, primarily as a specific or antidote for possible sulfur ills, have resulted in a considerable gain in desirable properties. One needs no marshaling of metallographic theory to convince himself of the general efficacy of these elements incorporated in steel, but it may be worth while, nevertheless, to digress further into this field of physical metallurgy.

Before having a "look" into the effects of the common alloying elements, it may be advisable to view the problem of stronger steels from the purely economical standpoint, but still through the eyes of the metallurgical engineer.

ECONOMIC FUNDAMENTALS OF ALLOYS

Members of the Society need scarcely be reminded that economy is one of the essentials of good engineering. In considering the economic fundamentals of alloys, or indeed of any materials, it is desirable to emphasize three facts. They need only be stated to be self-evident:

(1) The question as to the economy of a designated material becomes critical only when there is a choice of materials.

(2) If, as a result of its improved properties, the net cost of a substituted material is less than that of the material replaced, there is no economic problem to be solved. Manifestly, despite its higher cost per ton, the material in question would be used everywhere as far as it is available.

(3) A given material may be economical under certain conditions, and uneconomical under others.

It follows that the desirability of alloying steel with certain chemical elements, calculated to produce higher effective strength than ordinary grades, will vary according to the problem in question.

Having in mind these facts, some engineers have surmised that a simple chart could be prepared in which the higher cost per pound of each alloying ingredient, as a commodity, could be translated into final cost per ton per unit of resultant alloying content, and plotted against the corresponding improvement in given physical properties. A chart of this kind would be just what the civil engineer is seeking, but, unfortunately, those who operate steel mills, as well as Dame Nature, say that the matter is not quite as simple as that. Even if effects could be charted against percentage of alloying elements, comparative costs would not be indicated for the reason that rolling-mill costs vary greatly according to the quantities of a kind to be produced at a given time.

Quite apart from mill-operating conditions, however, such a chart is not feasible. As demonstrated subsequently, even the effect of individual alloying elements is involved, to say the least, and is not constant under all conditions. In many cases it depends on the inter-relation of other elements. For this reason, instead of one chart, one would require about as many charts as there are different types of steel, and these charts would be useless as aids in forecasting the properties of a new combination.

Most important of all, it must be emphasized that the improvement in certain properties which is afforded by many of the alloying elements is accompanied by a loss in other desirable properties. If Dame Nature and the economic cartographer attempt to join in holy wedlock, with metallurgy as sole officiating priest, the union cannot be blessed because the progeny would be as numerous and unmanageable as that of the "old woman who lived in a shoe."

Interpretation of Specimen Tensile Tests

It is well to reflect that the ordinary tensile tests, accompanied perhaps by compression tests, supply the engineer with some numbers which are not measures, exactly, of the precise properties which will be depended upon in the final structure, but are instead merely rough indicators of the possession of the needed properties. By way of example, a notch in a beam becomes a stress concentrator under conditions of bending, and failure may occur in a manner developing less than the expected load. On the other hand, in a carefully conducted tensile test, a bar in tension having a sharp circumferential notch may carry, without permanent deformation, a load in excess of the ultimate stress as ordinarily measured. A plate may show 30% or 40% elongation in the standard tensile test; and yet, when subjected to simultaneous

tensional stresses at right angles, it may break with only a slight percentage of elongation as measured along any reasonable reference distance Nevertheless, the standard tensile test, interpreted in terms of experience, is a valuable guide and the writers would defend its general use.

The fact is that the gross loading as ultimately reflected in any small region of the metal may be considered as a force tending to rupture the metal, with a maximum in one certain direction, and a force tending to cause flow (that is, shear) likewise at a maximum, in another direction in a shearing plane. If the maximum shear component exceeds the elastic limit in shear and the metal has any capacity whatever for plastic flow, some deformation, without rupture, will occur. On the other hand, if the maximum disruptive component exceeds the fundamental tenacity or cohesion of the metal, a brittle break will occur. The former may occur first, followed by the latter, by virtue of a change either in the relative magnitude of the two components, or in the elastic limit in shear of the material during the deformation.

In an ideal tensile test in which a uni-axial tension is applied uniformly across the cross-section of a moderately long specimen, the numerical magnitude of the resulting disruptive stress is just twice that of the resulting shear stress. If, therefore, the elastic limit in shear of the specimen is more than one-half that of its cohesion, the tensile specimen will fail with a brittle rupture accompanied by no elongation; and yet, just such a material may possess considerable fundamental plasticity, as can well be shown by applying a torsion test, in which the resulting maximum disruptive stress is numerically equal to the maximum shear stress, on any small element in the highly stressed periphery of the specimen. Other tests, such as bending a notched bar, afford still less opportunity for any flow than does the tensile test, and one must conclude that the quality of realizable plasticity in a broad sense depends actually upon the ratio of the elastic limit in shear to the fundamental resistance to disruptive stress, for the second of which no known means of evaluation exists. This reasoning is introduced only to show that the tensile test supplies only a glimpse from one viewpoint of the mechanical properties of a steel. However, experience has demonstrated that good structures result from material with certain tensile test characteristics and may not result from others, and having no better practical test it is utilized with assurance as far as static loads are concerned.

With respect to structures as a whole, it is rare indeed that any general permanent deformation is tolerable, hence the interest really centers in the stress that can be borne within the elastic range of loading. For this reason increasing reference is made to the so-called "yield point" of the steel. Since the departure of the metal from strictly elastic behavior begins with almost undetectable gradations it is now customary to specify a very small but observable permanent elongation as a working definition of the elastic limit or yield strength; 0.1%, or 0.2% is usual and occasionally a proof stress corresponding to a permanent elongation of 0.01% is specified. The breaking load computed as a stress over the original section of the test has certain interest, to be sure, but of necessity plays a less important rôle in design than the yield strength.

The need for a degree of plasticity will not be detailed in this paper. The inescapable necessity for joints and the proper distribution of stress, otherwise highly localized and concentrated in and about such joints, can only be cared for by some capacity for flow. It is generally believed that 25% elongation in a test piece, 8 in. long, with certain cross-section limitations, is adequate. It should be added, however, that elongation should always be referred to a specimen which has a definite shape and ratio of length to cross-section; otherwise, comparative figures may be quite misleading. The reduction of cross-sectional area at the point of rupture is a factor of some complex significance not wholly clear even to the most erudite metallurgists and not of vital moment to the engineer.

It is not uncommon to measure the energy required to break a small, standard, notched bar by impact and to take this number of foot-pounds (or kilogram-meters) into account as a putative quality index of the steel. Considering that the most plastic and ductile metals known can be made to break in a brittle manner (low impact value) by introducing a sufficiently sharp and effective notch, and considering further the assiduous avoidance of notches in design, it might appear that such notched-bar impact tests would not yield broadly pertinent information. However, the steels under present consideration do not break in the brittle manner under the notches of customary sharpness at ordinary temperatures. If the break at very low temperatures should be brittle, and, therefore, should show low energy absorption (foot-pounds), the engineer should not reject the steel summarily, but instead, he should perhaps break a few specimens, at the same sub-zero temperature, which have been prepared with a more gentle notch and see that it is perhaps the notch, rather than the metal, which has been tested.

It happens that structures do not always bear a constant static load, but are subject to frequent loading and unloading, or even to reversal of load. Under such conditions a failure may occur, after a very large number of load-change cycles, at a specific stress lower than the yield point. Tests of the resistance to repeated stress effects (fatigue) have been devised, and the familiar "endurance limit" expresses this property usually as a maximum fully reversed stress which can be borne in a specimen during 10 000 000 cycles. For many materials this value is found to be well above 45% of the ultimate strength. However, when the stress changes do not entail reversal, but rather result from loadings and partial unloadings (surge loads), the endurance limit applicable approaches the yield point. It has been found that the character of the surface of the stressed member exerts a tremendous influence upon the practical fatigue resistance, and to make the tests represent, as nearly as possible, the metal itself rather than the surface condition, a polished test specimen is used. Accordingly, it would seem that for the civil engineer the yield point would be a more significant figure than the endurance limit, but that the endurance limit should be known and taken into account for the material under contemplation if stresses nearly or wholly reversed are to be encountered. Of probably greater significance is the possession of adequate plasticity, such as is measured, in part at least, by elongation and reduction of area in the tensile test.

In an exploratory manner, formability and other criteria of suitability may be judged by the data from conventional specimen tests, but it is to be expected that the final judgment will be based upon tests simulating operating conditions in practice.

The steels discussed in this paper were designed to retain adequate ductility and to provide an increment of yield strength. In practice, they have already achieved a remarkable degree of success. The design of machines (particularly automobiles) long ago opened up a need for steels that could first be endowed throughout large sections with the maximum properties previously securable by careful heat treatment upon only small sections of the higher carbon steels. Actually, it was soon evident that properties somewhat superior even to the best obtainable in small sections of carbon steel were securable in the alloy steels. This was comparatively easy because, by special heat treatment, tremendous improvements over the "as-rolled" properties are securable through the control of the microscopic structure; medium and high-carbon alloy steels with attendant high strength can be rendered tough and plastic as well.

The problem in the field of Civil Engineering is vastly more difficult. Not only is cost a serious deterrent from special heat treatment of structural steel, but the shapes themselves are scarcely amenable to the rapid cooling and reheating involved in such a method of enhancing properties. Since, in most cases, the steel perforce must be used in the as-rolled condition, and since the modern method of joining metals by the newer welding processes must be facilitated, the limitations are very strict. Not long ago it was a commonplace to hear in the metallurgical schools that alloying elements were of practically no value except where heat treatment was to be applied. The statement, never quite justifiable, is now known to be farther than ever from the truth, and to have accepted such a statement would have been to have missed the entire development under discussion in this paper.

Means of Strengthening Steel

For the purposes of this survey, there are only three means of gaining strength in steel: (1) Cold working the members; (2) specially heat treating the members; and (3) incorporating alloying elements.

Cold Working.—Bridge wire is an outstanding example of this application, and the high tensile strength of cables is known to every one. Recently, cold-rolled strip, particularly a certain stainless steel, characteristically amenable to improvement by cold-work, and to spot-welding also, is becoming a very valuable material in movable structures, such as high-speed trains. One can scarcely visualize the extensive cold drafting of standard structural shapes.

Heat Treatment.—To the metallurgist, who realizes that the microscopic structure, and, hence, the properties of steel, depends upon the cooling schedule from an elevated temperature, the cooling of structural steel from the rolling temperature is, in itself, a heat treatment. Although this is proper, heat treatment, in current usage, generally means a subsequent controlled heating and cooling. Thus, for years (since 1914), heat-treated, carbon-steel, eye-bars

have been utilized in bridges, and more than 17 000 of them are now (1936) in place. A 0.35% carbon, 0.60% manganese steel is used, having properties as rolled corresponding to a yield point of about 40 kips per sq in. and an ultimate strength of about 70 kips per sq in.; the ductility of the untreated steel is approximately represented by an elongation, in an 8-in. by 0.5-in. specimen, of about 23 per cent. After the closely controlled heat treatment of the eye-bar, properties are developed corresponding to an average yield point of 57 kips per sq in. and an ultimate strength of 88 kips per sq in. A full-sized tensile test bar with a cross-section, 12 in. by 2 in., and 18 ft long, exhibits a ductility so great that, in the full 18-ft test length, an elongation of nearly 2 ft occurs (10.5%), or in the 1 ft encompassing the point of rupture, 30%; the reduction of area is 46 per cent. A higher carbon steel containing 0.60% carbon, with 0.55% to 0.75% of manganese, is similarly heat-treated to an ultimate strength of about 119 kips per sq in. and a yield point of 82 kips per sq in. The elongation in 18 ft is about 8%, with a reduction of area of 23 per cent.

With such uniform regular sections as eye-bars, heat treatment has proved entirely practicable and economical, but for the usual shapes it is probably not "in the picture" at present; nor is it likely to become so for large welded structures, since any improvement derived from heat treatment would be nullified in and near the weld.

Use of Alloying Elements.—Turning next to the third and most readily applicable means of securing a general purpose steel, with a moderate increase in load-carrying capacity, it is to be noted that the metallurgist has at his disposal the elements—carbon, manganese, silicon, copper, phosphorus, chromium, nickel, vanadium and molybdenum—as well as some other less common elements, as possible addition agents in a structural steel. As far as small increments of equal weight are concerned, the elements are arranged about in the order of their cost, beginning with the cheapest. One should not be led to believe, however, that the order of merit is the same; nor, indeed, is there any basis available for any order of merit whatever unless one single property is under consideration at a time, and unless the proportions of the other elements are held entirely constant for the comparison. If one were to begin with commercial steel of the lowest carbon content and highest purity, and incorporate therein increasing quantities of the various elements, it is apparent at once that the Brinell hardness is increased in the rolled product about as shown in Fig. 21. These curves are drawn as the best probable average of scattered data and should not be regarded as being precise. It is intended to refer to wrought material, hot-rolled to a reasonable thickness, say, $\frac{1}{2}$ to $\frac{3}{4}$ in., and cooled at a normal rate in air. The line for carbon in Fig. 21 refers to smaller specimens so as to reflect its effect upon hardenability. If larger sections are considered, the value at 1% carbon would be about 220 Brinell hardness. Hardness is not correlated perfectly either with yield point or with ultimate strength, but, in general, it increases with alloying elements in a manner such as to correlate somewhat with a value midway between the yield and the ultimate. Fig. 21

merely shows that the fundamental influence of alloys in iron is unique for each element; but such curves fall far short of telling the entire story. Added elements contrive to confer properties by several means, usually operating

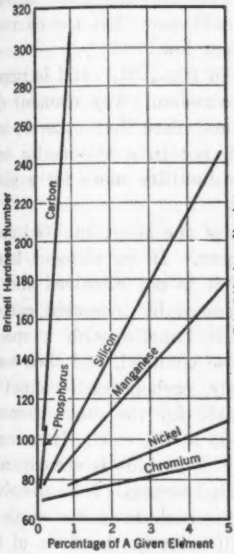

FIG. 21.—APPROXIMATE EFFECT OF SMALL ADDITIONS OF VARIOUS ELEMENTS TO NEARLY PURE IRON.

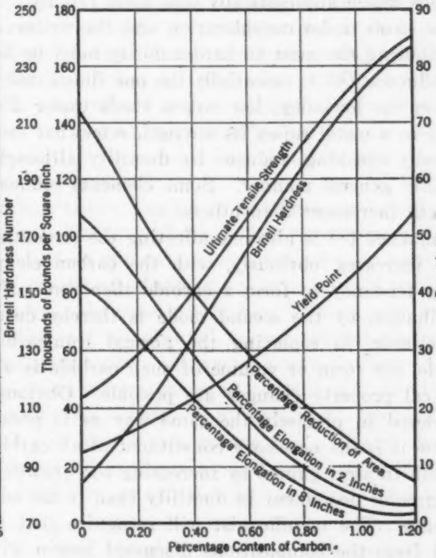

FIG. 22.—APPROXIMATE EFFECT OF CARBON CONTENT UPON THE TENSILE PROPERTIES OF STEEL, ASSUMING NORMAL MANGANESE CONTENT.

concurrently. The principal influences are, as follows: (*a*) Alteration of transformation characteristics (under-cooling and attendant fineness of microscopic structure); that is, "hardenability"; (*b*) solid solution hardness (and strength) increment in the iron itself; and (*c*) modification of the nature and the volume of the carbide constituent of the steel.

Another influence that almost warrants a separate listing has to do with the grain size in the heated condition; a fine grain generally connotes greater toughness.

Influence (*a*) is that which has to do with hardenability and, in the case of the higher carbon, higher alloy steels, such as some of the automotive steels—is of first importance. It is an influence which the element exerts by its presence in the steel at rolling temperature by determining the microstructure which finally develops upon cooling through the so-called critical temperature range at a given rate. It would operate to control the properties even if the alloying element were found to have vanished immediately after the steel had been transformed. Rapid cooling always produces finer distribution of carbide and, therefore, harder characteristics for any steel, and any of the alloying elements dissolved in the steel at rolling temperature acts

in a way practically equivalent to a more rapid cooling, because these elements retard the reactions at the transformation, or "critical", temperature. Thus, it is customary to reduce the carbon or the alloy content for the thinner sections which automatically cool more rapidly. This influence must be mild in the steels under consideration and the writers will show that the elements contributing the most to hardenability must be kept low.

Influence (*b*) is essentially the one illustrated in Fig. 21, and is important in the low-alloy, low-carbon steels under discussion. Any element dissolved in a metal raises its strength somewhat (some more than others), and, generally speaking, reduces its ductility although not in a systematic or a perfectly general manner. Some elements reduce ductility more for a given strength increment than others.

Influence (*c*) is also one affecting the strength of the alloy, but its importance increases, obviously, with the carbon element. If an element has a strong tendency to form a carbide then some of it is not dissolved and its contribution by the second mode is thereby decreased by increased carbon. If, however, in replacing the normal iron-carbide lamellæ with a special carbide, the form or volume of such carbide is also changed, and then some practical property changes are possible. Obviously, carbon itself cannot be considered in precisely the same way as is possible for the other elements because it is the necessary constituent of all carbide in the steel. In general, strength in steel gained by increasing the quantity of carbide is accompanied by a greater decrement in ductility than is the added strength from dissolved elements. The metallurgist will recognize that the carbide in the steels as rolled from the compositions discussed herein will exist in the form of the minutest microscopic platelets or lamellæ, a form not nearly so conducive to ductility as the spheroidized form found in fully heat-treated steels. In the spheroidized condition, as may be surmised, the carbide is in the form of roughly spherical particles barely visible under the microscope. It will be understood that these features of microstructure are nothing that can be seen by the eye in the fractured surface, but are known only through application of the metallurgist's technique of examining a polished and etched section microscopically. Perhaps a philosophy of alloy steels can be developed by considering the elements, one at a time.

Characteristics of Individual Alloying Elements

Carbon.—Fig. 22 shows the approximate change in tensile-test properties created by the carbon content in steels of normal manganese (0.45%) and silicon content as rolled in sections of the order of 0.75 in. thick. As might be predicted from Fig. 21, carbon is the most powerful element, weight for weight, utilized in influencing the properties of steel; it is customary, however, to exclude carbon when referring to alloys or alloying elements. Its marked effect upon strength properties is gained at a considerable toll in ductility, and long experience indicates that at about 0.20% to 0.25% (with comparatively low content of other elements), a broadly applicable optimum is reached for structural carbon steels. At this content, a considerable range

of other elements and of section is still permissible, and it happens also that the influence of carbon upon hardenability is not so great at this point as to preclude welding, bearing in mind the low content of other elements. Perhaps one may state that carbon contributes practically nothing by the second influence, that of solid solution, since at ordinary temperatures it is so nearly insoluble, and that the quantity of carbide as a microscopic constituent is proportional to the carbon content and, hence, a strong effect results in this (the third) manner. Furthermore, even with a minor content of other elements, carbon exerts a definite influence toward hardenability; only in its presence, and in proportion to its concentration, are other elements able to exert substantial influences toward hardenability.

Nevertheless, when need has arisen, engineers have not hesitated to use steels of higher carbon content. Because of the added requirement of wear resistance, rails carry about 0.75% of carbon; the eye-bars, already mentioned, are high in carbon since heat treatment eliminates a large part of the loss in ductility brought about by carbon. In cases wherein no welding is to be used and wherein joining problems are not complicated, carbon content higher than the usual can always be used with safety. However, where welding is to be utilized, the usual structural steel derives about all the strength that carbon alone can provide without excessively restricting other valuable properties.

Manganese.—After carbon and phosphorus, manganese is one of the most effective strengtheners of steel, rivaling chromium. Its effect may be greater than shown in Fig. 23 (*a*), which is an attempt on the part of the writers

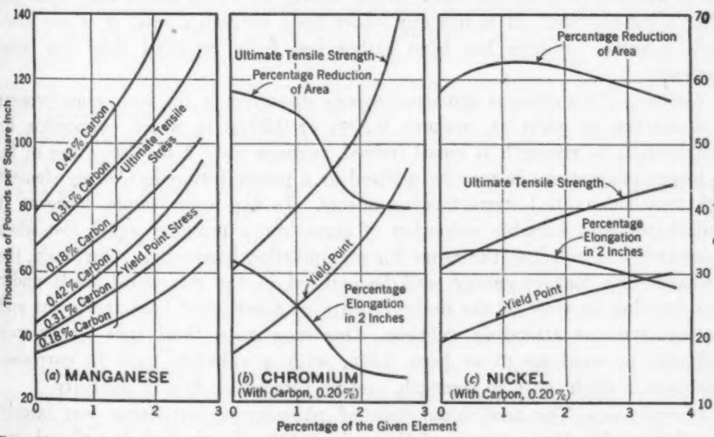

FIG. 23.—APPROXIMATE EFFECTS OF THREE DIFFERENT ALLOY ELEMENTS UPON THE TENSILE PROPERTIES OF CARBON STEEL. NORMAL MANGANESE IN CHROMIUM AND NICKEL CHARTS.

to correlate some scattered information. Manganese is an extraordinarily powerful hardening agent (Influence (*a*)), and it also strengthens greatly by solid solution. It has no particular carbide effect, although it divides itself between the iron solid solution and the carbide. It has the disadvantage, how-

ever, of taking a considerable toll of ductility in the as-rolled condition, apparently through its solid-solution effect. In general, it should probably not be used much in excess of 1% to 1.3% in any non-heat-treated, general-purpose steel, and for the greatest ductility, perhaps 0.50% to 0.75% is sufficient. In a broad way, the over-all manganese effects are not unlike ~~these~~ of carbon; with very low-carbon steel, manganese is perhaps one-eighth as effective as carbon in developing strength, but in somewhat higher carbon steel it is certainly more like one-fourth or one-fifth as effective, weight for weight, because its hardenability effect enters. In order to preserve good ductility in the manganese steels the carbon must be decreased somewhat and more than the equivalent effective manganese is then to be added in order to gain strength; but even this substitution has strict limitations. In the ideal high-strength, general-purpose steel, other helpful elements should be called into use.

Silicon.—This element is found almost entirely in solution in the iron (ferrite), and its solid solution effect is strong. In small amounts (that is, as much as about 1%), it appears to reduce ductility only moderately, and some report that it has a curiously minor effect upon the reduction of area in the tensile test. It has a significant effect upon hardenability which is, however, small in comparison with that of manganese, carbon, or chromium, and in the presence of these elements its effect upon hardenability through its influence upon transformation rate must be taken into consideration. It is a valuable aid in the low-carbon steels in securing strength, and may be utilized safely up to 0.75% or, in some cases, nearly to 1.0%, depending upon the other alloy content. If it has any effect upon corrosion rate, it is not obviously adverse. Silicon has been rather less fully reported than the other elements.

Copper.—This element remains entirely dissolved in the iron when present in quantities as great as, perhaps, 0.50% or 0.60%, in which proportion its contribution to strength is small indeed, perhaps only 2 to 4 kips per sq in. In larger proportions it may be utilized as a precipitation hardening element with very substantial strengthening effects. In the lower range, however, it contributes to a valuable reduction of corrosion, a property again lost when the quantity is well into the range for precipitation hardening. Obviously, the age-hardening feature cannot well be utilized in the structural steels under consideration in view of the undesirability of subsequent heat treatment and the requirements attending welding. One may state, then, that copper may profitably be used up to at least 0.5%, with a valuable gain in corrosion resistance, a slight gain in strength, and no perceptible loss in ductility.

Phosphorus.—The traditional fear of phosphorus brittleness was largely dispelled by the classical work of Unger in 1918[80], who showed that phosphorus in quantities considerably greater than 0.10% contributed strength without undue loss of ductility. Indeed under some conditions an increment in strength could be provided by means of phosphorus with a penalty against ductility less than if the same increment were gained through a higher carbon

[80] "Effect of Phosphorus in Soft Acid and Basic Open-Hearth Steels", by John S. Unger, *Year Book*, Am. Iron and Steel Inst., 1918, p. 172.

content. In other words, a reduction of carbon content with a deliberate addition of phosphorus yields a steel in which strength is increased and ductility remains constant; it is then a suitable element for the structural steel under discussion. More recently the effect of phosphorus to reduce corrosion has been recognized, and since this is a factor of increasing importance, incidental advantage is taken of its quota of strengthening effect, while securing at the same time a marked improvement in corrosion resistance. At about 0.07% the strengthening effect of phosphorus is such as to necessitate a reduction of carbon content, but quantities as great as 0.15%, or even more, are still useful under some conditions.

Chromium.—This metal exerts its greatest influence through its contribution to hardenability, and large additions demand either a low carbon content or a heat treatment. In higher carbon steels, its strong carbide-forming tendency is outstanding, but this effect is of less consequence in steels carrying only 0.15%, or less, of carbon. Its straight, solid-solution effect in iron is extremely mild as may be seen in Fig. 21. This is particularly true in the case of the yield point which is scarcely changed by a small percentage of chromium in very low carbon steels or in extremely slowly cooled higher carbon steels. The ultimate strength, however, is more markedly affected. Fig. 23 (*b*) illustrates the approximate influence of chromium upon the properties of a 0.20% carbon structural steel as rolled to a 0.5 or 0.75-in. section. In steels used in the as-rolled condition, it acts to control the microscopic structure and to foster the stronger structure in thin sections. Like manganese, therefore, it may best be used with a reduced carbon content.

The effect of high percentages (as, for example, 11%, or more) of chromium to develop an inert surface is so marked in the corresponding stainless steels that its modest contribution to corrosion resistance in the lower chromium steels passed almost unnoticed until recently. As an auxiliary element to raise strength with little loss in ductility and to encourage a harder structure from the transformation, it is useful and may be employed safely in quantities as great as about 1% in the present class of steels whenever manganese is not already relied upon for most of the strength increment.

Nickel.—This element, like silicon, exerts little or no influence upon the quantity or character of the carbide formed in low carbon steel. It is somewhat more effective as a solid-solution hardener than chromium, but has rather less influence upon hardenability. Its effects are mild but positive, and strength gained by nickel is often accompanied by very little or no loss of ductility. The only disadvantage in its use is the relatively large quantity required to secure marked increase in strength. Its improvement of corrosion resistance is well known and compares with that of copper except that it is not so effective, weight for weight. Where it may be used in relatively large quantity, and where ductility is extremely important, it is particularly well suited. Fig. 23(*c*) shows the approximate effect of nickel upon the properties of a 0.20% carbon structural steel as rolled to 0.5-in. to 0.75-in. section.

Molybdenum.—As a carbide-forming element, molybdenum exhibits a grain-refining influence probably next to vanadium in intensity. Even with low carbon steels the molybdenum, as ordinarily used, is to be found chiefly in

the carbide constituent where its effect is an indirect one through the grain-size effect mentioned previously. In this way, molybdenum may counteract some of the hardenability effects and promote a more advantageous distribution of the carbide than that of plain carbon steels. When it is dissolved at high temperature, however, as in the hotter zones of a weld, it exercises a hardening influence. In view of the cost of molybdenum, it is customary to use it very sparingly, in the alloys under consideration. The grain-size effect can be achieved, in large part, by other means, such as measured deoxidation utilizing aluminum in a special way. The outstanding value of molybdenum, revealed by its tendency to form persistent carbide globules, is manifest in the creep-resisting steels used at elevated temperature.

Vanadium.—The effect of vanadium, as ordinarily used, is essentially that of grain-size reduction, with its attendant control of hardenability and preservation of toughness. By this indirect influence it permits a more generous use of manganese, but does not enter the picture of low-priced structural steels to any great extent. It becomes a more important element in the higher carbon steels used in the heat-treated condition.

The foregoing comments show that the acquisition of high strength is easily securable by the addition to iron of practically any of the elements enumerated, but that in the case of the most effective ones the strength is secured at a considerable sacrifice in ductility. Carbon accomplishes its results through an increase in the non-ductile constituent carbide, whereas the other elements act more gently through solid solution effects and by a change in hardenability. To secure a greater strength with maximum preservation of ductility in the as-rolled condition, carbon can be used only sparingly, and even manganese and phosphorus must not be used in quantities contributing very greatly to strength.

Complex Steels: Simultaneous Addition of Several Elements

A fortunate circumstance is that the concurrent use of moderate quantities of several elements appears to produce a more favorable combination of properties than would result from a single element in an amount sufficient to produce an equivalent strength increase. Roughly speaking, in the small quantities under discussion herein, the effects of the elements are sufficiently additive to permit rough first approximations of properties from composition, but even those who introduced the early formulas for predicting tensile test data from analyses recognized some inter-relation which rendered linear formulas unreliable.

Suppose, for example, that the objective is a steel of 55-kip yield strength. This is easily accomplished by increasing the carbon content to about 0.50% and holding manganese to 0.45%, but by so doing the elongation in 2 in. is reduced to about 20%, and less for 8 in., a figure regarded as inadequate for general purposes by many engineers; but such a steel will not yield a weld of desired properties in the metal adjacent to the weld because of undue hardenability, and the semi-fused zone may be still more susceptible to the loss of ductility. If one uses about 1.60% to 1.85% of manganese and about

0.20% of carbon, the 55-kip yield point may be achieved and the elongation in 2 in. will not be far below 25%; but, on occasion, the weld may still not be quite as free from undue hardening as might be desired. Further improvement can be secured by further reducing the carbon and adding silicon; or, finally, by using still less manganese and adding yet another element, a very attractive set of properties is securable. Thus, for example, in a chromium, manganese, silicon steel (Cromansil), as rolled in 0.5-in. to 0.75-in. section, with carbon, 0.12%; manganese, 1.0%; chromium 0.75%; and silicon 0.75%, one would expect to secure about such tensile properties as ultimate strength of 80 kips per sq in.; yield point, 55 kips per sq in.; elongation, 26% in 8 in., and reduction of area, 55 per cent. Slight improvement may result from a further moderate decrease in manganese and increase in chromium and silicon. Similar improvements are obtained by the use of nickel in rather higher proportions, say, 2% to 3%, and some corrosion resistance is secured simultaneously. Whatever combination is utilized the corrosion resistance seemingly may be improved by the incorporation of as much as 0.50% copper and by the use of 0.10%, or more, phosphorus. A steel with which the writers happen to be familiar, is constituted in accord with the foregoing line of reasoning, with particular attention to high-yield strength and corrosion resistance, and has an average analysis approximately, as follows:

Composition (Percentages):

Carbon (maximum)	0.10
Manganese	0.30
Phosphorus	0.10
Silicon	0.75
Chromium	1.0
Copper	0.35

Average Properties in Ordinary Sections:

Yield-point stress, in kips per square inch	55
Ultimate strength, in kips per square inch	72
Percentage elongation in 2 in.	25
Percentage reduction in area	60
Izod impact, in foot-pounds:	
At 70° F	60
At −40° F	40
Endurance limit, in kips per square inch	45

There are obviously many alloy combinations from which to choose in securing the mechanical properties set as the objective of the new structural steels. In selecting examples thus far the writers have only expressed their concept of a logical design of alloy-steel composition. It should be borne in mind that there are few, if any, sharp maxima in the ductility-strength combination when properties are regarded as a function of composition. Indeed the optimum composition ranges for the principal properties are probably broad ones, and the minor desiderata may have to be taken into account

to enable a final choice to be made. An impression of the various alloy compositions offered to the trade may be gathered from an inspection of Table 3[51]. The writers are not responsible for certain apparent discrepancies that appear in Table 3.

The writers are persuaded that the low-carbon content of most of these steels is an important feature and one that is worthy of careful consideration. Not only is high carbon unnecessary in view of its replacement by larger additions of alloying elements in securing high yield strength (say, 55 kips per sq in.), but ductility in the as-rolled condition in thinner gages depends upon its being kept low; but still more important is the manner of hardening during rapid cooling after welding, which often is not easily preventable. Some engineers regard about 0.15%, maximum, of carbon as highly desirable in the general case, although a higher percentage may be satisfactory in some instances. Clearly, the lower the carbon content, with physical properties constant, the less will be the opportunity for dissatisfaction in this respect.

[51] "Low-Alloy, High-Yield Strength Structural Steels, An Extended Abstract", *Metals and Alloys*, March, 1936.

At the same time wherever welding is not used, or in cases amenable to stress-relief annealing following welding, the higher carbon steels are applicable, and they may possess still higher strength.

It is noteworthy that most of the low-carbon structural alloy steels manifest a relatively high endurance limit. Some of them are surprisingly high and others show an endurance limit of approximately 50% of the ultimate strength. Considering that comparatively few structures have to withstand full reversal of load, it is not believed that special consideration need be given this aspect of the question in the substitution of the alloy steels for ordinary structural steel.

Manufacturing Aspects

From the standpoint of the user, the manufacturing operations at the steel mill, involved in the production of the structural ferrous alloys covered by this paper, do not differ greatly from those used in the production of ordinary structural steel. There are differences, of course, in the manner in which the alloying elements are applied, in the furnace or in the ladle, in discard practice, and, in some cases, in the precise temperature at which the rolling process is finished, but it is believed that the civil engineer, who designs, fabricates, or erects structures in which the alloys in question are used, is not primarily concerned with these features. Indeed, operating practice differs in the several producing plants. Those who are interested may refer to the meritorious outline of mill practice in the production of the steels in question, which appeared in the Progress Report of Sub-Committee No. 2, Committee on Steel of the Structural Division, on Structural Alloy and Heat-Treated Steels[88].

Of greater interest to the civil engineer is the extent to which the special grades in various forms are readily obtainable from the steel mills. The fact that manufacturing operations are similar to those required for ordinary grades does not mean that the special grades are as readily obtainable; they are not as easy to manufacture in a wide variety of section for several reasons:

(1) At present, the demand for any given special grade is not as great as for ordinary grades; therefore, they are not rolled as frequently, or in as wide a variety of sections; and,

(2) The execution of orders for small tonnages of a given special grade must either await the accumulation of other similar orders, or the required items must be taken from stock. The probability of the existence of a stock of the desired grade, and in the desired form and length of section, is much less than in the case of ordinary grades.

For these reasons it is believed that prospective users should consult with the respective steel manufacturers as to the availability of a special grade of steel, for a designated structure, before they incorporate members of that grade into their design.

One interesting fact not always realized by users relates to the excess material produced. When an order for a given lot of special steel is taken,

[88] *Proceedings*, Am. Soc. C. E., March, 1936, p. 361.

the steel mills regularly produce more than the quantity ordered so as to provide against possible rejections. If no material is rejected the excess is either scrapped or placed in stock. The latter practice explains the occasional offering by the manufacturers of odd lots of a special grade.

Summary

By incorporating moderate proportions of the common alloying elements, already used in other alloy steels, and at the same time reducing the carbon content, structural steels are now manufactured, which possess increased strength, particularly yield strength, with little or no diminution of plasticity or ductility. Weldability and formability are maintained by virtue of this altered composition. Under suitable conditions these gains in desirable properties may make possible an over-all economy in the use of alloy steel instead of the structural carbon steel in spite of its higher cost.

When advantage is taken of the superior properties to reduce the thickness of members greater attention must be paid to corrosion resistance, because corrosive attack does not reduce the effective metal section in proportion to thickness, but irrespective of section. Fortunately, alloying elements can be selected which confer a reduced corrosion rate to the steel, and this is a valuable property wherever a protective paint or other surface cannot be maintained continuously.

A number of alloy combinations are effective in achieving these results; manganese, nickel, chromium, and silicon are probably the most effective strengtheners, as ordinarily used, and copper, phosphorus, molybdenum, and vanadium are useful auxiliary elements. Copper, nickel, phosphorus, and chromium contribute important resistance to corrosion.

In these low-alloy steels, when the carbon content is less than about 0.15%, and when the high yield strength is derived by judicious combination of the other elements, no serious hardenability interferes with welding processes, the formability is more than adequate, and the product is not unduly sensitive to commercial variations in composition or gage. The content of carbon or the powerful hardening elements should be regulated by the needed ductility and the needed freedom from air-hardening characteristics.

STAINLESS, HIGH-ALLOY STRUCTURAL STEELS

BY M. J. R. MORRIS[53], ESQ.

SYNOPSIS

In the realm of civil engineering the products discussed in this paper are new. The alloys generally used to-day are ferrous products of the mild structural steel type, which have definite physical qualities and stable surface characteristics. The Engineering Profession, therefore, has evolved a design within their limitations and, it may be stated, the curve of progress is now flattening out. Any hope of marked improvement in design involving this grade of steel does not appear possible.

Since about 1915 a class of steels has been produced in which the physical properties of the base (plain carbon) have been changed by the addition of alloys. This field of endeavor has been much capitalized in the structural steels for automotive engineering applications, but, otherwise, little use of these properties has been made by civil engineers; and, yet, this evolution in automotive practice accounted for the most important change in steel metallurgy within the last two decades, amounting in 1929 to 1 ton in 15 tons.

At the beginning of the World War a new chapter was opened, wherein the base plain carbon was alloyed with chrome, etc., to produce not only increased physical strength but also increased stability of surface. Unfortunately, this group has been termed stainless steels. They are not a single steel, but a large group, the base of which is approximately 12% chromium. This is the "corner stone" of the group which will be discussed in this paper.

INTRODUCTION

Steels designed under the specifications of the Society of Automotive Engineers have definite and desirable physical characteristics, but they do not possess the capacity to withstand various forms of corrosion; and it is this latter set of properties which enables this group to be used in lighter sections because of their better physical characteristics. It can thus be seen that one of the great drawbacks encountered in thinner sections of low-alloy, high tensile steels—surface deterioration—is not found among the high alloys, and now for the first time a group of steels is being developed which will have increasing fields of application.

Perhaps more than any other, the aircraft industry has exploited the use of stainless steels and of other high tensile alloys. This industry has been followed recently by the endeavors of the railroad companies. The Eads Bridge, at St. Louis, Mo., was a pioneer in raw products. It is a chromium

[53] Chf. Metallurgical Engr., Central Alloy Div., Republic Steel Corp., Massillon, Ohio.

steel structure. Alloying 12% chromium with base plain carbon produces a new alloy, its ultimate tensile strength being capable of variation from 50 to 160 kips[84] per sq in. by heat treatment. At the same time, this alloy is highly resistant to atmospheric, and ordinary water, corrosion attacks (referred to base plain carbon life, it would be infinite).

This grade is in its simplest form, and can be further modified by increasing the chromium content with, or without, increasing the carbon. These properties are shown in Table 4. The chromium series are modified with small quantities of nickel (say, as much as 2.5%) to improve the physical properties and with molybdenum and silicon to increase the stability of the surface. These alloys are ferritic in structure and magnetic, and generally respond to heat treatment as a means of increasing their physical properties.

[a] Maximum allowable. [b] Except Item No. 2. [c] Annealed. [d] Heat-treated or cold-drawn. [e] Soft steel, 0.10 calories per cu cm per degree Centigrade. [f] Trade designation by which the alloy is commonly recognized. [g] Heat-treated to improve physical properties. [h] Cold-worked to improve physical properties. [i] These items will harden on cold-working but since they are used only for heat resistance they are annealed only. [j] Sulfur. [k] Maximum. [l] Molybdenum. [m] Selenium. [n] Titanium four times the carbon content. [o] Columbium six to ten times the carbon content. [p] Brittle welds. [q] May check. [r] Fair to good.

In the austenitic group of stainless steels the base is chromium plus nickel (approximately 18% chromium plus 8% nickel) with less than 0.20% carbon. These steels have low yield points, but high tensile strength, in the annealed condition; but they have an extremely high degree of ductility. They are incapable of gaining increased physical properties by heat treatment; they can be hardened by mechanical work only. The range of physical properties is large as shown in Table 4. This base alloy has been modified by molybdenum, columbium, titanium, silicon, and copper, each of which contributes some desirable modification, depending upon the different field of application.

Molybdenum is added within a range of 2 to 4% to increase its resistance to wet corrosion particularly of the sulfurous acid type. Columbium is added in quantities equal, roughly, to ten times the carbon content in order to affect the stability of the carbon at elevated temperatures. The effect is to prevent separation of carbon at the grain boundaries in the form of carbides, which separation is undesirable, as this condition is more susceptible to corrosion. Titanium is added for the same purpose as columbium and in quantities generally five times the carbon content. It was the first ingredient so used and may be supplanted by columbium. These end points are attained also by lowering the carbon content only, but the drawback is that grain refinement is not maintained at the same time; hence, the foregoing modification was developed.

Silicon is added to increase resistance to dry corrosion or scaling at elevated temperatures. There is no marked increase in strength from the addition of this alloy. Copper is added at the present time for the purpose of increasing resistance to wet corrosion, and possible definite data on its rôle will be forthcoming in the near future.

Physical Properties

The physical properties of the alloys are given in Table 4. One item that should be emphasized especially is the elastic limit of the mechanically worked austenitic type; the degree of mechanical working necessary to attain this value properly is in excess of 25 per cent. It is then noted that the elastic limit is indefinite and the curve is continuous. The evaluation of this characteristic can readily be seen to be widely divergent, depending upon the method utilized. This fact is shown in Fig. 24(*b*). The characteristics of types of stainless steel that are hardenable by heating are shown in Fig. 24(*a*). This is of the same type as in all the steels patterned after the

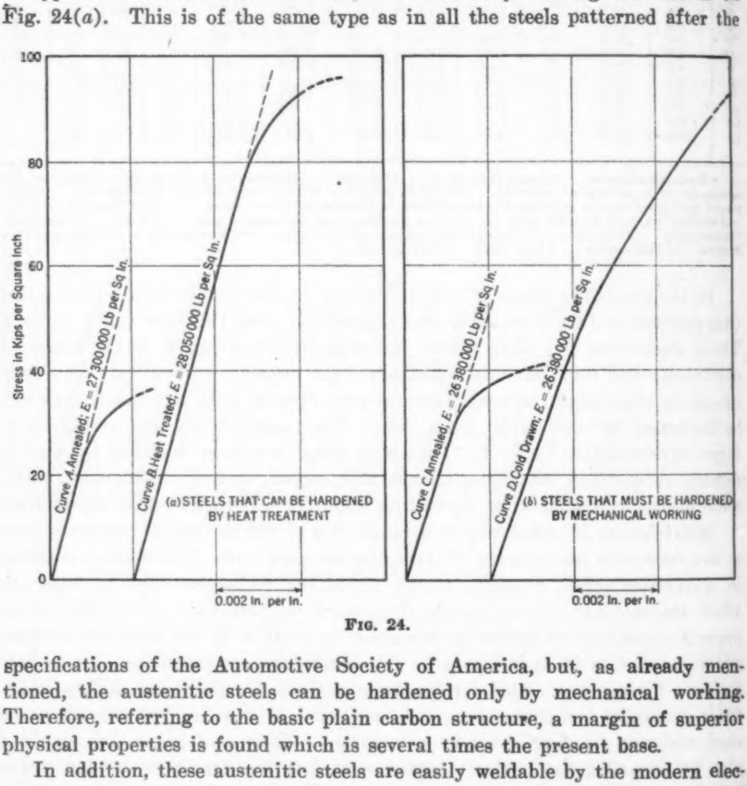

Fig. 24.

specifications of the Automotive Society of America, but, as already mentioned, the austenitic steels can be hardened only by mechanical working. Therefore, referring to the basic plain carbon structure, a margin of superior physical properties is found which is several times the present base.

In addition, these austenitic steels are easily weldable by the modern electrical or gas-welding methods. They can also be formed, punched, and forged without difficulty, but it should not be forgotten that they are stronger steels and, therefore, will require more energy to work. It is safe to state that they are being handled successfully to-day.

It is now logical to discuss briefly the most important property of this group of steels; that is, their corrosion resistance. No one steel in this field has properties adaptable to every case and it is for this reason that the word,

"stainless", has been unfortunate and, in fact, has hindered their proper development and use. It is just as improper to state that there is only one acid. Metallurgists know better to-day, and this important fact being appreciated is leading to more intelligent application and thorough understanding of these steels.

The civil engineer has various atmospheric conditions confronting him—from pure country air to sea air—and highly industrialized conditions. He encounters problems of diverse characteristics, from the practically non-corrosive to extremely corrosive types. These conditions can be analyzed much more readily to-day than in the past. Lastly, he meets a variety of soil conditions, which can be also measured much more intelligently to-day for their corrosion conditions. It can be seen, therefore, that knowing these conditions, the metallurgist and the engineer can design a more suitable steel product to serve a particular purpose.

Since about 1925, much has been done to stress the corrosion fatigue properties of steels. This emphasis has increased, definitely, the importance of obtaining the necessary information as to the medium of application. The surfaces must have a maximum degree of corrosion resistance.

Manufacture of Stainless Steels

Because of their high alloy content, all the stainless steels discussed in this paper are made in an electric furnace of a maximum capacity of 20 tons, generally approximating 10 to 15 tons. The ingots are generally rolled, but the more special types are much stiffer and are forged from the ingots into blooms, which are then rolled.

Being much stiffer than the ordinary plain carbon steels or structural alloy steels, stainless steels are slower to absorb heat and have a narrower working range. The mills, therefore, are different from those used for manufacturing plain carbon steel. They are usually slower and more powerful. It is necessary to have very good temperature control and good fuel conditions. These steels demand a more complete understanding of the mechanical working operations; otherwise, no resemblance of success is obtained and much disappointment results. However, these are days of definite control of operations, and rule-of-thumb and good luck should not, and cannot, exist.

It has already been stated that the rolling requires extra strength, but that the annealing and cooling conditions must have definite control. It is a matter of general practice to handle straight chromium types as all ferritic and hardenable steels are handled—that is, they are cooled very slowly. In the austenitic types, however, the reverse is necessary in the case of nearly all sections in present use. When cooled slowly, the crystalline structure of these types is endangered and rendered more or less useless, but this condition is so easily tested that there is absolutely no excuse for a poor product being shipped from the steel mill or by the fabricator. Generally, it can be stated that sections containing less than $\frac{30}{1000}$ in. cool rapidly enough in air so that this harmful condition is avoided. The thicker sections are quenched to increase their rate of cooling. Hence, it is seen that the two annealing treatments are opposite.

The entire group of these alloys is complex and at the present time their methods of manufacture and production are truly in the evolution period or flux; it is encouraging to be able to state that rapid progress is being made. In a period of little more than 10 yr a product has been transformed from the jewelry classification to one of promising expanding industrial uses, and it is computed that the production for 1936 is well on the way to 100 000 tons.

Application of Stainless Steels in Civil Engineering

The application of stainless steels should be divided into fields of endeavor. It has been shown in recent years that, on certain jobs, definite use can be made of this group of steels, and all such applications have been major investments of the more permanent type. It would be better to divide the various uses into fields that have passed beyond the pioneer stage and describe the better known uses in each field.

Dam Construction.—A proper field for the application of stainless steels has been in the construction of dams, such as in gate-rollers, guides, seal strip, and screw mechanism for raising and lowering the gates. All this use applies to the gate structure and mechanism. It is conceivable that the larger gates could be made of structural steels overlaid with stainless steels and, although there are not yet a sufficient number of cases upon which to base sweeping conclusions, it is felt that such a suggestion would be accorded a high preference. These applications are seriously dependent upon freedom from corrosion in order to keep the mechanism free to operate, galling and rusting being fatal. The rollers and guides usually contain 12% chromium, heat-treated to a Brinell hardness number of about 350. The seal strip is austenitic, with low carbon content, of the type analyzed in Items Nos. 5 to 10, Table 4.

At present, expansion joints between concrete blocks in dam construction are being made of a thin gage strip of low carbon steel. Several of the projects in the Tennessee Valley Authority have this form of construction. It has been thought that, in rock-fill dams, the water face should be of thin stainless sheets, and it is reputed that one such application is being installed in the Severn River, in Great Britain, as an experiment. The ducts controlling the water to and from the locks should present a proper application of stainless steels as liners; this is being considered in some designs at present.

One of the largest uses of stainless steel in dam construction has been on the Aswan Dam, in Egypt, in which about 2 500 tons were used. The dam is 1.25 miles long, and was built in 1892. At the end of 1928, an International Commission inspected it and reported the necessity of further raising and strengthening it. Accordingly, it was decided to erect masonry buttresses between the sluices, but instead of these buttresses being fixed to the face of the dam, they were to be laid against a layer of stainless steel plates placed against the face. The buttress thus was to become a live load. These alloy plates, with a high chromium and nickel content, are 7 mm (0.280 in.) thick, and of varying sizes to suit the dimensions of the masonry buttresses in conjunction with which they are to be used.

More than 100 tons of 4 to 6% of chromium steel were used in the construction of a dam completed in 1935 at Hawk's Nest, W. Va. The steel was used as concrete reinforcing rods and represents one of the first applications of alloy steels to this type of work. The 4 to 6% chromium steel was selected because, by its use, a high tensile strength (180 kips per sq in.) could be obtained without special heat treatment and also because the chromium content renders these rods much more immune to the rusting that always occurs in such applications.

Great quantities of stainless steel were used for sluice-gates, rollers, etc. on the Arapuni Power Project, in New Zealand. This is a unique installation because of the great head of water. The gate is the most heavily loaded in the world, the total water pressure on the face being 2 000 long tons.

In bridge design, the rockers and rocker-plates have recently been made of stainless, heat-treated steel. Some experts maintain that the solid floors of bridges can be modified profitably by the use of stainless grating structures, which are claimed to be stronger, considerably lighter, more rust resistant, and more resistant to wear. One bridge has been so modified. This development received its first important impetus from experiences with the George Washington Bridge over the Hudson River, in New York, N. Y.

Stainless steel wire was used for auxiliary counterweight cables on the Buzzard's Bay Bridge, at Cape Cod, Massachusetts. This steel was the type analyzed in Items Nos. 5 to 10, Table 4, and the cables were 1⅝ in. in diameter. These cables are in a position not readily accessible for inspection and the use of stainless steel is an added safety factor.

Sewage Disposal Plants.—Stainless steel products should find definite application because of their anti-fouling properties. Heavy pipe lined with stainless steel has been used in large quantities in the City Sewage Plant, at Milwaukee, Wis., because of its low friction factor.

Intakes.—In water systems supplying cities, etc., the austenitic and straight chromium types of steel have been considered. These steels have been applied on intake screens, the type used depending on the design; and generally they have been the austenitic type. The filter screen in artesian well installations has disposed of considerable stainless steel. These screens are of several designs, either wire or sheets being used. Wells of this construction are very easily cleaned. In filter beds, thought has been given to utilizing perforated stainless steel for the floors, the perforation being of such size as to eliminate certain of the coarser gravels.

In 1935, a huge intake crib was completed in Lake Michigan off the foot of Chicago Avenue, Chicago, Ill. It covers the intake from which water for the municipal supply is drawn from the lake through a tunnel below the lake bottom. Older cribs were constructed of granite. A unique feature of this attractive new concrete and steel structure is the stainless steel ring that lines the shaft. It serves to protect the shaft and to resist the rust and erosion that could be expected to attack other forms of construction. It is 39 ft in diameter, 10 ft high, and weighs 3 700 lb.

Reinforced Concrete Structures.—In reinforced concrete structures several problems are presented which may be helped sometimes by the use of stainless alloy steels. When ordinary steels rust, the products of this rusting occupy a decidedly larger volume than that occupied by the non-rusted product from which it came. This produces expansion stresses which may result in cracking the concrete. If the superimposed thickness of the concrete is slight, the steel work is soon exposed; if the concrete covering is thick, this rate of rusting is much less. However, this thought has been embodied in the construction of one dam and, although the alloy was not the true stainless type of steel, its use was a pioneering effort which embodied the principles.

In constructing a new reservoir near Sheffield, England, the engineers decided to demolish an old weir on the River Derwent and to build a measuring channel instead. This channel is unique in that its masonry bed is covered with a stainless steel sheet, the purpose being to prevent the growth of moss and other vegetation that would choke the flow and induce errors in the measurements. This application of stainless steel, although unusual, is entirely practical and is indicative of the extent to which foreign engineers are utilizing its advantages.

Finally, large roofs demonstrate the first use of metals possessed of corrosion-resisting properties. Lead was an early form—then copper, brass, and other non-ferrous products. Necessarily, all this preliminary experience was with such metals as these because of the known attributes of steel and iron products. In these special applications, as ably demonstrated by the roofs of the Pennsylvania Railroad Station, in New York, N. Y., steel and iron rusted quickly and were not easily worked. Stainless steels could be used in such cases with a saving in weight of at least 10 per cent.

St. Paul's Cathedral, in London, England, is a splendid example of how masonry structures that are weakening from age may be strengthened by stainless steel. A few years ago Government inspectors discovered that the huge dome of this famous old cathedral was showing signs of deterioration. Not only was the life of the magnificent structure threatened, but the fractures in the dome constituted a serious danger to worshippers. Tests were made both with tie-rods of strong common alloy steels and with rods of special stainless chrome-nickel steel. The rough oxidizable surface of the common alloy steels adhered to the cement readily, which at first seemed to be an advantage. However, it required a maximum load of only 2.85 tons to withdraw the plain rods. Then bars of stainless steel were rolled and indented so that a series of flat rods was formed. To withdraw these bars from the hardened cement took a maximum pull of 18.88 tons. The result is that stainless steel tie-rods, 40 ft long, threaded at each end, and 4 in. in diameter, are now firmly embedded in the walls of St. Paul's Cathedral to tie the inner wall to the outer wall of the dome.

Irrigation.—Much stainless steel is being utilized in irrigation practice partly to resist corrosion. The Shanan Plant, on the Uhl River, in Punjab, India, is an excellent illustration of this development.

CONCLUSION

It would appear, therefore, that stainless steels of various composition, permit the selection of a type with attributes that will fill the demands of any given engineering problem. At present, it is not as simple to supply them as in the case of the plain carbon steels because the cost would be excessive. When the cost is secondary, or when a high first cost is justified by hazards to life, they can be applied. However, although the application of stainless steels to safeguard life is increasing, this is not the only field. In large structures, weight will be materially reduced by designing these alloys in conjunction with the low carbon types. As in the case of the railroad and the airplane, conventional designs will not be followed but types of structures will be evolved. This will enable a more widespread use of stainless steels. The problem now is to learn to use their valuable properties.

LIGHT-WEIGHT STRUCTURAL ALLOYS

BY ZAY JEFFRIES[55], ESQ., C. F. NAGEL, JR.[56], ESQ., AND R. T. WOOD[57], ESQ.

SYNOPSIS

This paper is intended primarily to present those metallurgical principles and properties of the light-weight alloys which govern: (1) The selection of the most suitable composition, temper, or form of material; and (2) the selection of fabricating practices and degree of control required if the best results are to be obtained. As the paper embraces both aluminum and magnesium, and as their characteristics differ so widely, they will be dealt with separately.

PART I—ALUMINUM

HISTORY

Many aspects of the history of aluminum have been amply covered in the literature, especially in 1936, which marks the Fiftieth Anniversary of Hall's noteworthy discovery[58], an event which extracted this metal from the limited enjoyment of the few and made it available as a common article of commerce.

In spite of these previous writings, it is considered worth while to summarize briefly those pertinent events and developments that caused aluminum to become a structural engineering material. It may well be remembered that, for years, the position of this metal in the industrial "sun" was almost limited to essentially non-engineering applications, as, for example, the humble household cooking utensil. During those years, it was not deemed reasonable that such a light metal could do the world's "heavy work." It appears that it was not until aluminum alloys were used in the construction of aircraft that they were conceded the possibility of becoming engineering materials in any field.

In 1898, an Austrian, named Schwartz, constructed a rigid airship with the framework and outer covering of aluminum. Unfortunately, this ship was destroyed on its first landing and, hence, this effort should probably not be recorded as establishing the validity of aluminum alloys for engineering purposes. However, on July 2, 1900, Count von Zeppelin, after many difficulties, launched his first rigid airship. Gaged by the standards of that day the aluminum alloys, from which the framework of this ship was constructed, functioned satisfactorily. The composition of these early aluminum materials varied somewhat, but they were principally aluminum-zinc alloys. They were not heat treatable, but obtained their strength from the effects of the added alloying elements, coupled with cold working.

[58] "Fifty Years of New Product Development", by Messrs. Frary and Edwards, *Chemical and Metallurgical Engineering*, February, 1936, p. 64.

In 1909, Alfred Wilm, of Germany, brought forth an aluminum alloy, since known as duralumin, which was infinitely superior to those formerly available. The superior combination of qualities of this alloy, such as high strength, workability, and resistance to corrosion, very quickly indicated its usefulness as an aircraft material. This alloy, and the process by which it is manufactured, is of particular historical interest for two reasons: (1) It marks the first noteworthy instance in which the strength of an aluminum alloy was increased materially by means of a heat-treating operation; and (2) in later years, the explanation of this behavior, originated by P. D. Merica[89] and his associates, revealed to the world a new metallurgical principle and one which not only profoundly affected later developments in the aluminum industry but also the metallurgical advance of many other metals.

Marked progress has been made during the past fifteen years in acquiring an understanding of what occurs within the structure of the metal during and subsequent to the heat-treating operation. This has made possible an intelligent selection and control of the alloying ingredients and manufacturing processes, resulting in an ever growing list of improved and more useful products.

Especially during the early years of this development period the principal urge for higher strength, greater uniformity of properties, increased resistance to corrosion, and greater diversity in the form and range of sizes came from the aircraft industry. This was not unnatural. Several conditions in the aircraft industry immediately following the cessation of the World War, which corresponded approximately with the commercial introduction of the heat-treatable aluminum alloys, all conspired to bring about an intensely active development on a co-operative basis between the aircraft and the aluminum industries. The aircraft industry was in its infancy; the application of the metal was of even more recent date. There are few engineering fields in which the demand for perfection of properties is necessarily so highly exacting, in which the materials of construction must be utilized so efficiently, and in which the factor of safety must, of necessity, be calculated to such a fine point. At the same time, the penalty of a failure is terrific.

The industry proceeded with the best materials then available, setting specifications that called for the most constant vigilance for their fulfillment, but pressed insistently for continued improvement and advance. The aluminum industry responded, especially in the United States, and there ensued a development which resulted in the commercial production of a variety of new aluminum products not hitherto available. The guaranteed minimum yield strength was increased more than 100% in less than twenty years. New products were produced, possessing such excellent resistance to corrosion that they could be used bare without any protective coating whatever and this, in sheets, as thin as 0.0095 in.

The object of relating this history is not primarily to praise the aircraft industry (although praise is due), but to indicate the standards of achieve-

[89] "Heat Treatment of Duralumin", *Paper 347*, National Bureau of Standards, November 15, 1919.

ment sought during this development period. These same standards have governed the development of other aluminum alloys for other engineering applications.

The demands of other industries also contributed considerably during this period, and increasingly so. The railroads became actively interested in light alloy construction at least as early as 1923. Rightfully, they emphasized initial, as well as ultimate, cost; they stressed length of useful service far beyond that required for aircraft during that period. Aviation's first problem was to make something fly; and, next, to fly well and safely. Now it has reached the stage of adding "and economically."

Other industries came in for increased attention: The truck, the bus, the marine structure, construction equipment, building materials, sewage disposal equipment, and now the bridge industry.

Each field presented different problems, problems that differed as to technical characteristics of the material that were of governing importance, as to requirements dictated by design and feasible fabrication practices, and as to competitive costs. The result has been the development of a relatively large list of alloys and tempers, available in a very extended range of forms and sizes, some especially suited to one field, some particularly adapted to other fields. With the production of these new materials has come a substantial fund of knowledge of the metallurgical principles involved, an understanding of which is very helpful in the intelligent selection and use of these materials.

Important Metallurgical Principles of Structural Aluminum Alloys

Effect of Composition.—The more common metals used for alloying with aluminum are copper, silicon, manganese, magnesium, zinc, nickel, and chromium. Although occasionally only one of these alloys is added, frequently two or more are introduced, the quantity of each depending on the results desired. It is not possible to predict, definitely, the exact properties of a new composition, nor just how it will respond to various manufacturing processes; and yet certain general principles have been developed. The addition of any one of these elements results in increasing the ultimate strength, yield strength, hardness, shear, and fatigue or endurance values, usually at the expense of elongation, reduction of area, plasticity, and malleability. Magnesium is one exception. Although the strength is regularly increased (see Table 5), in conformity with the general principle, by the addition of

TABLE 5.—Effect of Addition of Magnesium Upon Mechanical Properties of Aluminum-Magnesium Alloys in the Annealed Temper

Magnesium content (percentages)	Tensile strength, in kips per square inch	Yield strength, in kips per square inch	Percentage elongation in 2 inches	Magnesium content (percentages)	Tensile strength, in kips per square inch	Yield strength, in kips per square inch	Percentage elongation in 2 inches

2.50	26.76	10.70	25.7	6.00	42.00	18.50	29.0
3.00	28.90	11.65	26.7	8.00	46.00	21.00	32.0
4.25	35.50	15.25	26.0	10.00	52.00	24.00	32.0

more magnesium, the elongation at first decreases, but later recovers. The modulus of elasticity is only slightly affected by alloying. The greater the quantity of the alloying element, the greater in general will be the effect upon the several properties. The magnitude of the effects also varies with the particular alloying metal; that is, the addition of, say, 2% of copper will not affect the mechanical properties to the same degree as the addition of the same percentage of magnesium. Each alloying agent possesses its own quantitative influence.

The aluminum most resistant to corrosion is that of highest purity; in other words, the general effect of alloying is to lower this resistance. Again, the several metals vary in their effects. The alloys with copper and zinc are among the least resistant; the manganese and the magnesium alloys are on a par with commercially pure aluminum. The alloy consisting of 1.25% manganese (3S)[60], possesses a resistance to corrosion quite equal to that of commercially pure aluminum (2S). Likewise, the alloy (52S) consisting of 2.5% magnesium plus 0.25% chromium, and the alloy (53S) that consists of 1.25% magnesium, 0.7% silicon, and 0.25% chromium, and can be heat-treated, all possess a resistance to corrosion that places them in the same class as commercially pure aluminum. Corrosion resistance is one of the properties of these alloys that frequently dictate their selection.

Although the corrosion-resisting qualities of any particular new alloy cannot be definitely predicted in advance, many individuals and organizations throughout the world have concentrated on studying the specific behavior of present commercial and experimental compositions when subjected to a wide variety of laboratory and service conditions, with the result that there is available a wealth of useful information from which the prospective user can determine fairly well whether a particular alloy will meet his requirement satisfactorily.

Another effect of change in composition that may be of importance is that upon weldability. All the commercial aluminum alloys can be welded by the various methods—such as torch, electric spot, seam, butt, and arc—but the facility with which this can be accomplished and the properties of the resulting joint vary considerably, depending on the composition and, in some cases, on the welding method. For example, some magnesium-bearing alloys are less readily weldable by the torch than most other aluminum alloys, whereas they lend themselves especially well to joining by the electric spot and seam methods.

Welding means joining by fusion, regardless of the source of heat. Hence, during the act of welding, a portion of the parent metal becomes molten and, later, re-solidifies. Some compositions are rather tender or "hot short" at temperatures close to their melting points and cannot easily withstand the relatively high local contraction stresses set up during solidification and cooling. This is the case with some of the copper and magnesium-bearing alloys, whereas the silicon-bearing alloys behave differently. An alloy (43S) of 5%

[60] The symbols in parentheses denote the trade designation by which the alloy is commonly recognized.

silicon possesses a relatively small solidification contraction, a low melting point, and a wide melting range.

Therefore, when a particular job is rather difficult to torch weld, because of the characteristics of the alloy or the complexity of the assembly, recourse is frequently had to a 5% silicon alloy (43S) for the welding wire. This is often the choice when the parts to be assembled must be held rigidly in a jig, a situation that prevents free movement of the parts to compensate for expansion upon heating and contraction upon cooling.

In any welded joint, there is a portion of metal that is in the form of a casting, unless the joint is of such a design as to permit the hammering, and thus the conversion, of the metal into its wrought state. Therefore, consideration must be given as to whether the properties of the particular alloy in the form of a casting will be satisfactory. Some compositions (99% aluminum) are as ductile and tough in the form of a casting as in their wrought state, whereas others have a relatively low elongation. Furthermore, the heat-treatable alloys, when in the form of a casting, do not respond to the heat-treating operation as quickly, nor to the same degree, as when in the wrought state. In the case of a torch weld, fusion takes place completely

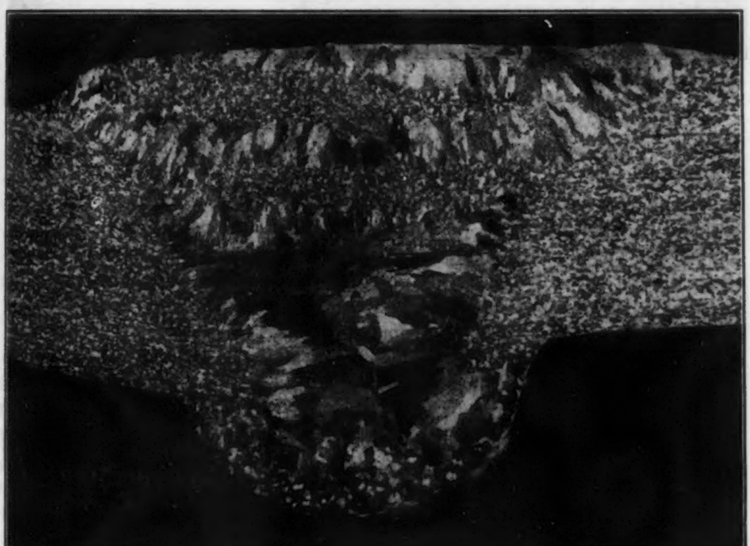

FIG. 25.—CROSS-SECTION OF BUTT TORCH WELD IN A 99% ALUMINUM SHEET. WELDING WIRE IS ALSO 99% ALUMINUM. (MAGNIFICATION, 7.5 TIMES.)

through the thickness of the parts being joined. On the other hand, electric spot and seam welding cause the melting of only a very small portion, and this area, in a properly made spot, does not proceed to the surface of the joint. This is illustrated in Fig. 25 and Fig. 26, which show in cross-

section a torch and a spot weld. The details regarding these matters have been well developed, and are available in current literature[a]. In Fig. 25, note that the metal in the welded portion has been melted completely through the thickness. In the case of the spot weld the area affected became molten

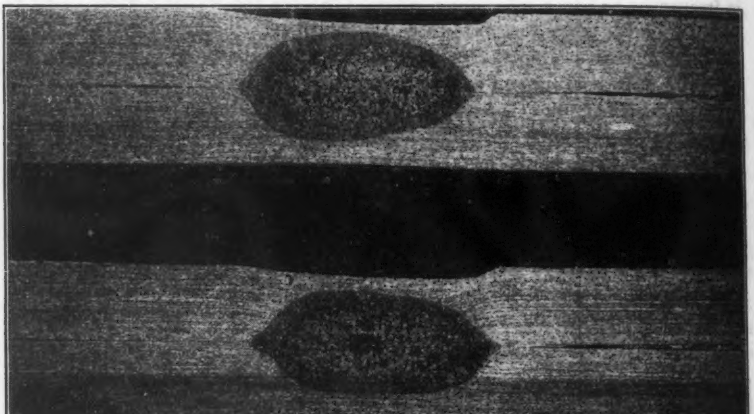

FIG. 26.—CROSS-SECTION THROUGH A LAP, ELECTRIC SPOT, WELD IN AN ALUMINUM-MANGANESE-CHROMIUM SHEET. (MAGNIFICATION, 10 TIMES.)

during the process. In Fig. 26, note that this dark area has not proceeded to the surface of the joint.

One of the major justifications for using aluminum in structural applications lies in its relatively low specific gravity in comparison with the other commercial metals. Although the specific gravity of the various aluminum alloys differs, this difference is so slight as seldom to constitute a factor in deciding whether to utilize one aluminum alloy rather than another. The greatest difference in this value among the present commercial aluminum alloys is about 3.5 per cent. Some of the alloys in which magnesium or silicon are the alloying agents are actually lighter than pure aluminum (see Table 6).

The coefficient of thermal expansion is also affected by the composition but here, again, the difference is so small as not to influence one's choice in favor of any particular alloy (except, perhaps, in some very special case), nor to argue against the selection of several different aluminum alloys in the same structure.

Other physical properties affected by composition are the electrical and thermal conductivities. These effects may be substantial. Typical values are shown in Columns (10) and (11), respectively, of Table 6.

*Remainder, aluminum plus normal impurities. † "Common alloys". ‡ Minimum allowable.

Effect of Cold Working.—As with other common metals, cold working affects the mechanical properties of aluminum and all its alloys. All the various strength properties, stiffness, and endurance values are increased, and the plasticity, malleability, reduction in area, and elongation, are decreased. The modulus of elasticity is not affected.

For certain types of deforming operations, such as the cold rolling of sheets, in which the reduction in thickness is an accurate measure of the degree of cold working, a formula has been developed by R. L. Templin,[62] M. Am. Soc. C. E., which permits the prediction of the new tensile strength after the material has been reduced in thickness any specified amount. This formula is,

$$T = T_0\ (1 + 0.9\ R) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which T = the new tensile strength, in pounds per square inch; T_0 = the tensile strength of the properly annealed metal; and R = the reduction in thickness expressed as a decimal. Aluminum products which have undergone an 80% reduction of cross-sectional area by cold working, without intermediate annealing, are considered "hard", and the rate of strain hardening up to this point may be considered constant. Equation (2) applies to cold working up to the equivalent of $R = 0.80$. Mr. Templin[63] also shows the relationship between the tensile strength and the yield strength, and offers a formula to calculate the new elongation. As these latter formulas are rather complex, and as their use is based upon certain limitations, too lengthy to include in this paper, the reader is referred to the quoted

[62] "The Aluminum Industry", Vol. II; "Aluminum Products and Their Fabrication", Edwards, Frary, and Jeffries, p. 406.

[63] *Loc. cit.*, p. 410.

reference. As a general rule the yield strength increases and the elongation decreases during the early stages of cold working at a much more rapid rate than the tensile strength increases. In annealed material, the yield strength is about one-third the ultimate tensile strength. With about 20% or more of cold working the yield strength is about 80 to 95% of the ultimate strength.

However, most of the forming methods are complex, or deform various portions of the metal in different amounts; for example, in forming a simple right-angle bend, only that portion of the metal approximately included within the bending arc becomes worked, and that to a variable extent. The fibers along the inside surface will have been subjected to compression, whereas those on the outer surface will have been subjected to stretching, both of which types of deformation affect the metal in the general manner just indicated. No formula has yet been devised which measures the magnitude of such working. When forming a shape in a draw press, the metal is stretched in a longitudinal direction and is deformed under compression in a transverse direction with usually no appreciable change in thickness. Furthermore, as the metal slides over the radius of the die, it is first bent 90° and immediately thereafter it is re-straightened. Such a complex deformation introduces a large amount of working. No formula exists, which predicts the degree of the cold work nor, quantitatively, the values of the new set of properties. Although certain problems would be simplified if such formulas were available, their non-existence is not a particularly serious handicap.

It is the fabricator's task to fashion the metal into the shape and design as specified without fracturing it. He must depend on his own past experience and that of others in like or similar cases, and to "cut and try" methods. If a sample specimen fractures upon attempting to form a certain bend, a larger forming radius must be used, or a softer temper, and perhaps the shaped part will have to be hardened by heat treatment. The manner in which the working is performed may be important at times; for example, when forming a rivet head, it is preferable to accomplish the deformation by one squeeze or by a few sufficiently heavy blows, rather than by a great many lighter blows. Under the action of one continuous squeeze, the metal is quite uniformly worked throughout its mass. With many light blows, a much larger percentage of the energy is first absorbed by the surface layers before the centrally located portions have become deformed at all. If carried to the extreme, such surface hardening may be the cause of starting surface cracks before a satisfactory head will have been formed. The principle in this case is that cold working hardens the material and gradually depletes its capacity to withstand additional cold deformation. The rate of this effect varies among the metals. Tin and lead harden but very slowly; copper, iron, and aluminum harden much more rapidly. The alloys of aluminum (and this is generally true for the other metals) harden more rapidly than the pure metal; that is, with large total amounts of cold deformation a re-softening (annealing) might be necessary with the alloy, whereas this might not be required with the pure metal.

The engineer, on the other hand, is interested mainly in this matter of work hardness, in terms of the capacity of the finished structure to perform

its intended purpose satisfactorily. This involves at least two questions: (1) Will the newly made structure possess adequate strength? and (2), will it retain that strength under the anticipated service conditions?

Because of lack of 100% accuracy of design methods, regardless of metal, influenced partly by the inability of any formula to take into consideration all the tolerances necessitated by commercial limitations, the answer to the first question is frequently determined by testing sample structures and accurately measuring the stresses induced in various members. With reference to the second question, it can be stated for aluminum and its alloys that the effects of cold work remain substantially constant unless some subsequent heating, sufficient in magnitude, should cause some change in the properties of the metal.

Cold work has little effect on the corrosion resistance of the aluminum alloys. As a matter of fact, there is some evidence that cold working may be slightly beneficial. Tests indicate that an alloy containing aluminum, copper, magnesium, and manganese (Item No. 4, Table 6) which has been heat treated and subsequently further reduced by cold working, is somewhat more resistant than the same alloy, heat treated but without the additional cold work. However, the magnitude of this difference is insufficient to give it commercial importance, other than to offer assurance as to the harmlessness of such cold work.

Cold work does not affect the weldability of any of the aluminum alloys. This would appear obvious as the heat, introduced by the welding operation, merely removes the effects of the cold working before the temperature of the metal has reached the point where welding can take place.

Cold work does not appreciably affect the specific gravity nor the thermal expansion. The electrical and thermal conductivity may be slightly reduced as indicated in Table 6.

Effect of Heating and Cooling.—When any aluminum alloy that has been merely cold worked is heated to its annealing temperature the effects of that cold work are removed immediately. This operation is called "annealing." Details of proper annealing practice for the several alloys are well covered by existing literature and will not be repeated herein. This softening effect is of importance to the fabricator as occasionally he must have recourse to annealing in order to re-soften the metal and thus permit of further cold deformation. Any of the aluminum alloys may be cold worked, annealed, and further cold worked any number of cycles desired. If the annealing is performed correctly, the product will possess properties identical with those of the annealed temper.

It is preferable to heat the material rapidly as this is conducive to producing a fine crystal structure—a coarse structure being somewhat weaker. The more rapid the heating, the finer the metal structure. This is more critical with small amounts of cold work (equivalent to about 4% reduction in thickness) than with larger amounts.

In the annealing of the "common alloys" (that is, those not susceptible to increasing strength by a "heat-treating" operation), no particular precaution

or care need be exercised against heating the metal somewhat above the required annealing temperature. Of course, heating the metal to, say, 800° F, when 650° F would have accomplished all that was desired, is unnecessary. It would be of value to have the furnace temperature substantially above the desired final metal temperature in order to re-crystallize quickly and thus obtain the finest crystal structure possible, but the load should be removed when the metal has reached the desired temperature. The feasibility of utilizing such a procedure depends on the particular furnace. Continuing to heat the metal beyond that point, and holding it there, is conducive to causing a coarser and, hence, less desirable crystal structure. Although no harm will result should the metal cool rapidly, such cooling is not generally of value. Something might be said in favor of permitting the mass to cool slowly on the grounds that the central portions of the load might not have reached the desired temperature, and such discrepancy would tend to be corrected by permitting a large mass to cool slowly.

With heat-treatable alloys, the principles are somewhat different. This can be better appreciated after covering the matter of heat treatment of aluminum alloys. No attempt will be made to describe in detail what occurs within the internal structure during and following the heat-treating operation. This also is well covered in the literature. Only a very brief résumé will be given herein.

The heat treatment of the aluminum alloys involves heating the metal to specified elevated temperatures, so as to put certain constituents in solution in amounts greater than their solubility at room temperature. Upon quenching the alloy, after such heating, it is in an unstable condition because of the excess of constituent in solution. This excess tends to precipitate, the effect being observable by an increase in strength, hardness, and reduction in general workability, but with no lowering of elongation values. In the case of certain alloys, such as the aluminum-copper-magnesium-manganese type, previously mentioned, this precipitation and self-hardening occur spontaneously at ordinary temperatures, very rapidly over the first few hours after quenching and gradually diminishing in intensity, substantially completing itself in about three or four days. The rate of this action may be retarded or completely postponed by placing the freshly quenched material in cold storage. Alloy 17S (Item No. 6, Table 7), when freshly quenched and placed in storage at 0°C, shows no precipitation after several days. Upon removing the material from cold storage and permitting it to warm again to ordinary temperatures, precipitation commences and continues in a normal manner. Advantage is taken of this delay in precipitation when it is desired to heat treat and quench a relatively large quantity of material at one time and maintain it in a soft and more workable condition for some days prior to forming the entire amount. Other compositions require a re-heating for several hours at temperatures approximating 300° F to cause this precipitation to occur to its maximum amount. The first heating and quenching cycle is termed "solution heat treatment," whereas the second type of heating is termed "precipitation heat treatment."

The foregoing indicates several principles of particular importance to the metal fabricator and the structural engineer. The highest strengths obtainable from these alloys result from heat treatment, although, of course, if the metal is subjected later to cold working the strengths may be increased still further. The fabricator frequently makes use of the fact that the metal is softer and more workable after the solution heat treatment, and before aging or precipitation has progressed to any substantial extent, by forming promptly after quenching. In certain more difficult cases, the metal may be formed in the annealed temper and the shape then heat treated.

Although each alloy has its most suitable heat treatment temperature, substantial solution of the constituent occurs below this optimum temperature and, in fact, the solution commences shortly above the annealing temperatures. Hence, when annealing the heat-treatable alloys, if fully annealed properties are desired, it is important to adhere as closely as possible to the recommended annealing temperature—namely, 650° F plus or minus 10 degrees. The rate of cooling is not important if these temperature limits have been observed. However, if these temperatures have been exceeded unintentionally, heat-treating effects may be avoided by slow cooling. As an extreme illustration, Alloy 17S (Item No. 6, Table 7), fully heat treated may be converted to the annealed condition by heating at 800° F for 2 hr and then cooling at a rate not exceeding 50° F per hr to less than 500° F. Occasionally, it is desired to produce some substantial softening, although without necessarily obtaining true annealed properties. In such an event, greater liberties may be taken with respect to temperatures and rate of cooling.

As the temperature of aluminum alloys is raised, the malleability and plasticity are markedly increased and the strength properties and resistance to deformation are decreased[64]. The metal fabricator may use this principle either to permit forming especially heavy sections, with less energy input than would be required by cold working, or to permit a severity of deformation that could not be accomplished cold without the metal fracturing. Even heating to as low as 400° F facilitates forming to a substantial extent. Occasionally, the material is heated to its proper heat-treating temperature and then, while still hot, pressed into the required shape, the cold dies producing substantial quenching effects[65].

There is not much difference in the resistance to corrosion between the several tempers of any common aluminum alloy. The word, "temper," in aluminum parlance, signifies any of the several metallurgical conditions in which wrought aluminum or its alloys is produced. For example, Item No. 2, Table 6 (containing 1.25% manganese, with the remainder of aluminum plus normal impurities) is produced in several "tempers:"

The soft temper is produced by annealing the alloy to remove the effects of cold working. The harder tempers are produced by strain hardening the

---

[65] U. S. Patent 1 751 500.

alloy by varying amounts after it has been annealed. The alloy that has been cold worked the maximum amount practicable in commercial manufacturing operations, is said to be in the hard temper. By proper selection of the amount of strain hardening, the quarter-hard, half-hard, and three-quarter-hard tempers are produced, in which the tensile strengths are intermediate between those of the soft and the hard tempers in the manner indicated by the fractional designations. As these various tempers are merely the result of cold work, and as heating merely removes this cold-work effect, heating common alloys has no material effect on the resistance to corrosion. The facts are different with the heat-treatable alloys. In the case of Item No. 6, Table 6, the temper possessing the greatest resistance to corrosion is the heat-treated condition. Heating this material at temperatures much in excess of 212° F, for any substantial length of time, impairs its resistance. On the other hand, Item No. 13, Table 6, possesses an excellent and like corrosion resistance in any temper and, hence, heating any particular temper of this alloy produces no effect on its resistance. As a general rule, the heat-treatable alloys are in their most resistant state when they have been subjected to solution heat treatment. However, there are exceptions, as noted. Hence, when resistance to corrosion is of real importance, and it is intended to heat the material, the specific characteristics of the particular alloy should be ascertained and procedure governed accordingly. For example, the heat introduced by torch welding is sufficient, for the most part, to remove the heat-treatment effect, and so adversely affect the resistance to corrosion of a small area on either side of the weld in Item No. 6, Table 6 (heat-treated temper). On the other hand, in the case of Item No. 13, Table 6, no such harm results. The detailed facts are well known and are available either in present publications or from the producer of the alloy.

Whether or not the alloy may have been heated previously, has no effect upon its inherent weldability. However, in certain cases, a previous thermal treatment might increase the quantity of the oxide film on the surface of the metal and this, in turn, may affect the ease of welding. Upon heating Item No. 6, Table 6, to rather elevated temperatures, an oxide film is formed that interferes quite markedly with spot welding. For this reason, in order to spot weld or seam weld Item No. 6 (the heat-treated temper) the surface along the line of welding should be cleaned with emery cloth to remove this heavy oxide film. This is not necessary in the case of all compositions. This, again, is a matter of specific information which, however, is available.

Heating may affect certain other physical properties. When heating merely removes strain hardening, the effect upon electrical and thermal conductivity is just the reverse of introducing cold work, as previously mentioned. In the case of those alloys in which heating changes the degree of solution of certain constituents, the general rule is that, as the quantity of constituent put into solution increases, the electrical and thermal conductivity decreases. This is illustrated in Table 6. Heating and cooling have no appreciable effect on specific gravity.

Available Forms and Specific Properties of Structural Aluminum Alloys

Wrought Products.—Table 7 shows the nominal composition and the mechanical properties of those wrought alloys of interest in structural fields.

[a] See corresponding Item Numbers in Table 6. [b] Cold worked after its last annealing sufficient to raise the ultimate tensile strength to a point half way between the annealed and the full hard tempers. [c] Forgings only. [d] Extruded shapes. [e] Minimum allowable. [f] Traces. [g] Equal proportions of manganese, chromium, and molybdenum. [h] Except as noted these values are for $\frac{1}{16}$-in. sheets. [i] These values are for 0.505-in. round bars. [j] Known commercially as Nicral.

In some cases these compositions and heat treatments are protected by patents. Column (3), Table 7, indicates that the remaining material, other than the alloying elements, is aluminum plus normal impurities, such as iron and silicon. For the specimens listed, Young's modulus of elasticity is approximately 10 300 kips per sq in. Column (13), Table 7, contains the yield-strength stress that produces a permanent set of 0.2% of the initial gage length[66].

Referring to Column (16), Table 7, it is to be noted that the elongation will vary somewhat with the form and size of the specimen. The Brinell hardness test (Column (17), Table 7) involved a 500-kg load, exerted on a 10-mm ball. The values in Column (14) are single shear values, computed from double shear tests. The endurance limit (Column (15), Table 7) is based on a 500 000 000-cycle of complete reversed stress, using a standard form of machine and specimen[67].

There are well developed and standardized procedures for determining the mechanical properties and other characteristics of metals and there are well defined and accepted units of measurement by which these properties may be expressed[68]. On the other hand, in the case of resistance to corrosion, no such unit of measurement exists. This quality is evaluated by various empirical tests co-ordinated with actual field performance[69]. These observations merely indicate how one metal, or an alloy of a metal, behaves under certain corrosive conditions on a relative basis with another. Thus, the resistance to corrosion of a certain grade of aluminum cannot be given a rating of D, whereas another grade of another metal would be assigned a rating of E (in which the letters are supposed to possess definite numerical value). One can only state that the first is "somewhat superior" or "very much superior" or "inferior" to the other. After due experience of course, one can state, correctly, that Metal A will perform satisfactorily in a certain service, whereas Metal B will not. An attempt to list the relative resistance of the various products in tabular form would be misleading, as any correct rating should take into consideration the various forms in which the alloys are available and the service conditions applicable in any case. Although the resistance to corrosion of Item No. 9, Table 7, heat-treated, is not as great as that of Item No. 8, similarly treated, the former is utilized primarily as forgings, relatively thick in section, whereas the latter, which is not available as forgings, is normally used in thin sections, and usually under far more severely corrosive conditions. The resistance to corrosion of forgings made of Item No. 9, has proved quite adequate in the fields where they are adopted. The matter, therefore, can best be treated by discussion rather than by any table.

In general, it can be stated that aluminum alloys belong to the class which may properly be described as metals resistant to corrosion. Items Nos. 1, 2, 4,

[66] Specification E8-33, Am. Soc. for Testing Materials.

and 13, Tables 6 and 7; and Item No. 3, Table 7, in all tempers, possess superior resistance. In fact, except under the most severe service, such as the marine, they usually need not be painted for protection. Referring to Table 7, Items Nos. 5, 6, 7, 8, 10, and 14 (heat treated) and Item No. 11 (in all tempers), are next in order and substantially equal. Normally, they should be painted, although, in relatively heavy sections, such as would generally be used with forgings of Item No. 5 (heat treated), this might not be necessary. Next, would come Item No. 15, Item No. 9 (heat treated), and Items Nos. 6 and 8 (annealed). The most satisfactory way for the prospective user to take care of this subject is to consult with the manufacturer who is to supply the material.

Aluminum alloys are available in the form of sheets, plates, wire, rods and bars, rolled and extruded shapes, tubing, rivets, and forgings, although not all the compositions listed in Table 7 are available in all these forms. Table 8 shows those forms that to-day are classed as "standard"; that is,

are regularly produced in routine commercial production. Exceptions are made when warranted; for instance, although Item No. 6 (heat treated), is the only composition regularly carried in stock in the form of rolled shapes, Item No. 10 (heat treated), has been produced in rolled shapes when the quantities required, have justified it.

Plates are being produced as heavy as 2 000 lb. Although there are limitations as to sizes of certain alloys and tempers, they are available in widths of as much as 120 in. and lengths as determined by the 2 000-lb weight. Heat-treated rolled shapes in various sections and sizes up to 12-in. channels are produced in lengths as great as 85 ft. Heat-treated extruded shapes are available in lengths of about 50 ft.

Item No. 6, Table 8, (17S) is available in all the various forms, and because it presents an unusually favorable combination of properties, it has ranked as the most generally useful of the strong alloys.

The particular merits of Item No. 10 (heat treated) (27S-T) are its relatively high yield strength and the fact that, as this temper is produced by aging for some hours at approximately 300° F, neither the mechanical properties nor the corrosion resistance is impaired should the material be re-heated to this temperature, or even to slightly higher temperatures. This behavior is of significance because it permits the use of hot-driven steel rivets in joining heat-treated members composed of this alloy, without fear that the heat, thus introduced, will adversely affect the properties of the aluminum parts. The most noteworthy applications of Item No. 10 (heat treated) to date, comprise the rehabilitation of the floor of the Smithfield Street Bridge[70], Pittsburgh, Pa.; the floor of the Stratford Avenue Bridge, Bridgeport, Conn.; the side walk and railing of the Covington-Cincinnati Suspension Bridge[71], across the Ohio River; and the railings on the Laredo Bridge, in Texas. A thorough study has been made, contemplating the use of aluminum for the trusses and floor of the famous Brooklyn (N. Y.) Suspension Bridge[72].

The corrosion resistance of Item No. 13, Table 8, (53S) which is of a high order, is substantially the same in all tempers. It is for this reason that this alloy has found wide use in the construction of sewage disposal plants, in the form of extruded sections in the architectural industry for the fabrication of windows and frames, doors, building fronts, and various ornamental constructions. Increasingly, such items have been treated by a patented process, which applies a hard, weather-resistant, and corrosion-resistant coating and one that facilitates cleaning.

Cast Products.—Table 9 gives the composition of castings that are of widest interest to the structural engineer and shows their typical mechanical properties.

As will be noted, the heat-treated, aluminum-copper (Item No. 23, Table 9) and aluminum magnesium (Item No. 24), alloys are the strongest. Item No. 23, Table 9, has been used rather extensively since about 1920, whereas the alloy (Item No. 24) is a more recent development and still requires special handling in the foundry. The latter represents the highest combination of strength and shock resistance yet attained in aluminum castings and is especially desirable for large sections. It has given good service performance as parts of large shovel dippers. Fig. 27 shows the back of a 7-cu yd dipper, 6.83 ft long, 4.90 ft wide, and 3.0 ft deep, weighing 2 326 lb. Fig. 28 shows one hinge for a 32-cu yd dipper, 12.58 ft long, 5.25 ft wide, and 1.50 ft deep, weighing 2 242 lb. These castings are of Alloy 220 (Item No. 24, Table 9).

* In the case of some of these alloys, the composition or heat treatment, or both composition and heat treatment are patented.

† Plus normal impurities, such as iron and silicon.

‡ Different type of heat treatment.

This should be considered a special alloy for unusually severe service. The alloy (Item No. 20) is used where service conditions require the maximum resistance to corrosive attack. It is more difficult to cast into intricate, leak-proof castings than the aluminum-silicon alloys, but has higher mechanical properties than

FIG. 27.—ONE HINGE FOR 32-CUBIC YARD DIPPER.

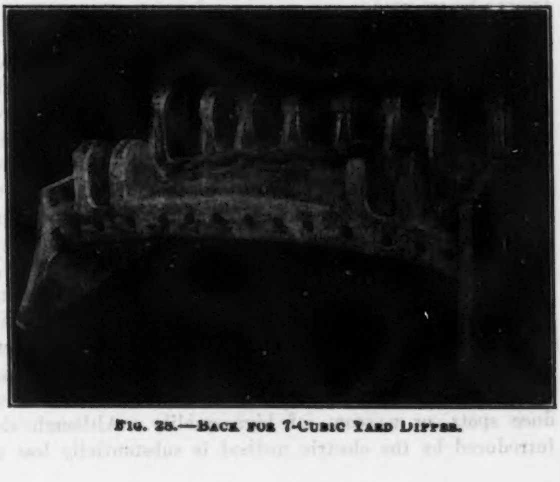

FIG. 28.—BACK FOR 7-CUBIC YARD DIPPER.

the alloy listed as Item No. 16, in Table 9, and is distinctly more resistant to corrosion. For this reason, it is utilized in the production of castings for use in sewage disposal plants, and for marine applications. The alloy (Item No. 21) is in a somewhat similar category, with equal resistance to corrosion, higher tensile and yield strengths, but with somewhat lower elongation.

The founding of aluminum alloys differs in many respects from that pertaining to other metals; in fact, each metal possesses its own foundry characteristics. It is important, therefore, when considering the detail design of any particular casting, and especially the pattern, to consult with the foundryman in order to permit of certain small modifications in design that might enable simplification of foundry problems, with consequent reduction in cost, that will insure the highest and greatest uniformity of properties.

The size and complexity of castings that can be produced varies so much with the particular instance that no general specifications can be given.

Metallurgical Aspects of Fabricating Structural Aluminum Alloys

Aluminum alloys are almost always cut by mechanical means, such as shearing, sawing, or machining. Torch cutting is seldom recommended because of the high heat conductivity which makes this method impractical. Furthermore, the heat introduced would have adverse effects in certain instances, as previously discussed.

Aluminum alloys are formed by all the common methods, although they are usually done cold. They are occasionally formed hot for heavy sections and for forging, although consideration should be given as to whether the degree of heating has adversely affected strength or resistance to corrosion, and whether the shaped part should be re-heat treated.

Joints are fabricated by torch, electric spot, seam, arc, and butt welding, and by riveting and bolting. The choice of method depends upon the results desired and as influenced by the effect of heat upon the particular alloy or temper being used.

When using rivets larger than ⅜ in. in diameter, the present usual practice is to use hot steel rivets. Due to the high heat conductivity of aluminum, the heat thus introduced is rapidly dissipated with small chance of harmful results, especially when the rivets are driven in a scattered manner. In sizes smaller than ⅜ in., rivets are driven cold and, in the case of Alloy 17S (Item No. 6, Table 7), promptly after quenching before age hardening has progressed to any extent. Use is also made of the fact that this aging is arrested by placing the freshly quenched rivets in cold storage as previously mentioned. This process avoids the necessity of co-ordinating the heat treating and driving operations.

Torch welding requires the use of a flux, which should be removed later by a thorough washing to prevent a chemical attack of the metal.

Because of the high thermal and electrical conductivity of aluminum, the ordinary electric welder is not suitable. Suitable spot and seam-welding equipment has been developed, which can be relied upon, consistently, to reproduce spots, or a seam, of high quality. Although the quantity of heat introduced by the electric method is substantially less than that arising in

torch welding, the effect of such heat should be considered. Arc welding is also being developed rapidly and is beginning to find commercial application. In this case, also, the amount of heating is substantially less than with torch welding, and harmful or annoying effects upon resistance to corrosion, or distortion, are greatly minimized. In general, torch welds of common alloys should be designed on the basis of the annealed temper. Although the heating does not fully anneal the heat-treated materials, there will be some softening and some over-aging in a small area on either side of the weld, thus reducing the strength and usually the resistance to corrosion. This effect can be corrected partly by a re-heat treatment. Usually, therefore, the strong alloys are not torch welded. The heating effects by the electric method are sufficiently less than by other methods so that it is coming into increasing use, especially in lighter work.

PART II.—MAGNESIUM

Historical

Although magnesium was isolated as an element as early as 1830, production of the metal on a commercial scale was not attempted until 1900 so that it can be truly called a product of the Twentieth Century. Historically, it was first produced about 1808 as a mercury amalgam by Sir Humphrey Davy who reduced the heated oxide with potassium vapor. In 1830, Bussy, the French chemist, obtained a fairly pure product by reducing magnesium chloride with potassium. In 1856, Deville and Caron used sodium for the reduction of the chloride followed by distillation in hydrogen, but the resulting metal was impure because of the presence of sodium and air reaction products. In 1863, Sonstadt developed a process in England based on the reduction of the anhydrous chloride by sodium, and a company was organized for small quantity production.

Commercial success was slow and the industry was of little importance until the electrolytic process was developed in Germany in the early part of the century. The development of fabricated products, such as sheets, castings, extrusions, and rods was undertaken and added considerably to the uses for the metal. The metal and its alloys were made and marketed under the name, Elektron, and, to-day, in England and on the Continent, this trade-mark is synonymous for magnesium alloys. Interest in the production of magnesium in the United States came in 1915 when the World War prevented importation from abroad.

General Metallurgical Principles of Structural Magnesium Alloys

Effect of Composition.—At present, most of the magnesium base alloys used in the United States, for structural purposes, are either ternary magnesium-aluminum-manganese or quaternary magnesium-aluminum-zinc-manganese alloys. The principal exception is the binary magnesium-manganese alloy which is used, preferably in the wrought condition, in applications where resistance to corrosion and ease of forming and welding are the chief requirements.

All the magnesium alloys now used for engineering purposes contain manganese. The binary magnesium-manganese alloys, usually containing 1.2 to 2.0% manganese, possess the greatest resistance to atmospheric and salt-water corrosion of any of the known magnesium base alloys, and manganese is added to the alloys containing aluminum, or aluminum and zinc, to enhance their resistance to corrosion. The manganese content of these alloys is rather definitely limited by the quantity of aluminum present and the possible variations are without influence on the more commonly determined physical properties. There is some evidence, however, that the addition of manganese to a wrought binary magnesium-aluminum alloy causes a marked increase in the proportional limit.

At present, aluminum is the most important element added to magnesium to produce structurally useful alloys. Alloys in commercial use in the United States contain aluminum in quantities varying from 3 to 13 per cent. Additions of aluminum in this range cause a marked increase in mechanical properties in both the cast and the wrought conditions.

Increasing the aluminum content of magnesium alloys causes changes in density, thermal conductivity, and electrical resistivity; but, in quantities up to 12% at least, the coefficient of thermal expansion is not greatly affected. The mean coefficient of expansion, a, for magnesium alloys from 0°C to any temperature, t, may be obtained from the following equation[illegible]:

$$a = (25.07 + 0.00936\ t)\ 10^{-6} \qquad (3)$$

The changes in density, thermal conductivity, electrical resistivity, tensile properties, and hardness brought about by the addition of increasing amounts of aluminum to magnesium are shown in Figs. 29 to 32, inclusive. In the sand-cast alloys, still other combinations of properties than those shown in the graphs may be obtained by aging heat-treated alloys containing more than about 8% aluminum.

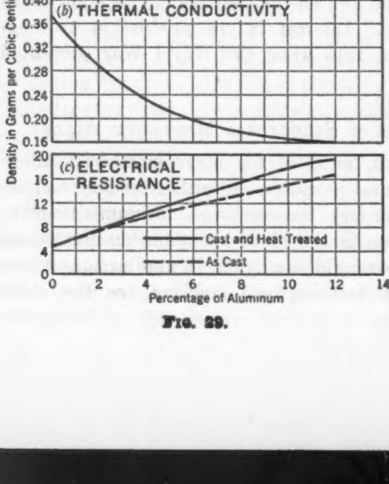

FIG. 29.

The shear strength and the compressive strength of magnesium-aluminum alloys tend to increase with the aluminum content in both the cast and the wrought conditions although this relation is more regular in the case of the wrought alloys. The shear strength of extruded pure magnesium is 16 kips per sq in. Additions of aluminum increase this value to a maximum of about 26 kips per sq in. in alloys containing 12% aluminum.

Additions of aluminum and zinc (either one or both) increase the endurance limit of magnesium

alloys at least up to the point where the combined content of alloying elements amounts to 10 or 11%; beyond this amount, reliable data on endurance limit are lacking. Numerical data as to the endurance limits of magnesium alloys are given in Table 10.

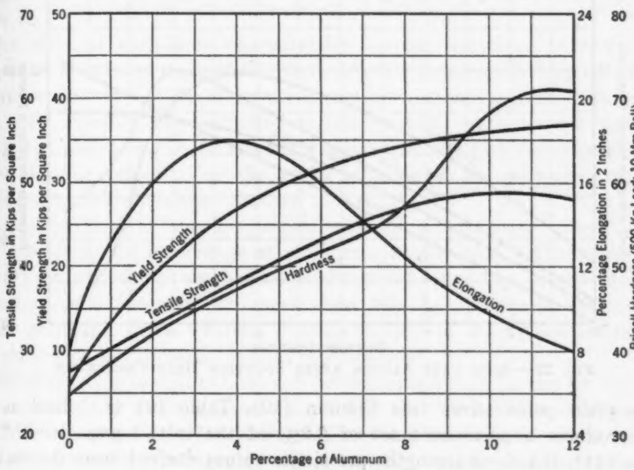

FIG. 30.—EXTRUDED ALLOYS.

The form in which these alloys are usually fabricated is as follows: Extrusions, Items Nos. 29, 30, 31, 32, and 33; sheets, Items Nos. 29 and 30; die castings, Item No. 38; sand and permanent mold castings, Items Nos. 34,

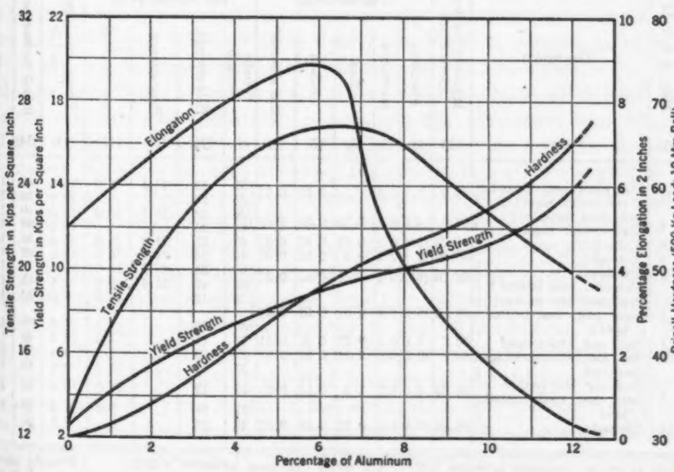

FIG. 31—SAND COST ALLOYS.

35, and 36; and, sand and semi-permanent mold castings, Item No. 37. Column (8), Table 10, gives the total allowable impurities, of which copper and nickel may not exceed the amount indicated in the starred footnote.

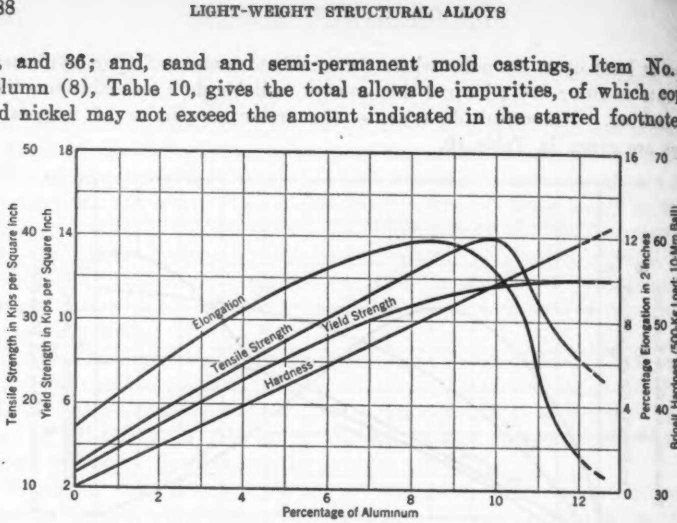

FIG. 32.—SAND CAST ALLOYS AFTER SOLUTION HEAT TREATMENT.

The yield point stress (see Column (10), Table 10) is defined as that which produces a permanent set of 0.2% of the initial gage length[66]. In Column (11), the shear strengths are single values derived from double shear

TABLE 10.—NOMINAL COMPOSITION AND TYPICAL MECHANICAL PROPERTIES OF MAGNESIUM ALLOYS

Item No.	Alloy, A. S. T. M.§	Description	Magnesium content (percentages)	Alloying Elements (Percentages): Aluminum	Manganese	Zinc	Silicon	Other elements*	Unit Stresses, in Kips per Square Inch: Tensile strength	Yield strength	Shear strength	Endurance limit	Percentage elongation in 2 in. * Such as copper (maximum allowable, 0.05%) and nickel (maximum allowable, 0.03%). † Wrought material. ‡Maximum allowable. §See A. S. T. M. Standards on Magnesium Base Alloys, 1936. Specifications B 92-36 T, B 93-36 T, B 80-36 T, B 94-34 T, B 90-36 T, B 91-36 T, B 107-36 T.

tests. The Brinell hardness number was based upon a 500-kg load on a 10-mm ball; and the endurance limits (Column (12), Table 10) were based on 500 000 000 cycles of stress. Composition has little influence on the modulus of elasticity. An average value suitable for design purposes is 6 500 kips per sq in.

The effect of aluminum concentration on the resistance to corrosion of magnesium-aluminum-manganese alloys depends to a considerable extent upon the microstructure. If the alloys are homogeneous that is, if all the aluminum is in solid solution, the corrosion resistance will decrease with increasing aluminum content, but if the alloys are heterogeneous, with considerable undissolved Mg_3Al_2 compound in the grain boundaries, the corrosion resistance will increase with aluminum content.

Torch welding of the magnesium-aluminum-manganese alloys becomes more difficult as the percentage of aluminum is increased. Alloys containing 4 to 5% of aluminum are welded without difficulty, but as the aluminum concentration is increased to more than 5%, hot shortness and cracking become gradually more serious. Torch welding of alloys containing more than about 8% aluminum is seldom recommended.

The alloys of magnesium used for structural purposes in the United States at present do not contain more than 3.5% zinc, and alloys with as much zinc as this are used only for casting. Zinc tends to make the alloys hot-short and for this reason the wrought alloys usually contain not more than 1% of this element. Like aluminum, zinc forms solid solutions with magnesium, and variations in zinc content are capable of producing changes in the mechanical and physical properties of the alloys.

The addition of zinc to binary alloys of magnesium and aluminum causes them to become more difficult to hot work and makes them less weldable. On the other hand, the addition of zinc usually improves the corrosion resistance and is slightly more effective than the equivalent percentage of aluminum in raising the tensile strength, yield strength, and hardness.

In the case of the magnesium-aluminum-zinc-manganese alloy used in the form of castings and containing a nominal 6% aluminum and 3% zinc, the zinc enters solid solution only after heat treatment and the changes in mechanical properties brought about by the zinc in this alloy are greater than can be obtained by adding an equivalent percentage of aluminum. In the sand cast condition, the 6% aluminum, 3% zinc alloy is stronger, more ductile, and tougher, and has a higher endurance limit than an alloy containing 9% aluminum. In the homogeneous heat-treated condition, the difference in mechanical properties is not marked, but the resistance to corrosion of the zinc-bearing alloy is very much superior to the 9% aluminum alloy. When these two alloys are artificially aged to enhance the yield strength and hardness, the beneficial influence of the zinc is again evidenced by greater strength, toughness, ductility, yield strength, and endurance limit combined with better resistance to corrosion than can be produced in the 9% aluminum alloy.

Although it is possible to weld alloys containing appreciable quantities of zinc, it becomes more difficult with increasing quantities. When the zinc content of wrought material is greater than 1%, or when the aluminum + zinc

content is 9% or more, hot-shortness and cracking become so serious that welding is not usually recommended.

Effect of Cold Working.—Magnesium and all magnesium alloys work harden very rapidly and, in general, the rapidity of work hardening increases with the quantity of alloying material present. Pure magnesium and the binary magnesium-manganese alloy sheets may be cold rolled about 25% before failure occurs, but magnesium-aluminum-manganese alloy sheets containing 4% aluminum harden more rapidly and are seldom cold rolled more than 15 per cent. Magnesium alloys are so refractory toward cold deformation that practically all wrought forms are produced by hot working and, for the same reason, practically all forming and shaping operations on magnesium alloy sheets, plates, tubing, or structural shapes are performed at elevated temperatures in the range from 225° to 350° C (437° to 662° F).

In common with other metals, magnesium alloys with sufficient plasticity to withstand cold working may be strengthened and hardened by this process. The effect on the mechanical properties may be seen by referring to Table 10, which gives the properties of sheets in the soft and hard tempers. It has also been found that cold working extruded alloys slightly (1%) by stretching has a beneficial effect on their properties. The stretching operation increases the tensile and yield strengths without reducing the ductility.

Cold-worked sheets usually have a slightly lower resistance to corrosion than annealed sheets of the same composition.

Effect of Heating and Cooling.—A comprehensive discussion of the effect of heating and cooling on magnesium alloys is impossible in the limited space of this paper. The effect of heating varies with the composition of the alloy, its previous history, the temperature to which it is heated, and the length of time it is held at high temperature.

When cold-worked magnesium alloys are heated, they become re-crystallized and consequently soft, and they lose tensile strength, yield strength, and hardness. This type of heating is termed annealing and a common method of annealing cold-worked magnesium is to bring the mass of metal to 650° F and allow it to cool in air. Sudden cooling of annealed material does no harm, but would serve no useful purpose. Hot-worked magnesium alloys, such as extrusions and forgings, usually have the best mechanical properties in the "as worked" condition and annealing tends to reduce the tensile and yield strengths without increasing the ductility. Wrought material is usually formed at temperatures that will anneal the metal and, for this reason, the heating to forming temperature should be as rapid as possible and the time at temperature should be curtailed. Annealing of magnesium-alloy castings is without benefit and, in many instances, will result in lower properties.

Magnesium alloys are amenable to heat treatments of the same type as those used for aluminum alloys as described in Part I; that is, a supersaturated solid solution of the alloying element or elements is effected by heating to a relatively high temperature followed by rapid cooling. This produces a structure that is substantially homogeneous, with certain characteristic mechanical properties associated with such a structure. If the maximum obtainable yield strength and hardness are desired, the solution heat treat-

ment is followed by heating the quenched (homogeneous) material for various times at lower temperatures, usually 12 to 20 hr at 300° to 350° F. This second heating or "artificial aging" is necessary because magnesium alloys do not age-harden at room temperature to any appreciable extent. The heat-treating temperature necessary to make them homogeneous depends upon the alloying constituent. Zinc may be put into solid solution at about 630° F, whereas 750° to 810° F is frequently used to effect the solution of the aluminum constituent.

As mentioned previously, wrought magnesium alloys generally possess their best mechanical properties in the as-worked condition and, for this reason, wrought alloys are seldom heat treated. In the case of magnesium alloy castings, however, heat treatment produces such a marked improvement in properties that the great majority of the castings supplied to the trade in the United States are in the heat-treated condition. The effect of heat treatment on the mechanical properties of cast magnesium alloys is shown in Table 10.

Heating and cooling have no effect on the welding characteristics of magnesium alloys nor on their specific gravity except that heat-treated and quenched alloys high in alloy content tend to "grow" very slightly if used at elevated temperatures. In common with aluminum alloys in which heating changes the degree of solid solution, the general rule is that, as the quantity of constituent put into solid solution increases, the electrical and thermal conductivity decreases.

The effect of temperatures encountered under service conditions must be taken into account when using magnesium alloys for engineering purposes. Although sub-normal temperatures as low as — 112° F have little or no effect on the mechanical properties, they undergo appreciable change at temperatures of approximately 300° F and more. Considerable data as to the effect of elevated temperatures on the properties of magnesium alloys are available and the one who is to supply the material should be consulted before magnesium is utilized in structures operating at elevated temperatures.

AVAILABLE FORMS AND SPECIFIC PROPERTIES OF STRUCTURAL MAGNESIUM ALLOYS

Wrought magnesium alloys are available as extrusions, sheets, plates, and forgings. Bars, rods, and structural shapes are produced by the extrusion process because of the readiness with which magnesium alloys may be worked in this manner. Rolled shapes and sections in high-strength magnesium alloys are not available at present. Because of the equipment and ingot sizes available, present extruded sections are limited in weight to about 300 lb and in size to sections corresponding to a standard 6-in. channel or I-beam. Rough press forgings are limited in weight to about 200 lb, whereas die forgings produced by hammering are limited to the forming capacity of an 18 000-lb hammer. Under present conditions obtaining in commercial fabricating plants, plates or sheets are limited in weight to about 80 lb, with a maximum width of 60 in. and a maximum length of 240 in.

Cast magnesium alloys are available as sand castings, permanent mould castings, and die castings. There are alloys readily adaptable for fabriction by all three methods, and the mechanical properties obtained compare favorably with aluminum alloy castings used for similar purposes. Particular atten-

tion is called to the high endurance limit of magnesium alloy castings as compared with most aluminum-base alloy castings. It should be mentioned, however, that sharp corners, notches, and other "stress raisers" seriously reduce the endurance limit of magnesium alloys, and this fact must be kept in mind when using such alloys in stressed structures.

Magnesium die castings and permanent mould castings are limited in size only by the die or mould equipment available. There is no inherent reason why magnesium castings of this type cannot be produced in the same sizes as die and permanent mould castings in other metals. Magnesium sand castings require a more specialized technique and oxidation inhibitors must be used in the moulding sand. In the present state of the art, sand castings with sections thicker than about 6 in., or which require more than about 1 500 lb of metal to pour would be difficult to produce. The composition of magnesium alloys is shown in Table 10.

Metallurgical Aspects of Fabrication of Structural Magnesium Alloys

Magnesium alloys may be fabricated into structural units or assemblies by machining, cutting, forming, welding, or riveting. The precautions to be observed when machining or cutting consist mainly in keeping the tool sharp and free from chips to avoid overheating and consequent firing of the chips. Cutting must always be done mechanically as the high heat conductivity of the metal and the tendency of molten magnesium to burn precludes the successful use of torch-cutting. If it is necessary to use a liquid coolant (magnesium alloys are usually machined without lubricant or coolant), one should be selected that will not tarnish the finished work. Mineral oils are usually satisfactory, but rancid animal oils or acidic soluble oils should be avoided.

Severe cold-forming operations should be avoided as they are likely to cause invisible cracks which, later, will cause failure. Hot forming must be performed at temperatures below the eutectic temperature for all alloys containing aluminum and zinc (either or both). The binary magnesium-manganese alloy may be heated to 450° C (842° F), if necessary, but usually 260° to 350° C (500° to 662° F) is hot enough. The wrought magnesium-aluminum-manganese or magnesium-aluminum-zinc-manganese alloys may be readily formed in the range, 260° to 350° C (500° to 662° F), and the alteration in mechanical properties caused by this heating is not important unless the heating is prolonged.

Magnesium alloys not too high in alloy content may be joined by torch welding and the various types of electric resistance welding known as spot, seam, and butt welding. At or near the weld, the structure of wrought materials reverts to that of a casting with consequent lowering of properties. This condition can be greatly improved by hammering the finished weld at temperatures in the range, 290° to 370° C (550° to 700° F), and with certain types of mechanically operated electric butt welders, a cast structure at or near the weld is avoided for the most part. In order to prevent corrosion, welding flux must be thoroughly removed from torch welds, and seam or spot welds should be freed from copper particles picked up from electrode tips.

Because of the danger of electrolytic corrosion (magnesium is electro-positive to all common structural metals), rivets for magnesium alloy structures

must be selected with care and, where possible, should be insulated with bitumastic paint. Magnesium alloy rivets cannot be used successfully because they would have a low shear strength and because even small sizes would have to be driven hot. Rivets of steel, copper, nickel, and copper-bearing aluminum alloys should be avoided. For joints not subject to high stresses, rivets of commercially pure aluminum (Item No. 1, Table 6) may be used, but for highly stressed parts, rivets of an aluminum base alloy containing 4 to 5% magnesium are recommended. As a further precaution against electrolytic attack, the contacting surfaces of riveted magnesium alloy sheets or extruded shapes should be painted before assembly. A synthetic resin varnish pigmented with $ZnCrO_4$ is recommended for this purpose.

When it is necessary to rivet magnesium alloy parts to other metals, electrolytic insulation must be provided. To prevent the possibility of cracks or notches that later will produce fatigue failures, rivet holes should be drilled instead of punched, the rivet size carefully selected to avoid overstressing the rivet hole during driving, and marring of the magnesium alloy part with riveting hammer should be avoided.

Conclusion

The past fifteen years have witnessed the recognition of aluminum as an engineering material in an ever-widening field of applications. This is due primarily to the relatively light weight of aluminum compared to that of other common metals. However, advantage could not be taken of this characteristic until alloys of high strength were developed. Especially in recent years, marked progress has been made in this direction. This has been particularly true in those fields, such as construction and transportation, in which the cost of moving the structure is a major item of operating expense. Although aluminum is a relatively new engineering material, the fund of information that has been developed regarding its properties and behavior, and the great variety of forms and sizes in which it has become available commercially, places it on an equal rank, in these respects, with the far older metals.

This paper indicates broadly the type and scope of the facts and materials now available.

Part II of this paper entitled, "Magnesium", shows that although that metal has not yet progressed as far as aluminum, it is following a somewhat similar path. As is the case with aluminum, so, also, the outstanding important characteristic of magnesium is its relative lightness. Marked improvement has been made in the properties of its alloys. Methods of fabrication have been developed so that, to-day, magnesium alloys are available in a great variety of cast and wrought products of known characteristics.

Acknowledgment

The writers wish to acknowledge their indebtedness to the Marion Steam Shovel Company, Aluminum Company of America, The Dow Chemical Company, and the American Magnesium Corporation, for assistance in supplying basic data, illustrations, and other material useful in the preparation of the paper.

CORROSION IN RELATION TO ENGINEERING STRUCTURES

By James Aston[73], Esq.

Synopsis

The corrosion problem may be considered from two angles, each encompassing quite an extensive field, and worthy in itself of the space normally allotted to a technical paper. The one phase, dealing with the fundamental mechanism of corrosion, is necessarily theoretical, and of secondary interest to the practising engineer. The other phase, pertaining to the relative utility of metals in engineering structures, is undoubtedly of major interest to a gathering of civil engineers. This latter subdivision is quite complex, involving factors of experience, of economics, of conjecture, of controversy, and of personal opinion.

It is the intention of the writer to take the middle ground, in the belief that some knowledge of the fundamental mechanism of corrosion is a valuable background for a more adequate balancing of the many variables which are presented by the multiplicity of service conditions, and to interlink this discussion of the fundamentals with an appraisal of materials and protective measures which have a bearing upon prolonging the life of structures by combating the ravages of corrosion.

The seriousness of corrosion loss may only be guessed at on the dollar basis. One finds estimates running into hundreds of millions of dollars and even into the billions, as the annual toll. The resulting tax is enormous, and the tangible depreciation or the cost of abandoning structures is exceeded in a monetary sense by the more intangible effects of designing structures heavier than the requirements of working stresses, substituting more costly metals for others that would meet design conditions on a more economical basis, modifying design and fabrication, and applying paints and other protective coatings—all occasioned by the allowances necessary to offset or to minimize the effects of corrosion.

Mechanism of Corrosion

The electro-chemical theory is most generally accepted in explaining the mechanism of corrosion. Aside from the metal involved, the essential factors are moisture and oxygen. Water serves as the medium of electro-chemical reaction; it must be in contact with the metal, and its activity will be accen-

[73] Metallurgist, Pittsburgh, Pa.

tuated or decreased by salts or gases in solution, temperature, etc., somewhat in proportion to their effect in increasing or decreasing the electrical conductivity of the liquid. Oxygen, dissolved in the water, plays a dual rôle: (1) It serves to oxidize the products of reaction to the familiar form (in the case of iron) of rust; and (2) it is a depolarizer, neutralizing the effect of hydrogen formed as a product of the customary reactions, thus enabling a continuity of electro-chemical activity which otherwise would be suppressed.

In the past, for iron in particular, undue emphasis was placed upon impurity or heterogeneity as an all-important factor in the inception and progression of corrosion. More recently, however, extraneous factors affecting the surface characteristics of the metal, and influencing the contact relationships with it of moisture and oxygen, have been recognized as playing an important rôle, at times, even to the extent that they overshadow certain of the internal characteristics of the metal. Rust may now be claimed to play a part in the progression of corrosion fully comparable to the other factors which formed the early basis of the electro-chemical theory. This later conception has served to amplify the theory, and to explain certain occurrences more rationally, notably pitting, which, at one time, were only vaguely understood.

All corrosion phenomena and effects revolve around the three essential factors: (*a*) The metal or metals concerned; (*b*) the moisture; and (*c*) the oxygen. The absence of any one of the factors will generally suppress the activity in its entirety, except in some special cases where a minor rate of progression may be observed. The rate, and more particularly the type, of corrosion resulting, will be markedly influenced by the relative balance in Factors (*a*), (*b*), and (*c*). Consequently, environment plays an important rôle in the problem of corrosion as related to structures.

Types of Service

Corrosion has most commonly been divided into three fields: Atmospheric, immersion, and soil. The metal may be considered common to all classes, the differentiation being primarily linked with the relationships between moisture and oxygen in the three types. Under atmospheric conditions there is a superabundance of oxygen. Moisture is the governing factor, with respect to its quantity, kind, and intermittent occurrence. Heavy precipitation naturally tends to increase corrosion. Contaminating gases of industrial atmospheres or the salt sprays of seaside conditions are aggravating influences. Of major significance is the interval between precipitations, and the opportunity thus afforded for the corrosion products to dry. Conditions favoring precipitation followed by relatively rapid drying will tend to spread the rust, rather than to concentrate the corrosion in pronounced pitting. Atmospheric corrosion is characterized by small, shallow pitting quite closely and uniformly distributed over the affected area. The result is a fairly uniform attack of the surface.

Immersion conditions represent an abundance of moisture and a varying, often deficient, supply of oxygen. The latter is a governing factor. True

immersion conditions may be defined as those in which the metal surface is wetted continually with little or no drying of the corrosion products. The nature of the water may aggravate or retard the corrosion. Most salts in solution in moderate quantities accelerate the effect; but under certain conditions there may be film precipitations on the surface of the metal which are markedly beneficial. Temperature is an important factor, with the result that, other conditions being equal, the most aggravated effects are experienced under the conditions prevailing in hot-water supply systems, in boiler-feed waters, and in steam-condensate returns. It is important to bear in mind that the degree of corrosion is not in proportion to the purity of the water. Relatively pure, oxygenated waters are more to be reckoned with than contaminated waters which are foul with organic matter. The blanket statement may be made that immersion service presents the most variable and complex conditions in the entire corrosion problem. Its results are manifested as a rule in scattered pitting of a relatively large and deep character, with much of the surface showing little or no corrosion. The result will depend in a secondary manner upon the water characteristics and oxygen supply, with the primary influence quite largely dependent upon how continuously the metal surface was kept wet.

Soil corrosion may be considered as occupying a position intermediate between atmospheric and immersion service. It offers a great variety of conditions, such as those in which leachy salts affect the composition of the water, and those in which moisture is retained or drained from the metal surface. Inherently, the soil may be considered as a sponge, acting in a secondary capacity in relation to the nature, amount, and frequency of the moisture supply and its accompanying oxygen. The degree, and particularly the type, of corrosion will vary with the foregoing combination of influences. The corrosion may be similar to the uniform type characteristic of atmospheric conditions; it often shows the aggravated pitting typical of immersion service; and, not infrequently, it will display peculiarities which are akin to those present in the case of acid waters.

Factors Involved in Alleviation

With the foregoing exposition of fundamentals and mechanism as a background, it will be valuable to consider what may be done toward remedial measures which will be effective against the deterioration of engineering structures. Obviously, attention may be focused upon the metals involved, or upon the environment—that is, upon the prevailing moisture and atmospheric conditions.

With respect to environment, artificial measures are limited to special cases. In underground structures, better soil may be substituted in the contact zone and, particularly, benefit will result from proper attention to drainage and the elimination of moisture retentivity in this contact zone. Where liquid conveyance is a condition, as in pipe lines, benefit may result from an adjustment of water characteristics. A notable example is that of Coolgardie, Australia, where internal corrosion was reduced markedly in a large pipe line by reducing the dissolved oxygen content of the water by evacuation.

In numerous instances, moderate applications of lime have proved effective. On the other hand, certain water treatments, which have for their objective the extreme softening of water for domestic and similar uses, have been harmful from the corrosion viewpoint because they removed from the water the natural film protection which results from the raw water. Hardening treatment for extremely soft waters, elimination of bicarbonate content, neutralization of acidity, and the introduction of film-forming constituents, such as sodium silicate, have improved the water characteristics in the limited fields where such applications are practicable. De-aeration may be, and is being, resorted to in boiler-feed waters, in hot-water supplies, and in hot-water heating systems. In general, the efforts are confined to above normal temperature conditions, under which the corrosion is most aggravated and which enable the remedy to be applied most effectively.

Unfortunately, in dealing with structures of direct concern to the Structural Division of the Society, artificial alteration of the environment is limited to a narrow range of special cases. From a practical standpoint, one must cope with the natural surroundings as they exist, and must make allowances in design for such deterioration as may be indicated by experience for the particular environment prevailing. In some cases it may be logical to minimize deterioration by selecting suitable material and by protective metal surfaces. In general the battle with corrosion must be fought through the structure itself, rather than through its environment.

A most important phase of the problem is the selection of the metal. From the standpoint of the designing engineer, this must be primarily because of its fitness as a load-sustaining material, and, in most instances, corrosion, although it cannot be ignored, becomes a secondary feature.

In discussing the fitness of metals from the viewpoint of corrosion, one enters the most difficult field. Situations vary, metals vary, and there is no blanket rule by which any metal may be claimed to be best adapted to all conditions. This phase of the discussion is difficult, also, because it assumes a severely controversial and competitive aspect, in which personal experience and bias, and commercial associations will necessarily be provocative of argument. It will be the purpose of the writer to present a summary of opinion and of the status of various metals that are of interest to the structural engineer.

The Metals of Interest

For purposes of discussion the metals of interest may be grouped into the non-ferrous and ferrous divisions; with a further subdivision of the latter into the iron group, ordinary steels, and alloy steels.

In the non-ferrous group, this discussion is limited to copper and its chief alloys, brass and bronze, and to aluminum and its alloys. It may be rightly contended that copper is selected for structural purposes because of its non-corrodibility or because it is ornamental. In no case is its choice an acknowledgment of superior, or even equal, physical properties of strength, ductility, or unit weight obtained at a competitive cost figure in comparison with structural steel.

For the aluminum group of metals, the same general statements may be made, except for the important modification that the desired physical properties may be obtained with lessened weight of structure, and this may dictate the choice of material. As a specific example, the use of aluminum floor-beams in the Smithfield Street Bridge, in Pittsburgh, Pa., may be justified from the engineering viewpoint as prolonging the useful life of an existing superstructure by lessening the dead load and thereby coping with the necessity of taking care of the heavier live load of existing traffic. In a somewhat similar manner, the higher cost of aluminum window frames and other parts of the Empire State Building, in New York, N. Y., may be justified or even offset, because of a lessened load on a costly supporting structure.

For the usual corrosion conditions prevailing in the realm of structural engineering, the metals of the foregoing non-ferrous group may be claimed to have a high order of immunity. Special conditions or locations may be cited as exceptions, without defeating the generalization. In all cases, their use in structures is of a limited, specialized nature. Occasionally, their corrosion value is a dominant factor in their selection, but more often this desirable characteristic may be taken as an added feature in a choice made because of special considerations related to design.

Except for very special conditions and applications along the lines noted, the structural engineer will confine his selection of a metal to the ferrous group. Economic considerations, necessitating individual analysis and judgment, will determine the choice among the several types of iron or steel comprising the group as a whole. The presentation which follows is an attempt at a general appraisal of their features of merit or demerit.

It is logical that ordinary steel should be considered first since it is, and probably always will be, the dominant metal for structures. Furthermore, it serves as a well understood standard against which the alternative metals may be properly appraised.

Structural Steel

The "Age of Steel" began with the inception of the Bessemer process in 1855, and the open-hearth method of Siemens shortly thereafter. Since then tremendous progress has been made in a technical as well as in a manufacturing sense. One may claim that the customary type of structural steel represents the "bed-rock" standard in its all-around features of cost and physical properties, to meet the general need. It is an adaptable material in the hands of the metallurgist, who finds that, through adjustment of chemical composition, aided by heat treatment where desired, a wide range of controlled properties is obtainable. The customary metalloids—carbon, silicon, sulfur, phosphorus, and manganese—may be added or held to any practicable limits, even to a virtual approach to zero. Limits are set by the cost of the operation in comparison with the advantages accruing.

For the foregoing five elements, and in the range usually encountered in ordinary steels, one may summarize the following facts concerning corrosion.

Carbon is added, as a rule, for the purpose of conferring the desired tensile, elastic, and ductile properties. Although there is an apparent gain, from

the corrosion viewpoint, as the carbon content is progressively lowered, the overwhelming advantage in fixing the percentage in accordance with the dictates of a standard fixed design relegates the corrosion factor into the background. Within the usual range, the influence of carbon upon the corrosion of the structure may be considered as relatively unimportant.

Silicon and manganese are the steel-makers' correctives, introduced to neutralize otherwise deleterious effects upon the physical properties. Although each may influence corrosion adversely as the quantity in the steel increases, the effect is no doubt small. In much of the literature and theory relating to corrosion, manganese has been given unwarranted prominence as a harmful agent. The structural engineer may rightly disregard these elements in the quantities customary in the steels that are of commercial interest, as serious factors in the corrosion of the structure.

Available evidence indicates that phosphorus has a retarding influence on corrosion, varying with conditions of service and probably being most pronounced in the case of atmospheric exposure. However, the well-known effect of phosphorus in promoting brittleness in steel will continue to dictate the low-phosphorus content of structural steel specifications. Design, and not corrosion, considerations will rule.

Sulfur is invariably recognized as being harmful from the corrosion viewpoint. It should be kept as low as possible with due recognition of the factors prevailing in any particular situation and of the added cost where abnormally low limits are demanded.

As a generalization, it may be stated that composition, within the specification limits set for plain structural steels, has little bearing upon its life from the corrosion angle. This generalization is subject to adverse modification, however, if steel is made so carelessly as to be characterized by segregation, non-uniformity, dirtiness, etc.

Cast and Wrought Iron

Before the introduction of steel, the iron group—namely, cast iron and wrought iron—formed the dominant materials available for structural uses. Cast iron has had an enviable record for corrosion service, especially for atmospheric and soil conditions. It is interesting to note that this is in spite of the fact that it is chemically the least pure and homogeneous of the ferrous metals. It is not reconcilable with a very widespread assumption that purity represents the goal in corrosion immunity; and it does lend support to the barrier principle of protection. In the case of cast iron, as corrosion proceeds, an increasing surface barrier of graphite flakes, aided perhaps by a tightly adherent layer of the corrosion products, serves to slow down, and to spread, the rusting effects. However, the brittleness and low tensile strength of cast iron, and its lack of desired fabricating qualities, will hold it to a very restricted and specialized place in modern engineering of structures.

One cannot impeach the integrity and experiences of those who believe that steel has failed to measure up, in corrosion service, to the standards set by wrought iron in the long history of its use. The Pillar of Delhi is a conspicuous example. England and Continental Europe contain many

examples of a later date, whereas wrought iron dating from the Colonial period of United States history, such as the Bowling Green fence in New York, N. Y., furnishes factual evidence to support the contentions of wrought-iron adherents. Furthermore, one cannot dismiss lightly the contemporary records within the relatively brief period which defines the Age of Steel.

Wrought iron has a place in contemporary engineering; that is, in specialized applications where corrosion and shock or fatigue stresses are encountered. Limitations in manufacture have been handicaps, resulting in restriction of markets to a few specialized lines, such as pipe and bar iron; and cost problems have narrowed the zone of utilization. The manufacturing handicaps for wrought iron have been overcome, and one should expect an expansion in its use, both in quantity and in diversification of application. In the structural field, aside from possible fatigue considerations, wrought iron offers no advantage over steel, from a stress or fabrication viewpoint. It must find its place where experience indicates that it will give an economic return in the necessarily specialized fields of utilization. Superior resistance to corrosion will be the basis of selection.

Commercially pure iron, or ingot iron, is a contemporary metal of importance. It is interesting to note that its development is due to an acceptance of the principle that wrought iron had rust-resisting qualities superior to steel and to a belief that high purity of base metal was the fundamental feature contributing to this superiority. This subject is the center of much commercial controversy. The steel interests contend that nothing has been gained over what may be expected with customary grades of mild open-hearth steel. The wrought-iron advocate will not admit that open-hearth iron has proved an adequate substitute for his products; and quite rightly contends that it is not wrought iron. Although the two have in common a high base metal purity, the ingot iron lacks the physical incorporation of slag filaments which are characteristic of wrought iron.

Alloy Steel

In considering the alloy steels, one is in the fairyland of ferrous metallurgy. The field is relatively unexplored and seemingly unlimited in extent. Actually, however, in the light of present knowledge and requirements, the useful territory is somewhat restricted. In comparison with customary steels, the alloy additions must result in improved strength characteristics, in comparable manufacturing and fabrication qualities, and must have a reasonable cost. To-day, the field seems to be covered by additions of chromium, copper, manganese, molybdenum, nickel, silicon, and vanadium—together with carbon —singly, or in various combinations. Covering the low-alloy steels Mr. J. C. Whetzel[14] gives the general range of elements, as follows:

Carbon	0.10 to 0.40	Copper	0.01 to 1.40
Manganese	0.20 to 1.70	Nickel	0 to 3.5
Phosphorus	0.01 to 0.20	Chromium	0 to 12.0
Sulfur	0.05 maximum	Molybdenum	0 to 0.40
Silicon	0 to 1.0	Vanadium	0 to 0.20

[14] *Proceedings*, Am. Iron and Steel Inst., May, 1935.

From the corrosion viewpoint, it appears that the carbon-silicon-manganese group has no particular merit and that the results of promise are in the combinations containing copper, nickel, and chromium.

Nickel steel (3.5% nickel) has been a standard, high-strength structural steel for many years. It has had a reliable performance record with high-strength characteristics, without the necessity of special heat treatment and radical deviations in manufacture and fabrication. The cost of the nickel addition has been the factor that has held this material to specialized applications in structures. The nickel content of the steel no doubt confers added corrosion resistance, but scarcely in proportion to the additional cost. Consequently, the use of nickel steel would not appear to be justified from the corrosion standpoint alone.

One of the most successful developments has been copper-bearing steel which has been successful because a small quantity of copper (0.30%) confers material benefit at low cost. Comprehensive tests by the American Society for Testing Materials indicate a substantial corrosion resistance under atmospheric conditions, particularly in industrial centers. A similar merit, however, cannot be claimed for immersion conditions. The added cost of this copper-bearing steel must justify its selection solely because of its corrosion characteristics; no benefit may be claimed because of its other physical properties in comparison with standard structural steels.

The results with higher copper additions (0.50% to 1.5%) are rather doubtful as far as structural applications are concerned. There is higher strength, and probably greater corrosion resistance, but the relationships of copper and iron in these higher ranges may lead to difficulties in manufacture and to unreliability in fabrication and in after service. It is not improbable that copper will play an important rôle in subsequent developments by recourse to other auxiliary alloying elements which will serve to shift the normal relationships of copper and iron, or to mask the otherwise detrimental effects. It may be that molybdenum has an influence of this character.

Low-Alloy Structural Steel

In the past few years there has been a marked impetus in the development and exploitation of new steels in the low-alloy group. Numbers of these alloys are on the market under commercial trade designations. The general types are well summarized by Whetzel[14] who gives the chemical composition, tensile and impact properties, and other characteristics. With a demand for lighter structures, the steel industry has endeavored to meet the competition of low-density metals by offering higher strength characteristics and consequent lessened section and weight. Quite naturally the greatest impetus has come through the transition which one observes in the transportation field. Promoters of the new low-alloy steels have the objectives of stepping into the territory so ably filled in the past by the use of nickel steel, but at a reduced cost. Manganese, silicon, and copper are the agencies presenting the greatest possibilities, because of the moderate required amounts and the low base cost of the alloy metals. Alone, or in various combinations, and often in association with

nickel, chromium, molybdenum, and vanadium, one finds, to-day, the general list confronting the structural engineer.

As a matter of fact, the manganese and silicon structural steels have been used for a considerable period. From the corrosion viewpoint, they may be likened to ordinary steel and their selection should be made only because of benefit from a design basis.

In appraising the low-alloy steels from the standpoint of corrosion service, one quite commonly overlooked feature is worthy of emphasis. The basis of selection is almost invariably higher unit strength and consequent reduction of weight. In most structural shapes, this means little change in the over-all surface exposed to the elements and a reduction of section thickness in proportion to the increased strength of the metal. Consequently, if the strength is doubled, and the section thickness is reduced one-half, with a unit corrosion-merit value of twice that of ordinary steel, the life of the structure, as far as comparative corrosion is concerned, would be the same. In effect, therefore, in the selection of structural materials, the benefit to be derived, as far as it relates to corrosion, will be only to the extent that the corrosion-merit ratio exceeds the strength ratio for the metals under consideration.

In general, a proportionately high order of corrosion resistance in the low-alloy group does not appear to be attained unless the quantities of chromium or nickel, singly or in combination, are relatively high. In such a case the engineer is faced with a high-cost spread and the possibility of manufacturing and fabricating peculiarities. The writer believes that selection of metals in the low-alloy group would not be justified in engineering structures, as a major substitution for plain steels, if all other physical factors were the same, and corrosion was the only service consideration. On the contrary, where design characteristics of the several types dominate the selection, the equivalent corrosion characteristics may be considered as an additional premium obtained with certain of the materials; or the selection may be made by proper appraisal of all factors—strength, corrosion, and cost—peculiar to the competing metals. Obviously, with this criterion as the logical basis of choice, each structure becomes an entity unto itself—a problem for individual solution.

As illustrative of some considerations involved in any generalization regarding the low-alloy steels, one may cite an interesting alloy combination noted by Whetzel[14]. A chrome-copper-silicon-phosphorus addition gives to this steel the properties of the medium high-tensile group. It is claimed that the detrimental effects to be expected from abnormally high phosphorus (0.10% to 0.20%) are masked by the complex alloying relationships, and cold shortness is not induced in the metal. Graphs are given by Whetzel showing comparative corrosion in industrial atmosphere for two years, and the citation is made that copper-bearing steel has a resistance of two to three times that of ordinary steel, whereas for the chromium-copper-silicon-phosphorus combination the ratio is four to six times. If these comparisons are borne out by long-time service experiences, one would have a rational basis for the evaluation of the alloy for structural needs, with adequate balancing of all factors—strength, corrosion, and cost. Such evaluation at

present would be unwise, since ultimate life cannot safely be predicted upon short-term, progress data. Furthermore, in the corrosion field, results vary markedly with conditions of service.

The greatest promise in the structural field is in adding alloys of low cost, in quantity and kind, which will give a positive corrosion merit warranting selection in competition with the usual grade of structural steel even if there should be little or no gain in the other physical properties.

One might almost claim that corrosion, for the conditions confronting the structural engineer, has been conquered by alloys of the 13.0% to 16.0% chromium, or the 18.0% chromium with 8.0% nickel classes—the high-alloy group. These steels have the ideal quality of forming thin self-healing surface films in usual environments which, in the last analysis, is the goal that the corrosion specialist dreams of achieving. However, aside from questions of fabrication and peculiarities of properties under certain conditions, stainless steels have very limited, specialized applications in structures because of a relatively high unit cost.

Surface Protection

Corrosion is a surface reaction, so that surface considerations or applications form a logical method of attacking the problem. Furthermore, in view of the fact that a ferrous metal of moderate cost is, and will remain, the dominant one for structures, and that rusting will occur in some degree, paint or equivalent surface applications are required in most installations, if only for æsthetic reasons. An admirable paper on the surface protection of steel has been presented by Mr. F. N. Speller[19]

Of the metallic coatings, interest centers upon hot-dip applications of zinc or tin. Of the two, galvanizing only need be given serious attention because of the high cost of tin. Although galvanizing forms a good protection for most exposure conditions, the cost is relatively high. Painting is usually a necessary accompaniment; and application of zinc is impracticable on the sizes and shapes used in large structures. In certain cases, such, for example, as bridge parts to which access for painting after erection is difficult, a zinc coating applied by hot-dipping, or by the metal-spray method, may be advantageous. Every one is familiar with the extensive use of galvanizing in building sheathing and in electrical transmission towers. In general, however, zinc and metallic coatings, as a whole, are of minor interest to the structural engineer.

As a protection against corrosion, the non-metallic coatings have merit only because they isolate the metal surface from contact with its environment —moisture in particular. The necessary qualifications are firm adherence to the underlying metal, a continued imperviousness, and resistance to disintegration during exposure. The metal surface is an important feature since dampness, grease, or rust affect adherence. Furthermore, the evidence is that iron or steel which corrodes to a dense, adherent rust is of decided advantage in the effectiveness of a paint coating, in contrast with results where the steel corrodes to a flocculent, loose type of rust. Paints containing pigments of the red lead, or of the chromate, types appear to have an inhibitive action on

[19] *Transactions*, A. S. M. E., June, 1935.

the corrosion of the steel base. To this extent they are of advantage in the contact zone; that is, in the priming coat.

Paints comprise the most important material available for the surface protection of structures. Coatings of greater thickness, such as bituminous or Portland cement mixtures, are more commonly applied in underground protection. In such cases, inaccessibility after erection demands a coating of reasonable permanence, since repeated renewal, as in painting, is practically out of the question. The fundamental features of protection are similar to those noted previously. In addition, the bituminous coatings should possess sufficient plasticity to yield under slight movement, and to resist cracking, and yet be of proper consistency to hold up under temperature influences and to resist deformation under earth pressures. For pipe lines, as an example, this has been satisfactorily accomplished by reinforcement with wrappings of burlap or asbestos embedded in the bitumen.

The Future

The metallurgist has advanced materially in his knowledge of the mechanism of corrosion. Likewise he has made progress in the improvement and development of materials for utilization by the engineer against its ravages. For this latter, more practical, accomplishment one may credit the eternal rivalry and struggle for supremacy among the several competing groups involved in the manufacture of materials for structural uses. One may look into the future with confidence of further progress which will be measured by: (*a*) Betterment of existing materials; (*b*) possible development of new types; and (*c*) reduction of cost spreads which will re-orient the economic basis of selection. After all, corrosion is an economic problem to an even greater degree than it is a technical one. There is no specific formula by which metals may be evaluated; results under one set of conditions are not necessarily transferable to another environment. Unfortunately, there is yet, no quick time test for appraising comparable to the tensile test which makes the diagnosis of physical properties reasonably satisfactory. Experience and good judgment remain as the best guide in selecting materials for corrosion service.

On the side of the structural engineer, the advances in knowledge and in materials open up a broader field for selection and economic placement. There are numerous places where special materials, even at higher cost, are justified from the viewpoint of corrosion alone. In bridges, there are inaccessable parts, such as connections and floor members; and, in buildings, harmful conditions may be encountered in foundations and where there is exposure to the atmosphere. Submerged structures (piers, etc.) present a serious problem, whereas the atmospheric conditions associated with marine and many industrial structures are conducive to accelerated deterioration. For these special cases it is good engineering to weigh all factors carefully and to select such metals or protective measures as experience and good judgment may indicate. However, in the broad field of structural engineering, and in spite of prospective development in the higher strength alloy steels, plain carbon steel will continue as the dominant material. The corrosion problem will remain as a serious handicap. The best defense will be "keep on painting."

STRUCTURAL APPLICATIONS OF STEEL AND LIGHT-WEIGHT ALLOYS

A SYMPOSIUM

ACTUAL APPLICATIONS OF SPECIAL STRUCTURAL STEELS

By V. D. Beard[76], M. Am. Soc. C. E.

Synopsis

Within the meaning of the title selected for this paper it seems advisable first to preface the discussion by mentioning the steel adopted as the standard of reference, and then to give a list of materials to illustrate what are properly designated "Special Structural Steels":

(*a*) The standard selected as most suitable for the purpose is Carbon Steel A. S. T. M. Specifications A7 and A9. Comparisons of the special steels will be referred to this standard.

(*b*) Special structural steels, which draw their distinction from their physical properties, or their resistance to corrosion, or in some cases from both, afford a considerable variety. Representative members of this group are the following: High-carbon heat-treated steels; carbon steels containing copper; silicon steel; manganese steel; nickel steel; manganese vanadium steel; Cor-Ten; Cromansil; chromium steels; the stainless steels; and carbon steel, cold-drawn, for cables and wire rope.[77]

Bridges — Long Spans and Monumental Structures

Typical examples of structures in which special steel was used, are as follows.

San Francisco-Oakland Bay Bridge.—This great structure symbolizes an epoch in American bridge building. Approximately 4.5 miles of the 8.5-mile crossing consists of various types of bridge construction in which 200 000 tons

TABLE 11.—Physical Characteristics of Special Structural Steels

Medium carbon steel	62	37	28
Silicon steel	80	45	28
Nickel steel	85	55	34
Heat-treated eye-bars	80	50	34
Cable wire	220	150	82

of steel were used. The individual units, when viewed apart from the entire project, are notable bridges in their own right, and merit rather detailed description because of the extensive use of special structural steels. These

steels are classified as shown in Table 11 with regard to ultimate strength, yield point, and unit stresses.

The West Bay Crossing, from San Francisco, Calif., to Yerba Buena Island, is composed of two, nearly duplicate, double-deck, parallel wire cable, sus-

pension bridges (see Table 12). The following tabulation will give an idea of the various types of steel used and their relative weights:

Distribution	West Bay Crossing, San Francisco-Oakland Bay Bridge (Tons)	Distribution	West Bay Crossing, San Francisco-Oakland Bay Bridge (Tons)
Silicon steel in towers, cable bents, and center anchorage	18 500	Phosphor bronze	25
Heat-treated eye-bars and pins	350	Cable wire	18 700
Nickel steel	280	Cable castings	830
Silicon steel on suspended structure	24 000	2.25-in. suspender ropes	113
Manganese steel rivets	300		

The percentage of this weight that was of special steel may be noted by reference to Table 13(*a*). The East Bay Crossing, from Yerba Buena Island to Oakland, Calif., is composed of four 280-ft deck spans, one cantilever bridge with a 1 400-ft main span, and two 500-ft side spans, five 504-ft through spans on bents, fourteen 280-ft deck spans on steel bents and masonry piers, and ten 82-ft plate-girder spans. A comparison of this 1 400-ft cantilever with the Quebec and Firth of Forth Bridges is shown in Table 14. The special steels in this structure, their distribution in the various parts of the structure, and the percentage of the total tonnage, are given in Table 13(*b*).

TABLE 13.—DISTRIBUTION OF SPECIAL TYPES OF STEEL IN THE SAN FRANCISCO-OAKLAND BAY BRIDGE (WEIGHT, IN TONS)

Type	(a) West Bay Crossing					(b) East Bay Crossing					
	Towers 2, 3, 5, and 6	Pier No. 4	Stiffening trusses	Floor-beams and stringers	Total	Cantilever span	Towers and bents	500-foot span	Lattice truss spans	Girder spans	Total
Silicon	17 500	500	15 000	6 950	39 950	7 400	3 525	6 500	10 250	350	28 025

Tables 15(a) and 15(b) show the chemical and physical properties of the special steels: For nickel (Table 15(a)) as averaged from the first ten melts; and for silicon (Table 15(b)), as averaged from thirty melts, ten from each of three mills. There are 370 tons of low-nickel chrome heat-treated

TABLE 14.—COMPARISON OF MATERIAL USED IN THESE CANTILEVER BRIDGES

Bridge	Span length, in feet	Total weight, in tons	Material Used (Percentages)			
			Nickel	Silicon	Heat-treated bars	Carbon
San Francisco–Oakland Bay	1 400	20 900	16	40	10	34
Firth of Forth	1 700	30 000	....	....	....	100*
Quebec	1 800	62 900	27	....	....	73

* Medium carbon steel.

pins in the cantilever structure which vary in size from 11½ in. to 24 in. in diameter and which have the chemical and physical properties shown in Table 15(c). The manganese rivets were furnished to the specifications shown in Table 15(d).

Golden Gate Bridge.—The Golden Gate Bridge is the longest single suspension bridge in the world (see Table 12). It is a single-deck structure and is 90 ft wide from center to center of stiffening trusses, providing for a 60-ft roadway and two 11-ft sidewalks. The 700-ft towers are of the fixed-base, flexible type. The live load on the stringers was four 24-ton trucks and two 50-ton street cars abreast, with 50% impact for stringers and 25% for floor-beams.

Silicon steel was used for the top 200 ft of the towers and for the cross-strut below the roadway. The allowable unit stresses were 24 kips per sq in. on silicon steel and 18 kips per sq in. on carbon steel, except as follows (units are kips per square inch):

Carbon steel in stiffening trusses	21
Silicon steel in stiffening trusses	32
Silicon steel in lateral bracing	32
Silicon steel in flanges of floor-beams	22
Carbon steel in webs of floor-beams	16

There were 20 000 tons of silicon steel used on this bridge, and 2 500 tons of heat-treated eye-bars were used in the anchorages.

George Washington Bridge.—This well-known bridge over the Hudson River, in New York, N. Y., is a suspension bridge with a 3 500-ft center span. It is 106 ft wide, center to center of stiffening trusses[78]. Silicon steel was used for the chords of the stiffening trusses for the side spans, whereas nickel steel was used in the center span. Silicon steel was also used for the main columns of the towers and main material of the floor system, whereas carbon steel was used for the tower bracing and for details of the tower and floor.

The weight of steel on the bridge was divided as follows, in tons: Wire, 29 000; carbon steel, 31 000; silicon steel, 30 000; and nickel steel, 2 350. The towers contained 23 800 tons of silicon and 15 200 tons of carbon steel.

Ambassador Bridge.—This international bridge over the Detroit River at Detroit, Mich., is of the suspension type. The towers are 363 ft high. The 47-ft roadway carries five lanes of traffic, and there are two 8-ft sidewalks. The chords of the stiffening trusses are of silicon steel whereas the webs are of carbon steel for which unit stresses of 32 and 24 kips per sq in. were used. The cables were originally spun with heat-treated wire that had an ultimate strength of 220 kips per sq in. and a yield of 194 kips per sq in. This wire proved to be unsatisfactory when placed in the bridge, because of its inability to stand the bending stresses, and was replaced. The new wires were cold drawn (see Table 12), with the physical requirements of ultimate strength of 215 kips per sq in. and yield point of 144 kips per sq in., measured at an elongation of 75% in an original length of 10 in. A very extensive series of tests were made. Only 4 in 300 showed less than 215 kips per sq in., the lowest being 210 kips per sq in. A total of 45 yield-point tests met the specification requirements. Tension tests for permanent elongation indicated a proportional limit of 103 kips per sq in., which is well above design stresses. Creep tests showed very little difference between straight wires and those bent around sheaves. No wires broke over sheaves or at the point of tangency.

Delaware River Bridge.—This suspension bridge at Philadelphia, Pa., has a main span of 1 750 ft and side spans of 751 ft 8 in. The towers are 337.5 ft high. Three grades of steel were used in this bridge: Silicon steel for the main compression material of tower posts, web members, and lateral systems of stiffening trusses, and some of the heavy girders in the approaches; nickel steel for chords of stiffening trusses; and structural steel for the remainder. The two special steels were used to effect economy in weight (webs of stiffening trusses), or to secure great flexibility within the elastic limit of the material (in the towers, and still more so in the truss chords).

A unit stress of 24 kips per sq in. was used for the silicon steel in the towers for the sum of axial and bending stresses due to dead load, congested load, wind, and temperature. Including the secondary stresses, the allowable unit stress was 27 kips per sq in.

For the nickel steel (yield point, 55 kips per sq in.) in the chords of the stiffening trusses, a unit stress of 40 kips per sq in. in tension was used, and 35 kips per sq in. in compression, with the top chord working stress reduced 3 kips per sq in. on account of lateral forces; 32 kips per sq in. in

[78] *Transactions*, Am. Soc. C. E., Vol. 97 (1933).

tension was allowed for silicon steel in the web members and $32\,000 - 140\,\frac{L}{k}$ lb per sq in. in compression. For the laterals, the allowable unit stress for silicon in tension was 32 kips per sq in. and $30\,000 - 100\,\frac{L}{k}$ lb per sq in. in compression, but some value greater than 10 000 lb per sq in., of this was absorbed by participation in the chord stresses.

The Bayonne Bridge.—This bridge, which spans the Kill van Kull, is the longest arch span in the world. It has a span of 1 675 ft, a rise of 274 ft, and a width of 74 ft, center to center of trusses.

The total weight of steel in the arch is 17 160 tons, of which 4 000 tons is silicon and 4 700 tons is manganese steel. The 2 000 ft of viaduct approaches contained 4 150 tons of silicon and 350 tons of manganese steel. The allowable unit stresses on the three materials, in kips per square inch, were: For carbon, 20; for silicon, 27; and for manganese steel, 33. The special manganese steel for this bridge was specified as shown in Table 15(*e*).

Bridges—Movable Spans

The Cape Cod Canal Railroad Lift Span, at Buzzards Bay, Massachusetts, the longest lift span on record, is 544 ft, center to center of piers. The lift span is composed of silicon steel, except the chords in the end panels (see Table 16).

The Burlington-Bristol Lift Span over the Delaware River is 533 ft 9 in. long. Light weight was obtained in this structure by the liberal use of silicon steel and a special light-weight floor. It was estimated that each pound added to the floor meant an additional cost of 12 cents in the trusses, towers, etc.

The 408-ft railway lift span, at Boonville, Mo., which carries the Missouri, Kansas, and Texas Railroad, was designed for E-70 loading.

The Hackensack River Crossing of the Delaware, Lackawanna, and Western Railroad, is a lift span 198 ft long. The maximum lift is 95 ft. To reduce the lifted load, an open deck was used, with silicon steel for the trusses and floor-beams.

The West Madison Street Bridge, in Chicago, Ill., is a double-leaf bascule. A total of 519 tons of nickel steel was used in the trusses and floor-beams.

The North Wabash Avenue Bridge, in Chicago, is a double-leaf trunnion bascule. In the trusses, 329 tons of nickel steel were used.

The South Harlem Avenue Bridge, in Chicago, is a double-leaf deck-riveted truss span, 224 ft, center to center of trunnions, and carries a 56-ft roadway and two 8-ft sidewalks. In the trusses, counterweight boxes, and two floor-beams, 812 tons of silicon steel were used.

The Outer Drive Bridge, in Chicago, is a double-leaf deck-riveted truss, 264 ft, center to center of trunnions, and carries two 38-ft roadways and two 14-ft sidewalks. The trusses and trunnion girders contain 1 965 tons of silicon steel.

Railroad Bridges

The Bessemer and Lake Erie Railroad High Bridge, over the Allegheny River, consists of two double-track continuous truss bridges. Silicon steel was used for the stringers, floor-beams, jacking girders, and for the main members of the trusses, except that the tension top chords over the piers were heat-treated eye-bars. The total weight of steel was 10 000 tons, of which 54% was silicon.

The three-span continuous truss bridge for the Chesapeake and Ohio Railroad, at Cincinnati, Ohio, is a double-track railroad bridge, 1 575 ft long. The center span is 675 ft and two side spans are 450 ft long. Silicon steel was used throughout at a unit stress of 24 kips per sq in. The resultant saving in steel weight was approximately 19% of the weight of a similar structure built of carbon steel using a unit stress of 18 kips per sq in. The decreased weight due to the use of silicon steel was particularly advantageous from an erection standpoint.

The railroad bridge across the Tanana River, for the Alaska Railroad, has a main span 700 ft long and 600 ft of plate-girder approaches. The live load was E-50. The item of freight was large and made the use of alloy steels attractive. Nickel-steel eye-bars were used on the 700-ft span, and silicon steel was used for all main members, the floor system, pins, and large detail parts. Silicon steel was also used for the flange angles of the 60-ft plate girders in the approaches.

The Atchison, Topeka and Santa Fé Railroad High Level Bridge, over the Illinois River, near Chillicothe, Ill., is a double-track structure, 1 696 ft long, consisting of a 400-ft and a 470-ft two-span continuous deck truss; a 440-ft through truss span; a 235-ft deck span; and two 68-ft plate-girder spans. The design live load was E-70. Silicon steel was used for all chords and main diagonal members, with carbon unit stresses increased 50% for tension and 40% for compression.

The Martinez-Benicia Bridge across Suisan Bay, in California, is a double-track railroad bridge, 5 600 ft long, built for the Southern Pacific Company. It consists of a 328-ft vertical lift span; seven through truss spans, 526 ft long; one deck span, 504 ft, and one deck span, 264 ft long; and a 780-ft approach viaduct. It was designed for E-90 loading, with unit stresses one-third higher than the standard. Silicon steel was used for the main members, except in the bottom chords where heat-treated eye-bars were used. The total weight of steel was 22 000 tons, of which 12 500 tons was silicon and 2 750 tons, heat-treated eye-bars.

The main river crossing of the Louisville and Nashville Railroad Bridge, over the Ohio River, at Henderson, Ky., consists of a double-track simple span, 670 ft long, and four double-track simple spans, 500 ft long. Silicon steel was used for the trusses, stringers, and floor-beams. The 670-ft simple span has a dead load of 14 kips per lin ft, and the total weight of steel in this span is 4 550 tons, of which 4 200 tons is silicon. The trusses are about 80% of the total weight of the span. The 500-ft simple spans weigh 2 500 tons each, of which 2 200 tons is silicon, and the trusses are about 67% of the total weight.

The Huey P. Long Bridge, over the Mississippi River, at New Orleans, La., is a combined double-track railroad and highway bridge (with one 18-ft roadway on each side). In the main spans and approaches 31 000 tons of silicon, steel was used. The 1 850-ft cantilever bridge and the five simple truss spans have a total weight of 20 000 tons, of which 11 000 tons are silicon steel and 1 400 tons, heat-treated eye-bars. The trusses, except minor members, are of silicon steel and heat-treated eye-bars. The railroad stringers and floor-beams are silicon, whereas the highway portion and the bracing are carbon. (For full-sized tests of heat-treated eye-bars for this bridge, see Table 15(*f*).)

Highway Bridges

The highway bridge over the Ohio River, at Louisville, Ky., consists of two 1 870-ft cantilever bridges, each composed of one anchor arm of 362 ft, one anchor arm of 500 ft, two 224-ft cantilever arms, and a 373-ft suspended span. It is 43 ft center to center of trusses and has two 6-ft sidewalks. The total weight of steel is 13 460 tons, of which 5 140 tons are silicon and 1 180 tons are heat-treated eye-bars.

A part of the Tri-Borough Bridge, at New York, N. Y., is a highway suspension bridge, having a 1 380-ft span and two 705-ft side spans. The 270-ft towers are of the fixed-base flexible type, having main columns of silicon steel with carbon-steel bracing. The stiffening truss chords are silicon steel, and the diagonals are carbon steel. The 96-ft floor-beams are of silicon. The total weight of silicon steel on the bridge is 15 000 tons. Each of the cables (20.63 in. in diameter) has 37 strands of 248 wires, 0.196 in. in diameter, and a total area of 277 sq in.

The Mount Hope (Providence, R. I.) Wire Cable Suspension Bridge has a 1 200-ft main span and two 504-ft side spans. The chords of the stiffening trusses are of silicon steel with working stresses of 34 kips per sq in. in tension

and 28 kips per sq in. in compression. The material in the two 11-in. cables, is the same as for the Ambassador Bridge, previously cited.

The main structure of the cantilever highway bridge across Carquinez Strait, in California, is 3 350 ft long and consists of two 1 100-ft main spans, a 150-ft central tower, and two 500-ft anchor arms. Silicon steel was used for the main material of the towers, and for the compression members and the built tension members of the trusses. Heat-treated eye-bars having an ultimate strength of 80 kips per sq. in. and a minimum yield point stress of 50 kips per sq in., were used for the principal tension members. The total weight of steel in the main bridge is 11 400 tons, of which 5 400 tons is silicon and 1 370 tons, heat-treated eye-bars.

The eye-bar cable suspension bridge, at Florianopolis, Brazil, has a main span of 1 113 ft 9 in., and carries a 28-ft roadway. In this bridge a part of the cable, which is composed of heat-treated eye-bars, acts as the center part of the top chord of the stiffening truss. The heat-treated eye-bars were specified to have a minimum ultimate strength of 105 kips per sq in., a minimum yield point stress of 75 kips per sq. in., and an elongation of 5% in 18 ft.

The eye-bar suspension bridges over the Ohio River, at Point Pleasant and St. Marys, W. Va., have a 700-ft main span and two 380-ft side spans and carry a 22-ft roadway and one 5-ft sidewalk. These bridges are similar to the Florianopolis Bridge, except that in addition to the eye-bars replacing the twelve center panels (of twenty-eight panels) in the main span, they replace the first seven panels from the cable bent (of fifteen panels) in the side spans. The physical characteristics of the special heat-treated eye-bars in this bridge are given in Table 15(*g*).

The self-anchored, chain, suspension type of bridge was used on the 6th, 7th, and 9th Street Bridges over the Allegheny River, at Pittsburgh, Pa. The center span is 442 ft long, with two side spans of 221 ft. Each chain was made of eight and nine eye-bars alternating with a maximum section of 230 sq in. These eye-bars were heat-treated to a minimum yield point stress of 50 kips per sq in. and an ultimate strength of 80 kips per sq in.

The Waldo-Hancock Bridge, in Maine, is cited as an example of the twisted-wire strand cable, suspension bridge. It has a main span of 800 ft, and two side spans of 350 ft. Each $9\frac{5}{8}$-in. cable consists of 37 strands of $1\frac{3}{8}$-in. wire rope. The ultimate strength per strand is 216 kips and each strand was pre-stressed to one-half this amount. The modulus of elasticity, after pre-stressing, was 26 600 000 lb per sq. in.

Buildings

Special steels have not been used extensively in tier buildings. In one of the buildings of Radio City, in New York, N. Y., silicon steel was used in a part of four columns in order to reduce the size.

The Tower Building for the Cleveland Terminal Company, in Cleveland, Ohio, is a 52-story building, being about 300 by 247 ft for 16 stories, and then a set-back tower, 489 ft high, has a base that is 98 by 98 ft. The total weight of steel was 16 850 tons, of which 4 610 tons was silicon.

The hangar built for the Goodyear Zeppelin Corporation at Akron, Ohio, is 325 ft wide by 1 184 ft long ("out-to-out" of doors) by 180 ft clear height, having eleven lattice arches spaced on 80-ft centers and two diagonal half arches at each end. Silicon steel was used for the main arch ribs only. Of the total weight of 7 210 tons, 628 tons is silicon.

In the Richmond Power Station, at Philadelphia, Pa., there are 10 000 tons of steel in the switch house, turbine hall, and boiler house, of which 8 000 tons is silicon. Silicon steel was used for all the principal members of the main building framework, except the framing of the turbine hall roof. Tests from sixty-five heats are listed in Table 15(*h*).

The United States Post Office Building, in Philadelphia, Pa., covers an area of 380 by 460 ft, and has five floors and a roof. The total weight of steel is 17 700 tons, of which 1 740 tons is silicon. Silicon steel was introduced in this building when two hundred and fifty-two 36-in. silicon beams without cover-plates were substituted for carbon beams with cover-plates.

The addition to the Post Office Building, at Washington, D. C., is an irregular-shaped structure (width, 230 to 120 ft; and length, 418 to 368 ft; height, six floors and roof). The total weight is 7 180 tons, of which 2 975 tons is silicon. Silicon steel was used for the heavy plate girders, the double girders, part of the column slabs, part of the floor-beams (usually 24 in. and deeper), and about 62% of the trusses and columns.

Special Structures in Which Transportation or Other Costs are Factors in Making the Use of Special Steels Economical

One of the best examples is the steel derrick used in the erection of steel bridges. The additional cost of the special steel is more than compensated for in three ways: First, the saving in weight reduces transportation costs as the derrick is shipped to and from the tool house to the bridge sites; second, the larger capacity; and third, the saving in weight in the steel of the bridges due to smaller erection stresses.

Silicon steel derricks were designed for use on the San Francisco-Oakland Bay Bridge. With a 103-ft mast and an 85-ft boom, one of these derricks weighed about 32 tons and made lifts of 59 tons. A similar carbon steel guy derrick weighs about 34 tons and has a lifting capacity of 46 tons. For slightly less weight a silicon steel derrick will lift about 40% more load.

The traveling crane is another type of special structure in which saving in weight, due to the use of high tensile steels, more than pays for the additional cost, because power consumption is reduced. The writer knows of three mill types of cranes, 120-ft span, which have a 40-ton main hoist and a 15-ton auxiliary hoist. The main girders are riveted plate girders. A reduction in weight of 40 000 lb is due to the use of manganese steel. It was necessary to deepen the girders 1 ft (compensating for the higher unit stresses on a material having the same modulus of elasticity as the carbon steel) in order to keep the deflection the same as for the carbon-steel cranes. It is generally not economical to use special steel unless the crane span is more than 100 ft.

The single-track railroad viaduct of the Pittsburgh and West Virginia Railway Company near Banning, Pa., was being built on a new line, so that additional erection equipment could not be readily sent to the field. In this viaduct there were two 120-ft carbon steel plate girders, weighing 65 tons each, the weight and reach of which were beyond the capacity of the erection derrick. Permission was obtained to design the girders for the use of silicon steel. The silicon girders weighed 53 tons each and could be handled by the derrick.

Alloy steels are seldom used in mill building, but in the Open-Hearth Building for the National Tube Company, at McKeesport, Pa., some of the crane girders were 115 ft long. The type of erection rig used to construct mill buildings does not have the capacity to handle long heavy girders. The girders, in this case, were designed for silicon steel, thus reducing the weight to 93 tons which could be handled by two locomotive cranes.

Bridges in the United States have been growing longer and heavier, and with this growth have come increased stresses and larger field rivets. Because of the stiffer material and more thicknesses it is becoming increasingly difficult to draw connecting members tight for proper rivet driving. The erectors find it necessary to use pneumatic tools to tighten fitting-up bolts, which strip the thread or break the ordinary carbon-steel bolt. Manganese steel fitting-up bolts which are now used extensively, obviate this difficulty and can be utilized over and over again. Even the hand wrenches are being made of manganese steel. The specifications for this material are given in Table 15(*i*).

All bars forming grills for the tunnel intake for the New Kanawha Power Company, at Hawks Nest, W. Va., were special Cromansil steel welded to the main frame of carbon steel. It is of interest to note the latitude of the specifications (see Table 15(*j*).

A great variety of special forging steels and a considerable tonnage of stainless steel are used in the movable dams constructed for the Federal Government. Abrasion-resisting steel is also used in the structural steel work of chutes for the U. S. Coke and Coal Company.

Copper-bearing steel is coming into more general use on account of its corrosion-resisting properties. In some cases, particularly for the Louisville and Nashville Railroad Company, it is specified for steel in the floor of bridges and other parts likely to be affected by brine from refrigerator cars. In many cases, such as the San Francisco-Oakland Bay Bridge, it is specified for all parts of the structure. A minimum of 0.20% copper is usually specified.

Wire rope is used not only for main cables and hangers on suspension bridges, but also for hangers on several riveted bridges, such as the Bayonne, N. J., Bridge and the West End-North Side Bridge, in Pittsburgh, Pa. It is also used for counterweight and operating ropes on lift bridges.

It has recently become necessary, in certain work, to design and detail structural steel so that it can be transported by airplane. The usual requirements are that the weight of a piece shall not exceed 2 000 lb and that the

piece can be loaded through a 3 by 7-ft door. The advantage of the saving in weight which is offered by the use of special steels, is apparent in such cases.

Shop Practice for Special Structural Steels

The fabrication of special steels has brought new problems to the shops because equipment was designed and powered for handling carbon steel. The equipment or capacity to fabricate the high tensile steels varies with each individual plant. The following discussion of shop practice is based on the typical or general equipment, and it must be realized that each plant may have some one tool with more power or capacity.

Cambered plates in heavy gages cannot be straightened with straightening rolls or in a press. Camber is removed from the large thick plates by planing the edges. The strength of high tensile steels is such that the usual fabricator is not equipped to straighten it as he would straighten rolled carbon steel. Efforts to cold-straighten heavy plates ($\frac{3}{4}$ in. and more) have produced badly cracked edges. One large fabricator prefers to divide plate thicknesses greater than $\frac{7}{8}$ in. into two thinner plates stitch-riveted together.

Some plates, $1\frac{1}{4}$ in. and more in thickness, cracked at the sheared ends when an attempt was made to flatten a slight shear bow by passing the plates through cold rolls. This bow was caused by the pressure of the movable shear blade on the outer ends of the plates where they were not supported by the fixed blade or die. The difficulty was overcome by planing $\frac{1}{4}$ in. from sheared ends and straightening the plates in the press. Subsequently, the bowing was avoided by turning the plates around so that in cutting both ends, the main body of the plate rested on the die of the shear.

As piping is deeper in silicon ingots than in carbon steel, angles should be ordered long enough for a preliminary shearing (or milling) at each end, in search of pipes.

It has been reported that the silicon plates for the towers of the Golden Gate Bridge were sub-punched with fewer punches broken than the plates for the towers of the Philadelphia-Camden Bridge. The records show that the average of the latter was as given in Table 15(k), whereas, the former, at the time the report was made, was as shown in Table 15(l).

A test has been devised which records on an indicator card the force of the punch, simultaneously with its penetration into the plate. Other tests have been made on power input required to drill and plane. Plates were used which had passed silicon steel acceptance tests and were of about the same strength. One analysis was: Carbon, 0.26%; manganese, 0.84%; and silicon, 0.27%; and the other was: Carbon, 0.35%; manganese, 0.84%; and silicon, 0.25 per cent. The former punched with 10% less maximum pressure than the latter. In drilling and planing, the difference was nearly the same, and in the same direction.

In 1929, a group of twenty-four types of high tensile steels in various structural shapes were studied to determine which of the different grades could be fabricated successfully with the present bridge shop tools. As described in Table 15(m), all these steels were in the manganese-silicon

group and represented various combinations of these elements with carbon. In addition, there were a few sections containing about 2% nickel. The sections included $\frac{1}{2}$-in. and 1-in. plates, 8 by 8 by $\frac{3}{4}$-angles, 12-in., 40.8 lb I-beams, and 14-in., 425-lb C-beams. These sections were subjected to various bridge shop operations which included punching, drilling, reaming, milling, planing, and coping, with the results noted in Table 17. Test coupons were cut from each item and tensile, bending, and hardness tests were made (see Table 15(m)).

[a] Considered impracticable; too difficult. [b] Satisfactory at speeds and feeds slightly less than those required for silicon steel. [c] Not quite as unsatisfactory as Item No. 28. [d] The shock to the punching machine was terrible. [e] Satisfactory at speeds less than Item No. 31. [f] Similar to Item No. 36. [g] Fair results. [h] Flanges split. [i] Practical at very low speeds.

In this general discussion, it should be recognized that two steels of the same ultimate strengths do not necessarily possess the same ease of fabrication, and that with the newer steels, current knowledge of this phase is quite incomplete.

Shearing.—Shears have been rated and powered for carbon steel, and it is not practical to reduce the speed. Consequently, with the higher tensile steels the capacity is correspondingly reduced. For silicon and manganese steels the shears are rated at approximately 75% capacity; for example, a large shear is rated to shear a carbon-steel plate, 1 in. thick by 100 in. wide. This same shear will safely shear a silicon plate, $\frac{3}{4}$ in. thick by 100 in. wide. The shear blades are not changed for the alloy steels, since the blades used for carbon steel are the hardest obtainable.

Punching.—The old "rule of thumb" for punching carbon steel was that the material should not be thicker than the size of the hole to be punched. With silicon steel and manganese steel, whether sub-punching or full-sized punching, and regardless of whether the holes are $\frac{13}{16}$ in. in diameter, or larger.

the shop prefers a maximum thickness of $\frac{3}{4}$ in., whereas for nickel steel the preferred maximum is $\frac{1}{2}$ in. Heavier material than this puts too great a strain on the machines. When punching alloy steels, the speed of the punches is usually reduced about 25 per cent.

It is a recognized fact that, with variations in composition, alloy steels may vary in hardness, and that some melts punch more easily than others. Where the specifications permit full-size punching, the shop will try to punch silicon and manganese to a maximum thickness of $\frac{7}{8}$ in. and nickel steel to a maximum of $\frac{9}{16}$ in. If the metal is too hard, as shown by the breaking of the punches or the strain on the machine, the holes will be drilled.

Because of the excessive breaking of the punches due to the harder alloy steels they have been re-designed. Larger fillets are used where the section of the punch changes radically. The stress concentration at this point was accountable for 50% of the punch breakage.

It is desirable to maintain scrupulously, or if possible exceed, the edge distance (and rivet-center distances) ordinarily specified. With 1-in. rivets, no angles with legs less than 4 in. should be used in the design.

One of the items that causes additional punching costs is the special handling due to punching holes of two sizes in the same plate because sizes of shop and field rivets are not properly proportioned, or the amount of reaming varies for shop and field rivets.

Drilling from the Solid.—With the harder alloy steels drilling from the solid is a matter of speed and feed. Thickness is not a factor unless the plates are stacked. The shop practice of sub-drilling, assembling the member, and reaming holes to size, or of assembling the member and drilling holes full sized, varies with the fabricating plants and also varies in an individual shop; it is determined by the types of work being fabricated.

The reduction in speed of the machines when drilling special steel can be seen from the report of plants as shown in Table 18.

The drilling of alloy steels requires more grinding of drills, which also entails the added cost of changing the drills more often. One plant reports that, in comparison with ordinary carbon steel, drills used in silicon and manganese steels must be ground somewhat more often, and those used in nickel steel, twice as often. One plant reports on nickel-steel bridge chords (in which the number of holes to be drilled per member averaged 539, with a thickness of $2\frac{5}{8}$ in.) that the best record on one chord required the drills to be changed fifty-five times, whereas on one chord the drills had to be changed ninety-seven times. For comparison purposes, they estimated that on a similar chord of carbon steel they would have required eight to ten drill changes.

The feed of drilling varies with the different alloy steels and even on one piece of angle or plate, and can only be stated as being less than for carbon steel.

Reaming.—Reaming of holes is more universally specified for alloy steels than for carbon steels. It will be noted from Table 18 (a report on the reduced speeds necessary with special steels) that the reduction is not as marked as noted for drilling.

Milling.—Planing speeds for silicon, manganese, and nickel steels are generally reduced about 25%, and the feeds are changed to suit the particular hardness of each metal. It is difficult to get a smooth finish on these alloy steels on account of the tool wear.

Chipping.—The increased difficulty of chipping silicon and manganese steels may be covered by stating that the speed is reduced about 25 per cent. Nickel steel is extremely difficult to chip under any conditions and depends on previous treatment, whether sheared or cold sawed; if cold sawed, it is almost impossible to chip, and may require pre-heating.

Flame Cutting.—Flame cutting of carbon steel of structural grades leaves a perfectly ductile edge for milling or chipping. If silicon steel is flame cut the edge is air-hardened, and it is difficult to edge-plane or mill. However, a milling cut of $\frac{5}{32}$ in. will remove all trace of damage. The portion affected by the flame varies in hardness and although the piece usually can be edge-planed without serious difficulty after a cutting torch is used near the surface to be planed, it is sometimes necessary to pre-heat it. Manganese and nickel steels offer more difficulty. If either is flame cut, it cannot be planed (without special treatment that is not practical).

Experiments with a special portable heat-treating and flame-cutting machine indicate the possibilities of flame cutting some of the alloy steels (the standard nickel, manganese, and silicon types), leaving an edge of sufficient ductility for further shop operations. The results of the bend tests and drift tests indicate that the process will meet any required specifications.

Bending.—In discussing alloy steels it is usually stated that the radius required to bend a plate cold depends upon the thickness of the plate, as expressed by:

$$r = C\,d \qquad (4)$$

in which r = the radius of bend; C = a coefficient; and d = depth, or thickness of the plate.

The writer has noted, in various papers, that, for plates with $d = \frac{3}{4}$ in., or less, $C = 2$ for Cor-Ten; 2.5 for Man-Ten; and 3.0 for Cromansil.

The radius required for bending a plate cold should vary with the kind of steel, the thickness of the plate, and the angle of bend. Table 19, which

	0.625	0.75	1.625	1.875			
	0.875	1.00	2.75	3.0			
	1.125	1.25	3.75	4.25			

illustrates these variables gives the minimum radii required for bending silicon and nickel-steel plates. These radii are to be used when the bend is transverse to the plate. When the bend is longitudinal (that is, when the bend line is parallel to the direction of rolling the plate) these radii should be increased slightly.

Assembling.—The increased stiffness of the special steels makes it more difficult for the fitting-up bolts to draw the steel together into perfect contact, but this close contact is necessary for the driving of satisfactory rivets. The smallest fitting-up bolts which the shop should use are $\frac{3}{4}$ in. in diameter. This means that the minimum diameter of the holes should be $\frac{13}{16}$ in. Where sub-punched and reamed work is specified, the minimum shop rivet should be 1 in. in diameter. The increasing use of alloy steels and the difficulties of fitting up properly have necessitated the use of stronger fitting-up bolts, and the fabricating plants are beginning to make them of manganese steel. One plant now uses 100% manganese bolts for all bridge work.

Rivets.—The manufacture of carbon-steel rivets and their use in fabricated steel structures has become standardized. The need for a rivet of higher strength to match the special steels was recognized. Nickel-steel rivets with a nickel content of 3 to $3\frac{1}{2}$% have been used on a few structures, but have been so invariably unsatisfactory from every standpoint that they should not be specified for any structural steel work. However, tests have been made on rivets that meet Steel Specification No. 2115 of the Society of Automotive Engineers (carbon, 0.10 to 0.20%; manganese, 0.30 to 0.60%; silicon, 0.15 to 0.30%; and, nickel, 1.25 to 1.75%) which indicate that this grade is suitable for hot riveting and will develop a shearing strength comparable to that of other high-strength rivets in use to-day. Whereas silicon steel is admittedly not a forging steel and not satisfactory for rivet material, manganese steel

has been found to be satisfactory both for manufacturing and driving. Shipbuilders have found that manganese steel makes a good high-strength riveting material. They have used it in large quantities and have had considerable research work done to establish the best chemical composition.

A large number of manganese rivets was used on the Bayonne Bridge (see Table 15(*e*), Item No. 2). The maximum rivet was 1¼ in. in diameter by 10¾ in. long. The rivets were tapered if the length was five or more times the nominal diameter. Later experiments indicated that this rivet material was a little too hard, and a more satisfactory material has been developed (see Table 15(*d*)). For the San Francisco-Oakland Bay Bridge the largest manganese rivets were 1¼ in. in diameter by 10½ in. long, 1⅛ in. in diameter by 9½ in. long, and 1 in. in diameter by 6¾ in. long. These rivets were tapered the same as for the Bayonne Bridge.

The driving technique for manganese rivets differs considerably from that for carbon rivets. The more important differences are: (1) Manganese rivets must be more carefully heated; (2) they are more easily burned than ordinary rivets; (3) the range of temperature is small between a proper driving heat and a burning heat; (4) more time is required in driving than for ordinary rivets; (5) the cost of driving is estimated at 10% greater; (6) it is necessary to burn off the heads before backing condemned rivets out; (7) it costs about twice as much per rivet to remove them; and (8) with the proper attention to heating and driving there will be no more cut-outs than for ordinary rivets. There is a need for a standard specification for high-strength structural rivets.

The action of riveted joints is a controversial subject and some criticism of manganese rivets has been offered because the tests show that they have an initial slip at lower values than carbon rivets. However, the point should be brought out that the factor of safety is not based on the initial slip value, but on the relation of the working stresses of the material and details, such as rivets, to the yield points, and upon the actions of these materials under laboratory tests and actual use, when stressed between these limits. Tests made for the Bayonne Bridge showed that carbon rivets averaged from 0.004 in. to 0.008 in. more slip than the manganese rivets. Other tests have shown a contrary result.

In order to maintain the factor of safety for the structure, the rivet factor must be maintained on an equal basis with the main material between the working stress and up to the yield point. Taking an average of all available tests, it seems fair to state that the slip for manganese and carbon rivets will be of approximately equal magnitude through the range of stress in which the designer is interested. At ultimate values the manganese rivets have a larger factor of safety than carbon rivets.

In 1906, tests of nickel and chromium steels were reported at the University of Illinois[19] with the following conclusions:

(*a*) The ultimate shearing strength of rivet joints depends on the shearing strength of rivet material, and this is influenced by the relative hardness of rivets and plates;

[19] "Tests of Nickel-Steel Riveted Joints", *Bulletin*, Vol. 8, No. 26, Univ. of Illinois, Urbana, Ill.

(*b*) The ratio of the yield point stress in riveted joints to ultimate shearing strength of riveted joints is about the same as the ratio of the yield point stresses of plates in tension to the ultimate strength of the plate.

(*c*) In riveted joints designed on the basis of ultimate strength, the strength of the rivet material and of the plate material is of prime importance, and use of special steels of great strength may be of advantage.

(*d*) In riveted joints designed on the basis of the frictional hold of rivets there is little advantage in using rivets of special steel since joints with such rivets show about the same resistance to first noticeable slip as joints with ordinary carbon rivets; and,

(*e*) There was a noticeable slip of the joint, generally, at loads within the ordinary working shearing stress of rivets.

Tests by Commander E. L. Gayhart[80], U. S. N., were made on high-strength steels and rivets. He stated that joints fabricated with high tensile steel showed resistance to slip greatly inferior to that shown by medium steel—values so low that it appears doubtful whether any great part of the load could be considered as carried by frictional forces. In terms of single shear stress, according to Commander Gayhart, the stress in the rivet at which the first slip occurs is so much less than customary design shear stresses, and is so greatly affected by the number of rivets in the joint, that it does not appear desirable to design riveted joint construction on the basis of frictional resistance but rather by the commonly used method of proportioning on shearing and bearing.

As the designer depends on the bearing of the rivet on the plate to carry the stress, there is no advantage in using high-strength rivet steel in carbon plates; for example, on the Bayonne Bridge a bearing value was used for the manganese rivets, of 45 kips per sq in., on manganese plates; 40 kips per sq in. on silicon plates; and 30 kips per sq in. on carbon plates. As 30 kips per sq in. is also used on bearing carbon rivets on carbon plates, it is evident that the value of a manganese rivet and a carbon rivet in bearing on a carbon plate is the same.

Welding.—The scope of this paper does not permit the introduction of very much material on the subject of welding for to the writer's knowledge no structural steel bridges or buildings have been constructed in which the special steel was welded to carry stresses. However, considerable welding on special steels is being done in the plants. Pre-heating and annealing of large structural members is not practical; practically all the welding is done by the metallic arc.

Considerable confusion exists at present because there is no standard or definition stating what chemical or physical qualifications a steel must have in order to be classed as of weldable quality. The various steel companies list their special steels as those that can be welded, whereas the specifications of the American Society for Testing Materials do not list them as "steel suitable for fusion welding." On one hand the United States Navy

[80] "An Investigation of the Behavior and of the Ultimate Strength of Riveted Joints Under Load", by Commander E. L. Gayhart, U. S. N., *Proceedings*, Soc. of Naval Archts. and Marine Engrs., Vol. 34 (1926), p. 55.

Department is quoted as being definitely against the use of the silicon-manganese types of steels for welded stress-carrying members; and yet U. S. Navy Specification No. 48S 5e specifies (under high tensile steel of weldable quality) a steel with the characteristics listed in Table 15(*n*).

Probably the most interesting point to be emphasized in the welding of special steels (for the purpose for which welding is used in structural shops) is that generally the ordinary soft steel, coated, welding rods are used rather than the special rods developed by various manufacturers. The technique required for the ordinary coated rods is much simpler, and the strength developed is more than ample for the fillet welds.

Tension tests were made on full butt welds in manganese-steel plates using several of the special welding rods and all the welds developed more strength than the parent metal. However, many of the special steels are subject to "air-hardening" or grain growth, so that if it is necessary to bend the steel, or if it is subject to bending stresses, the air-hardened surface must not be located on the tension side, unless the steel can be annealed, which is usually not practical for structural steel work.

Welding of special steels in the fabricating shops has generally been confined to: (1) Tack welding for assembling; (2) fillet welding fillers for permanent work; and (3) some welding of silicon slabs for shoes, with special supervision. Covering this type of welding, it is stated[77] that in the fabrication of the towers for the Golden Gate Bridge, it was desired to tack-weld the shaft angles and the web-plates so that the full thickness could be drilled from the solid steel simultaneously, with no subsequent separation before riveting. The question was raised as to whether this tack-welding would embrittle the silicon steel harmfully, which was of the composition listed in Table 15(*l*). Specimens, therefore, were tack-welded, broken apart, and bent; other specimens were drilled and bent until cracks appeared around the drilled holes. The broken weld edges would bend farther than the drilled holes before cracks appeared. Other plates were tack-welded on the edges, drilled, riveted, and bent. The rivets sheared before any cracks appeared in the welds. It was proved, therefore, that the tack-welding was not detrimental to the structure in comparison with the other acceptable processes of fabrications. This was not intended to, and did not, touch on the question of welding for transmission of stress.

Stress-strain data for the silicon steel used in the towers of the Golden Gate Bridge are listed in Table 20, the average chemical composition (previously discussed) being given in Table 15(*l*). Specifications for standard mill tests required that the yield point, or the drop of the beam, should be equal to, or greater than, 45 kips per sq in. The proportional limit was defined as the point on the stress-strain curve at which the rate of deformation is 50% greater than it is at the origin.

Sketches of the test coupons, and their standard position in plates and angles, are shown in Fig. 33. These specimens were made about 0.505 sq in. in diameter, except for material 0.5 in. thick, or less; in the latter case the

physical characteristics for this series being listed in Table 15(*o*). Fig. 35 illustrates the type of specimen tested in Table 15(*o*) and in Fig. 34. The letters, *C*, *B*, and *A*, indicate the location of coupons corresponding to Items Nos. 63, 64, and 65, respectively, in Fig. 34.

Heat-Treated Eye-Bars

Heat-treated eye-bars are made in two grades: (1) Grade HT—high tensile strength (Table 15(*f*)); and (2) Grade HT Special—special high tensile strength (Table 15(*g*)). When acceptance of eye-bars depends on the results of full-sized tests, the standard requirements are as shown in Table 21. When chemical and physical properties are specified, the following standards

TABLE 21.—Specifications Based on Full-Sized Tests

Description	Grade HT*	Grade HT Special†
Tensile strength, minimum, in kips per square inch..................	80	105
Yield point, minimum, in kips per square inch..................	50	75
Percentage elongation in 18 ft., minimum........................	8	5

* See Table 15 (*f*). † See Table 15 (*g*).

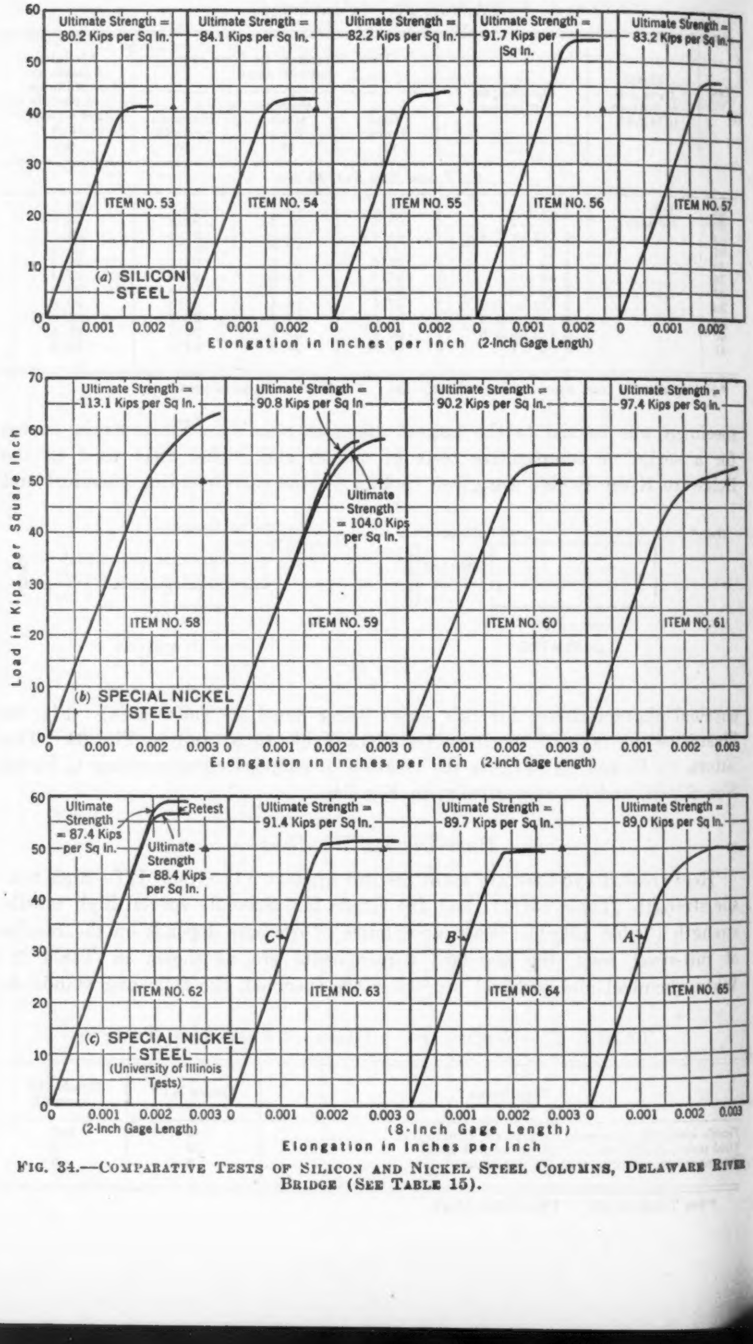

FIG. 34.—COMPARATIVE TESTS OF SILICON AND NICKEL STEEL COLUMNS, DELAWARE RIVER BRIDGE (SEE TABLE 15).

are satisfactory and will result in eye-bars that will meet full-sized test requirements:

	For high-tensile strength eye-bars
Percentage of carbon.......	0.30 to 0.40
Percentage of manganese....	0.50 to 0.75
Tensile strength, minimum, in kips per square inch....	70
Yield point, minimum......	0.5 of the actual tensile strength

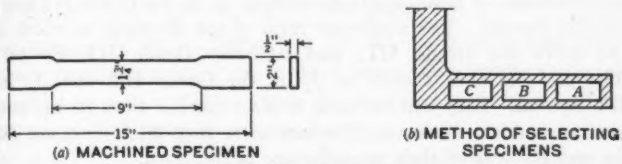

FIG. 35.—STANDARD TEST SPECIMENS, DELAWARE RIVER BRIDGE.

All specifications for chemical and physical properties of specimen tests for the special high-tensile grade steel must be referred to the manufacturer of the eye-bars. The modulus of elasticity of all grades of eye-bars is approximately 29 000 000 lb per sq in.

Brinell tests for hardness are sometimes required on heat-treated bars. They are made to determine the uniformity of hardness throughout the length of the bar. These tests are for information only, and do not form a basis of acceptance.

Method of Manufacture.—The process of making heat-treated eye-bars is, briefly, as follows: The head on one end of a bar is formed by repeating the operations of heating, upsetting, and rolling, until the correct proportions are attained. A hole is punched in the head while hot, somewhat smaller than the finished bored hole, and the bar is allowed to cool. After cooling, the bar is sheared to the correct length, turned around, and a head is formed on the opposite end of the bar in the same manner as described previously.

This process insures a quantity of metal adequate to form the head completely. Excess metal is squeezed out between the dies on the two sides of the head and, later, is sheared off while hot. The rough edges on the sides of the head due to this shearing, are chipped smooth.

Heat-treatment of high-tensile and special high-tensile eye-bars consists of heating, quenching, and tempering. After removal from the tempering furnace, the eye-bars are cooled in the air. The bars are straightened, and the pin-holes in the two heads are bored simultaneously. When Brinell tests are made, they are made just prior to boring.

Full-Sized Tests.—Orders for eye-bars customarily include a small percentage (about 3) of full-sized test bars which are tested to destruction in a 2 000-ton hydraulic horizontal testing machine. Test bars are selected from the finished bars except that those from bars too long for the testing machine are selected from the full-length bars after the heads on one end have been

formed. They are then cut, and the second head is formed to make the longest bars that can be tested.

The maximum distance, from center to center of pin-holes, with the ram of the testing machine at the beginning of the stroke, is 42 ft 6 in. The minimum is 3 ft 9 in. The length of stroke is 8 ft. The desired maximum length of the test bar is 35 ft.

Details of Eye-Bars.—High-tensile and special high-tensile heat-treated eye-bars are made in widths of 10 to 16 in. and in lengths, from center to center of pin-holes, of from 72 ft 7 in. (maximum) to 13 ft 0 in. (minimum). The excess thickness of head over body is about $\frac{1}{16}$ in. for Grade HT and $\frac{1}{8}$ in. for Grade HT Special. The minimum ratio of pin diameter to width of bar should be 0.875 for Grade HT, and 0.93 for Grade HT Special eye-bars. The pin clearance should be $\frac{1}{32}$ in. for Grade HT and $\frac{1}{50}$ in. for Grade HT Special. They can be made in sizes smaller than 10 in., but it is usually not economical to do so. Eye-bars more than 60 ft long are difficult to handle, and the cost of their manufacture is increased.

Conclusions

The use of special alloy steels has become increasingly prevalent, and is covering a wider range of structures as engineers are becoming more and more acquainted with its advantages.

Acknowledgments

The material which forms the basis of this paper was collated from a number of articles in *Engineering News-Record* and various papers published by the American Society of Civil Engineers, especially the Progress Report of Sub-Committee No. 2, Committee on Steel, of the Structural Division on Structural Alloy and Heat-Treated Steels[81]. EVOLUTION OF HIGH-STRENGTH STEELS USED IN STRUCTURAL ENGINEERING

By LEON S. MOISSEIFF[82], M. AM. SOC. C. E.

SYNOPSIS

The development which led to the use of higher strength steels for bridges in the United States is outlined in this paper.

The rapid increase of population by natural growth and immigration and the industrialization of the country demanded transportation facilities for freight and men. Heavy trains required bridges of great strength, and crowded cities demanded structures with many tracks and wide roads. The wealth of the country and the growth of automotive transportation called for comfort and speed and led to the building of large bridges of long spans. Engineers, by the use of higher strength steel, were able to construct many great structures. The reasons governing the design of most large American bridges afford an excellent illustration of the evolution of the use of higher strength steels, and are related in detail.

The practical advantages of higher strength steels are feasibility of construction and economy of cost. They are readily seen. The limitations of these steels are not quite so apparent. They are discussed at length from their technical and practical aspects.

INTRODUCTION

During Man's long struggle for existence with the forces of Nature he has acquired a mass of knowledge about phenomena around him and a number of ways of manipulating and forming the many materials among which he found himself. Out of the want of Man grew his knowledge of Nature and his ability to appraise and apply the strength of materials. Under the incessant pressure of his surroundings he acquired tools and skill in handling them and rules and numbers for Nature's behavior. In the course of time he learned that by applying these rules the same task could be done with less labor, at the same time, creating a better product; and thus labor began to be co-ordinated, rules pertaining to natural phenomena grew into science, and the planning and execution of work became engineering.

In the course of this evolution, engineering became the application of scientific principles to meet the practical needs of Man in the best way, with the least expense of labor and materials. It is based on necessity and economy, which are two hard masters to please. At times, one or the other prevails, but necessity is the more compelling.

[82] Cons. Engr., New York, N. Y.

Transition from Wrought Iron to Steel

The meandering road of evolution is well illustrated by the changes that occurred during the transition from wrought iron to medium steel and from that to soft steel, in the United States and Central Europe.

Building Construction.—At about the beginning of the Twentieth Century steel came into use for frames and floors of multi-storied buildings. The growing demand for office buildings, hotels, and high-class apartment houses foretold the consumption of an enormous tonnage of steel for construction purposes. It became clear to the makers of steel that, although there would be a demand for large tonnage, there would also be a demand for a low-cost steel to compete with other building materials. It was realized that high strength and special qualities of steel were not required for this type of structure, which transmitted its loads directly to the foundations and which was not subject to impacts and reversals of stress.

It was important, from the point of view of the consumer, that the fabricated steel should be bought at a low price and that it be dependable; and from that of the producer, it was important that it should be manufactured in large tonnage without special precautions and manipulations and that it could be easily punched and fabricated. Above all, it was important that the fabricated product should be acceptable to the consumer and that there should be no rejections. This meant the avoidance of interruptions and the advantages of mass production. The demand, in the case of such relatively simple structures, was not for a steel of higher qualities developed like a race horse—highly nervous in behavior—to meet special requirements, but a dependable material that could stand abuse in fabrication—developed like a truck horse and possessing as little temperament. This was achieved by abandoning the medium steel that had prevailed before that period for bridges and adopting a soft steel of an average tensile strength of 60 kips per sq in., and a yield point, then known as "elastic limit," of one-half the tensile strength, as the standard material for engineering structures. To be more exact, the limitations for tensile strength were from 55 to 65 kips per sq in.

Steel Manufacture.—The demand at the beginning of the Twentieth Century for steel led to far-reaching re-organization of the steel manufacturing companies. A process of agglomeration set in; smaller mills were consolidated into large units, and in the process of co-ordination, many were abandoned in favor of enormous plants with capacity for large tonnage. Dispersed and competing fabricating companies were united in large groups which were more than able to compete with the remaining smaller independent organizations.

It cannot be regarded as a mere coincidence that while such re-organization took place in the United States, a similar process was effected at the same time in Central Europe, especially in Germany. It is still less accidental that, there also, after a systematic study of the advantages of soft steel, it was adopted as the standard material. By these changes and re-organizations the manufacturers were able to offer the market a uniform

and dependable steel at a reasonable cost and a wide confidence in the product was created. In fact, in rare instances only did the consumer exercise his right of inspection at the mills and shops; the material was accepted on the Manufacturers' Certificate. Time has shown that, in general, the development was in the right direction and that the confidence in the product was justified.

Transportation.—The rapid growth of the United States and the great development of its industries brought with it enormous demands for transportation facilities for freight and men. One has but to consider that during the fifty years from 1880 to 1930 more than 27 000 000 people immigrated into the United States and that, in the same period, the total population of the country increased from 50 000 000 to 123 000 000, to realize the tremendous impetus given to transportation. The revenue of the railroads increased 64% in the first decade of the century and in the first two decades it increased three and one-half times. The growth of commerce and industry produced a demand for transporting the increased tonnage of freight and the greater number of passengers created by the new conditions. This demand was met by the double-tracking of existing railroads and by the use of longer trains and more heavily loaded cars, which required heavier locomotives with greater axle loads. By about 1900 the heaviest axle loading specified for railroad bridges was 43 000 lb; the weight of one engine and tender was 145 tons and the load following it 4.2 kips per lin ft. The 1935 Specifications for Steel Railway Bridges of the American Railway Engineering Association call for an axle loading of 72 kips per lin ft, followed by a uniform load of 7.2 kips per lin ft. The weight of one locomotive and tender is 256 tons. The increase in axle load is two-thirds and that in the engine, three-fourths. The comparison of these specified figures illustrates vividly the growth in the live load of modern railroad bridges.

Bridge Construction.—The double-tracking of railroads brought with it the building of new bridges for heavier loads. At the same time, the increase in revenue-producing freight and passenger traffic made it financially worth while, in some instances, to extend railroad lines and to bridge wider rivers, and, in other instances, to shorten routes and reduce grades. All these effects of the growth of railroads called for stronger and longer bridges.

The larger number of railroad bridges of the period were built of the new standard soft steel of a tensile strength of 55 to 65 kips per sq in. It was then known as the "railroad bridge grade" of steel. Whenever bridge engineers desired a higher grade for their bridges (largely because they felt that the severe strains and impacts to which the bridges were subjected justified a stronger steel) the mills rolled a special grade of a tensile strength of 60 to 70 kips per sq in., and a yield point of one-half that of the ultimate strength. The proximity of the tolerance limits of this steel to the standard steel being 5 kips apart, permitted overlapping and gave the mills a chance to use the higher melts of the standard steel for the special steel.

Demand for High-Strength Steel

Some bridge engineers, however, were not satisfied with the two grades of steel offered by the manufacturers and insisted on a higher grade of material for their bridges. They specified a steel of a tensile strength of 62 to 72 kips per sq in., and a minimum yield point of 35 kips per sq in. The steel industry looked with scant favor on specifications which called for material different from the standard product. The demands of the engineers were not always readily met and their path was not "strewn with roses." In spite of discouragement, individual engineers adhered to their demands, and a number of larger bridges were built of this higher strength steel. Finally, it became quite usual for engineers to ask for a special carbon steel for more important bridges.

It is quite in order that a structural engineer should demand for his particular structure a material which physically may be better suited for its task, provided he can obtain it from the manufacturers at a price that will justify it economically. It is also in order that the manufacturers should not wish to disorganize their regular procedure of production, both in the mills and in the shops, unless the demand is great enough to compensate them for it. As the demand for the higher quality of material becomes larger and steadier the manufacturers finally see the necessity and the reasonableness of acceding to the demands of the consumers, and they realize the advantage of adopting the modified material as their standard.

Specifications.—More recent changes in the economy of the commercial and industrial life of the country and, no doubt to some extent, the competition of reinforced concrete, have led to the consideration of a slightly stronger steel which will enable engineers to produce their structures more economically. The tendency has finally crystallized in the adoption of a specification by the American Society for Testing Materials (Standards Serial A7-34), which forms the basis of the Specifications for Steel Railway Bridges of the American Railway Engineering Association.

These specifications are a product of the co-operation of the consumers and the producers, the designing engineers, and the mills. The specified material is practically the medium steel of 1903. Its physical qualifications are: Tensile strength, 60 to 72 kips per sq in., and yield point, one-half the ultimate strength, but not less than 33 kips per sq in.

Economy.—It is understood that the manufacture of this steel will cause no increase in cost to the mills. A slight increase in the cost of fabrication in the shops may be expected, due to the greater wear and tear on tools and machinery. The same material will probably be used for all kinds of structures and will thus become the standard American structural steel.

Rapid Mass Transportation.—While the foregoing developments in railroad transportation were progressing and exerting their effect on railroad bridges, similar and still more important changes were modifying life in cities and affecting the character of city bridges. The extraordinarily rapid growth of population in cities due to immigration and the inflow from

farm to city produced overcrowding and overflow into suburbs. The effect on the means of transportation is readily understood. The mechanism of commerce and industry is based on the co-ordination of many agencies, which can function properly only when the precision of time is observed. Many people must come to the city—to mills, shops, stores, and offices—and they must come there within a definite time on every working day. Moreover, the time is the same for each of them, within an hour or two. They also must return to their homes within other hours as closely set. Thus, the busy life of the city has produced the term, "rush hours." To transport this great and bustling mass of people, electric cars were running on busy streets and, later, entire trains were operated over elevated or subway structures, to achieve high-speed traffic uninterrupted by crossings. Larger and heavier cars were required and longer and longer trains were operated, attaining a length of ten cars in the Subway System of New York City. The higher speed of rapid-transit trains increased the danger of collisions and telescoping, and the underground operation of these trains made the adoption of all-metal, fire-proof cars imperative. All these requirements added weight to the cars. Thus, the weight of rapid-transit cars filled with passengers grew from 1 to 2 kips per lin ft of train.

In some cities the cars and trains had to be brought in over large streams requiring bridges with long spans. The bridges had to provide sufficient passage for cars and trains converging from many directions, and multiple tracks had to be provided on the bridges. At the same time, the increase in the wealth of the country justified the replacement of slow ferry traffic by long-span bridges. The growth of cities and the increased density of their population demanded provision for much heavier live loads than the old-time city bridge. It also demanded provision for the future growth of the frequency and continuity of these live loads.

Automotive Transportation.—During the twenty years, 1916 to 1936, a new factor in transportation began to exert a marked influence on the financing and building of bridges which, properly, should receive consideration. Favored by the increase of wealth due to the World War, the enormous development of automotive transportation of passengers, as well as of freight, brought with it new demands on bridges. Many capacious first-class highways were built throughout the United States and millions of automobiles are rolling over them at ever-increasing speeds. The new mode of travel by machine differs much from the old way by horse-drawn vehicle. It is not limited to immediate neighborhoods; its mileage is unbounded. It is swift and impatient; time has become essential. The automobilist, therefore, is willing to pay for his undelayed travel; and he does pay.

Long-Span Bridges

Toll Bridges.—The economic aspect of bridges thus took a new turn because of automobile travel. Although toll bridges were built during a hundred years, all over the country, they were able to pay on the investment only because the structures were relatively small and cheap to build, and the

low toll that the traffic could bear was sufficient to make the enterprise successful. Larger bridges could not be built on the expectations of income from tolls before the arrival of the automobile. The Brooklyn Bridge is a fair example. Gradually, the older toll bridges were being taken over by the State authorities and made free or replaced by modern bridges. All this was changed by automotive traffic. The unlimited traveling radius of the automobile and its high speed multiplied the number of vehicles on the highways and the higher standard of operating expenses made it possible and reasonable to charge substantial tolls.

The financial possibilities of building first-class bridges of longer spans were changed by the new factor completely. Where municipalities and Government agencies heretofore could build bridges only by borrowing funds, carrying and amortizing the bonds and maintaining the structures from general taxation, the possibility now offered itself to maintain the bridge, pay the interest, and amortize the bonds within a reasonable number of years from the income collected by tolls. The opportunity was quickly seen and taken. Practically all long-span highway bridges built in recent times are toll bridges. All the large highway bridges have been financed on the basis of toll income: The Delaware River, the Ambassador, the bridges of the Port of New York Authority, the New Orleans, Tri-Borough, Golden Gate, and San Francisco-Oakland Bay Bridges, and numerous less costly structures all over the country.

With this development new problems in the economic relations of bridges appeared. It was not enough to build a safe, substantial bridge of good appearance to accommodate present and future traffic but, first, the structure had to be designed not to cost more than the traffic would bear, and, for privately built bridges, a fair profit had to be earned. The full import and weight of economic design and construction made itself felt in the planning of toll bridges.

Highway Bridges for Motor Traffic.—With the development of highway bridges for automotive traffic, new conditions were created. Although the live load per lane of traffic on a bridge is lighter for automotive travel than for rapid-transit trains or trolley lines, the dead load of the bridge is greater. Automotive travel requires a floor with a continuous non-skidding surface, preferably fire-proof. Heavy automobile trucks have high axle concentrations which must be sustained at any point of the roadway by the pavement and its supports. The dead load of highway bridges has increased as compared with the live load. This shift of loads exerts an influence on the selection of the type of the most suitable and economical structure. Suspension bridges display their best advantages with high uniform loads and, therefore, have come to the foreground. Heavy dead load and relatively light live load also favor higher strength steels.

Economy of Materials.—The heavier live loads and the longer spans of bridges placed before bridge engineers the problem of technical performance. The question arose whether the available engineering materials were adequate and efficient to sustain the great forces developed in large bridges. Necessity demanded a material stronger than the available structural steel.

It is an essential characteristic of a bridge that it has a tendency to use stronger materials in its construction. It spans a horizontal distance by transferring the gravitational forces on the span to its abutments. The magnitude of the resisting forces increases with the weights on the span and with their distance from the bridge abutments. It is evident that the longer the span the heavier will be the bridge and the greater will be the forces required to uphold the equilibrium. To resist these forces acting through the material of the bridge, either more material (and, therefore, still more weight) is required, or a material of higher strength must be substituted which will resist the greater forces without adding to the weight of the structure. This states in different words what is known to all engineers, that with an increase of span a bridge becomes heavier at a rate greater than in a simple proportion. Thus, in the longest highway bridges, the ratio of dead load to live load becomes 5 to 1 in the George Washington Bridge and 5.25 to 1 in the Golden Gate Bridge.

Heavy and long-span bridges, therefore, will require excessively large members to meet the enormous forces developed in them. The sectional areas and weights of the members become difficult to fabricate, to connect, and to handle. The structure appears to outgrow its proportions, which are intimately tied not only to the bridge as completed but also to the machinery and capacity of the fabricating plants and the available transportation facilities. Finally, the cost of the structure becomes excessive and defeats its object economically. The application of suitable and stronger steels frequently makes the building of the bridge feasible and financially possible.

The aim of all bridge engineers, therefore, has always been to reduce the weight of the longer bridges by utilizing materials of higher strength. The history of bridge engineering shows that almost in all instances of longer bridges their designers have endeavored to obtain a material which, either by its strength or its dependability, would enable them to allow higher intensities of stress, and thus reduce the weight to be carried. Generally, this has been accomplished with more or less success.

Reasons for Adopting Higher Strength Steels

So far the general outline of the play of social and economic forces which has led to the demand for stronger steel has been discussed in general without direct application to built structures. Generalizations afford a bird's-eye view and give a historical panorama, but they do not supply the direct information and practical understanding which concrete examples offer. These will be brought out in the following paragraphs.

In relating the various reasons which have led engineers to adopt a higher strength steel for the several structures which will be discussed, the writer wishes to call attention to an observed phenomenon in the records of human investigations and history. In the meandering of human thought and in the constant play of forces, interests, and changing conditions, events and decisions evolve neither along smooth straight lines nor along continuous curves. Many a jolt is experienced and frequently the chain of events is

interrupted. It is only by looking backward through a duration of time that people are able to perceive the general tendency and its flow and to describe it as sequences and logical action. Thus, the observer on the shore may see far away a smooth sea and a placidly moving ship.

Limitations to Progress.—The structural engineer in the past has had little choice in his search for the higher strength material. Laboratory tests, no matter how carefully made, can only indicate the quality of the product and establish its probable behavior when produced under mill conditions in large tonnage. Engineers have also learned, sometimes to their sorrow, that the mass product may develop failings and defects that cannot be anticipated in the laboratory samples, and even in small ingots. The engineer has often had to act in the rôle of stimulator and pioneer, and the manufacturer has brought out the new material with more or less enthusiasm and apprehension. It involves a risk in money and reputation to contract under specifications, which necessarily are rigid, to roll and fabricate the new steel. A higher price must necessarily be set to cover the cost of uncertainties and novelty to equipment and personnel.

Several instances may well illustrate the reasons which prompted the introduction of the use of nickel steel for bridges. At the beginning of the century two bridges over the East River—the Queensboro and the Manhattan—were being planned by the Department of Bridges of New York City.

Eye-Bars in the Queensboro Bridge.—The Queensboro Bridge is a double cantilever structure with two main spans of 984 and 1 182 ft. Originally, it was designed for two rapid-transit tracks, four trolley tracks, a roadway of 35.5 ft, and two sidewalks; after the letting of the contract two more rapid-transit tracks were added. In accordance with the loads then established, the specified congested live load was 16 kips per lin ft, and the average dead load, 35 kips per lin ft. The dead and live load stresses in the panels of the upper chord attain a maximum stress of 19 000 kips. Using the proportional unit stress which could be allowed on eye-bars of medium steel (20 kips per sq in.) about 950 sq in. of bars would be required. As built, the nickel-steel eye-bars have a greatest sectional area of 680 sq in., consisting of 20 bars, 16 by $2\frac{1}{8}$ in. An increase of 40% in sectional area would thus be required if the bars were made of carbon steel. As the largest eye-bars available were used, it meant a proportional increase in the number of bars. The increased weight of the tension members would add to the dead load and, in its turn, would require more bars. Structurally, it meant that the width of the chord and the length of the pins would have to be increased, which again would lead to further increase in dead load.

An increase of 40% in the number of bars would have required the widening of the upper chord in the panels of maximum stress from its present width of 90 in. to more than 120 in. The greater number of bars in the chord, in turn, would involve the widening of truss members to unwieldy proportions.

The engineers discussed various alloy steels with metallurgists and manufacturers, and, finally, the Carnegie Steel Company, in 1902, made a heat of steel containing 3.26% nickel, 0.21% carbon, and 0.53% manganese. From

it 21 eye-bars were manufactured by the American Bridge Company in sizes of 6 by 1 in., 6 by 2 in., 8 by $1\frac{1}{2}$ in., and 10 by $1\frac{1}{4}$ in. Tests were made of specimens and of full-sized eye-bars, annealed and not annealed. The results of the tests indicated that a good structural material had been obtained which could be depended upon for bridge purposes and which, after further experimentation, could be specified to meet a yield point of 48 to 50 kips per sq in. and an ultimate strength of 100 kips per sq in.

In 1903 a further set of eight bars of basic open-hearth steel, containing 3.24% nickel, was made and tested. When tested, the full-sized eye-bars developed an elastic limit of 46 to 49 kips per sq. in., and an ultimate strength of 84 to 87 kips per sq. in. This gave assurance that a high-strength steel could be manufactured into eye-bars on which, for dead load and regular live load (8 kips per lin ft), a tensile unit stress of 30 kips per sq in., and for dead load and congested live load (16 kips per lin ft), a stress of 39 kips per sq in., could be allowed. During the construction of the bridge the bars were ultimately made to meet a minimum elastic limit of 48 kips per sq in., in full-sized tests, and an ultimate strength of 80 to 85 kips per sq in.; elongation in 18 ft, 9%; reduction of area, 40%; and bending, 180° around a pin of twice the thickness[83]. In this first application of nickel steel to bridge construction about 6 000 tons of eye-bars and pins were consumed.

The introduction of nickel as an alloy to the steel for the eye-bars of the Queensboro Bridge offers a good illustration of the causes which have led to the use of high-strength steels for bridges. A stronger steel was desired to hold the number of eye-bars and their section within manageable limits. The steel had to be as dependable and as workable as the standard bridge steel. A percentage of about 3.25 of nickel added to the steel supplied the necessary strength and quality, and this material was adopted for the eye-bars of the bridge. The type and general dimensions of the structure were not affected by the selection of the stronger steel.

Stiffening Trusses in the Manhattan Bridge.—Another illustration, but of a different character, of the use of high-strength steel is presented by the events which led to the use of nickel steel for the stiffening trusses of the Manhattan Bridge in New York City. It was planned at the same time as the Queensboro Bridge and was designed for four rapid-transit tracks, four trolley tracks, a 35.5-ft roadway, and two footwalks. For this capacity a congested live load of 16 kips per lin ft was adopted.

The dimensions of the bridge and its dead and live load created a problem for the engineers. The bridge had to clear the East River between pier lines and the length of the main span was determined by the location of the bridge and the width of the river between pier-head lines at 1 470 ft. A desire to present a well-balanced appearance made the side spans 725 ft. Before the development of the deflection theory of suspension bridges a reasonable design of stiffening trusses for a bridge with suspended side spans

---

[83] "Nickel Steel Eye-Bars for Blackwells' Island Bridge" (later, Queensboro Bridge), by William R. Webster, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXIV (1909), p. 289.

of similar dimensions, and a live load as heavy as two-thirds that of the dead load, would require trusses of great depth and extraordinary chord sections to come within allowable unit stresses and limited deflections as then computed. The introduction of the deflection theory led to a more correct determination of deflections and made it possible to design the bridge with relatively shallow trusses. Their depth of 24 ft was determined by the cross-section of the bridge, which has a double deck, and the required clearance for the rapid transit trains on the lower deck. It may be pointed out that this was the first suspension bridge of its kind and character designed in accordance with the deflection theory and built with shallow trusses.

The behavior of a suspension bridge is such that, given the general dimensions and the dead and live loads, its stiffness will be controlled more by these factors than by the stiffness of the suspended truss itself. This is explained by the fact that in the computations of the stiffening truss, the moment of inertia is not directly proportional to the deflection, and exerts a relatively small influence. However, it must follow such deflections as the system of forces on the cables and the elasticity of the latter will compel. In other words, the truss must bend in conformity with the cable deflections and it can only mitigate them. It is well known that in a beam of given depth deflecting to a given curve the stresses in the chords will be proportional to the degree of curvature. With the general dimensions of the Manhattan Bridge and its dead load a congested live load of 16 kips per lin ft will develop stresses of such intensity that the standard medium structural steel could not sustain them within its elastic limit. True enough, a uniform congested load moving on many lanes, either in unbroken or broken lengths, will rarely assume the positions which will cause maximum stresses in suspension bridges with side spans. In accordance with this argument the designers have given full consideration to the probability of maximum stresses in the stiffening trusses and have allowed high unit stresses on the selected material. The adopted material, however, had to have an elastic limit high enough at no time to cripple the trusses by exceeding that limit.

After the results obtained from the tests of nickel-steel eye-bars for the Queensboro Bridge, it was a matter of course for the engineers to turn to nickel steel as a material which can develop a sufficiently high elastic limit and ultimate strength for the moments and deflections of the stiffening trusses. Accordingly, the specifications for the nickel steel for the stiffening trusses of the Manhattan Bridge called for the following physical requirements:

Ultimate strength	85 to 95 kips per sq in.
Elastic limit, minimum........	55 kips per sq in.
Percentage of elongation in 8 in.	$\frac{1\,600 \text{ (minimum)}}{\text{Ultimate strength}}$
Percentage of reduction of area.	40 (minimum)

As shown by the results of the acceptance tests of all the heats rolled, the material furnished actually developed an average elastic limit of 55.9

to 59.8 kips per sq in., and an average ultimate strength of 87.2 to 90.8 kips per sq in. Having in mind the high intensity of loading assumed and the low probability of the positions of maximum stresses, a stress of 40 kips per sq in. in tension, properly reduced for compression, was allowed on this material. The permissible unit stress was thus 73% of the elastic limit of the steel. Altogether 8 000 tons of nickel steel were consumed in the Manhattan Bridge.

The recently proposed revised A. S. T. M. Specifications for Nickel Steel differ from those of the Manhattan Bridge in 1906 only by raising the tensile strength to 90 to 115 kips per sq in. and by lowering the reduction of area to 30 per cent.

In the case of the Manhattan Bridge the introduction of a stronger steel was due to a necessity which came from the character of the type of the structure and its dimensions and loads. If there were no steels of higher elastic limit available the bridge could not have been designed as it was. In this case the type and general dimensions of the structure were substantially affected by the selection of the stronger steel.

Nickel Steel in the Quebec Bridge.—In the construction of the present Quebec Bridge the Board of Engineers, which was created after the failure of the first bridge during its erection, make painstaking and careful studies of all phases of the work. It made extensive tests of carbon and nickel steel eye-bars and columns and, after careful considerations, it incorporated 16 000 tons of nickel steel in the structure. In the report[64] on the Quebec Bridge, the Board states: "Nickel steel was used wherever it would effect a saving in weight of the structure as a whole, and, by this means, notwithstanding its higher price, be a factor in reducing total cost."

Nickel Steel in the Delaware River Bridge.—The Delaware River Suspension Bridge, between Philadelphia, Pa., and Camden, N. J., was designed for a congested live load of 12 kips per lin ft. It has a span of 1 750 ft and a reinforced concrete roadway 57 ft wide; its design dead load is 26 kips per lin ft. The same considerations that led to the adoption of nickel steel for the stiffening trusses of the Manhattan Bridge led to the use of a high-strength steel for the trusses of the Delaware River Bridge. Realizing the need of high-strength steels in bridge building, the engineers of the Delaware River Bridge had in mind the possibility of opening the field for such steels, in order to encourage steel makers to produce various suitable high-strength steels and to foster competition. The specifications for the stiffening trusses, therefore, called for a special steel having a minimum yield point of 55 kips per sq in. and a minimum tensile strength of 90 kips per sq in., without specifying a definite alloy. It gave a free opportunity to steel manufacturers to offer an alloy to meet the physical requirements. The manufacturers finally furnished a nickel steel containing an average of 3.2% nickel.

One of the peculiarities of stiffening trusses in suspension bridges is that the shear is relatively low and that the web members are relatively light.

[64] "The Quebec Bridge": Report of the Govt. Board of Engrs., 1919.

It was found that the web members in the trusses of the Delaware River Bridge, if made of nickel steel, would under-run the desirable minimum sections, and, consequently, they were made of silicon steel. This is the first instance in which a differentiation was made in members of a truss by using higher and lower steels. A total tonnage of 5 150 tons of nickel steel was consumed for the bridge.

The San Francisco-Oakland Bay Bridge.—A still more recent illustration of the use of nickel steel is furnished by the San Francisco-Oakland Bay Bridge in which the high-strength steel was used in two structures of the same bridge for different reasons. This project consists of a twin suspension bridge over the West Bay and of a cantilever structure and nineteen truss spans over the East Bay. It is a double-deck structure. The main span of the cantilever structure is 1 400 ft and the especially heavy dead load, due to the wide roadways, made it of major importance to hold the size and weight of the truss members within reasonable limits. To minimize the sizes of the stiff members 3 400 tons of nickel steel were consumed. The reasons for using stronger steel here were purely technical and not economical.

Still another instance in which a higher strength steel was used for technical reasons is furnished by the center anchorage of the suspension structure. The West Bay is about 10 000 ft wide and is crossed by twin suspension bridges, each having a main span of 2 310 ft. For a uniform fixed load over the entire length, the structure could have been built with three main spans and two side spans; but for a moving live load of 7 kips per lin ft, the bridge would be too flexible both for the towers and for the stiffening trusses, and would thus become impassible for traffic. To limit the deflections of the bridge a central anchorage pier was built which will restrain the motion of the cables by the stability of its weight. A simple solution was found to connect the cables to the pier and to each other by positive means. The cables of each of the bridges which meet at the central anchorage are displayed from their compacted cylindrical shape the same as at the land anchorages. The individual strands that constitute the cables are laid over thirty-seven anchor shoes, each of which is engaged by a pair of eye-bars similar to the usual suspension-bridge construction. Here, the similarity ceases. The eye-bars are not connected to other bars embedded in concrete, but at their free end they are connected by pins to vertical steel plates. In this way the plates are only intermediate links connecting the cable ends of the twin bridges. The cables are thus tied to each other continuously by bars and plates of steel. The steel tie-plates are made large enough (23 by 35 ft) to extend downward to provide for a pin connection to a steel structure anchored and embedded in the masonry of the central anchorage pier. The anchorage restrains the horizontal motion of the cables. When it is considered that the pull in the cables at the central anchorage may reach 36 400 kips per cable and that the unbalanced pull may attain 10 600 kips, the importance of the tie-plates—their size and their function—can be realized. Each cable connects to four plates by

means of thirty-seven pins and the plates connect to the anchorage by a pin 27 in. in diameter. The geometrical dimensions are such that the distribution of stress in the plates is of the greatest importance. Although, in accordance with theoretical computations, the strength of silicon steel plates was sufficient for the purpose, the engineers felt that excess of strength in the steel was of special value in this case and that the well-known toughness of nickel steel would be much in place. The tie-plates, therefore, were made of nickel steel, requiring about 280 tons. In this instance, merely technical considerations and not economy were the determining factors. Not only was the higher tensile strength of the material considered but also its toughness.

Manganese Steel in the Bayonne Bridge.—In 1927 the engineers of the Port of New York Authority were planning a bridge over the Kill van Kull connecting Staten Island, New York, with the mainland at Bayonne, N. J. After much study it was decided to build an arch with a single span of 1675 ft between centers of bearings. The trusses were designed to act as three-hinged arches with the lower chords as continuous ribs from end hinge to end hinge. The lower chord was designed to sustain all the dead load and part of the live load, the upper chord and the web members acting merely as a participating and stiffening truss.

The greatest reaction on the pins is nearly 31 400 kips per truss. It was desirable to limit the thickness of the assembled plates and splices for riveting purposes but, above all, considerations of weight were governing. For every pound of weight added an additional pound of steel was required to sustain it; economy, therefore, decided the issue.

At that time, advanced engineering had already recognized the fact that the function of the various parts of a structure and that of their constituent members and details, demand in some parts greater strength and in others greater stiffness. It had realized that it is good design to utilize various grades of available steel and that, by the proper use of these various steels, a better and a more economical structure can be built. Modern design, therefore, will utilize steel of various strengths. Where the usual stresses must be met and where stiffness is of importance, the common carbon steel will be used; where greater forces must be sustained, medium strength steel such as silicon will be generally utilized. Finally, where exceptionally great forces are met and the members become excessively bulky, high-strength alloy steels will be introduced. This tendency was recognized systematically in the design and the proportioning of the various parts and members of the Bayonne Arch. The main material of the lower chord is high-strength alloy steel throughout; that of the top chord is silicon steel, except the three end panels which are of carbon steel; all the web members are of carbon steel, except some which were made of silicon steel because of erection stresses; all lateral bracing and sway-bracing are of carbon steel.

For the high-strength steel an alloy containing 3.25% nickel and having a minimum yield point of 55 kips per sq in. and a tensile strength of

90 kips per sq in., was specified. In the specifications it was stated, however, that, with the approval of the engineer, the contractor might substitute for the nickel steel another steel which would meet the physical requirements for nickel steel and in all other respects be equivalent in quality. The American Bridge Company, as the lowest bidder, was awarded the contract, and it offered as an equivalent substitute a carbon manganese steel at a reduction of $15 per ton below the price of nickel steel. The carbon manganese was to have the chemical and physical qualities indicated in Table 22.

TABLE 22.—CHARACTERISTICS OF MANGANESE STEEL, BAYONNE BRIDGE

Description	Specification, Port of New York Authority	Tests of actual product§
Chemical Properties (Percentages):		
Carbon	0.40*	0.33
Manganese	1.80†	1.63
Phosphorus	0.04†	....
Sulfur	0.05†	....
Silicon	0.10 to 0.30†	0.18
Physical Properties:		
Yield point stress, in kips per square inch	55‡	58.6
Tensile strength, in kips per square inch	90‡	101.6
Percentage elongation in 8 in.	1 600‡ / Actual tensile strength	19.5
Percentage reduction of area	30‡	42.6

* Maximum allowable; preferably not more than 0.35 per cent. † Maximum allowable. ‡ Minimum allowable. § 168 melts and 968 tests.

After a careful investigation, which included tests from a heat especially rolled for the purpose, and the adoption of precautionary provisions and more rigorous requirements regarding testing and inspection, the Port of New York Authority permitted the use of manganese steel in substitution for nickel steel. The total saving in price was about $80 000.

The average results obtained on the standard tests of manganese steel rolled for the chords of the Bayonne Arch are cited for comparison in Table 22. The elastic limit, being the Johnston point, was found to be 46 kips per sq in. None of the steel specimens was heat-treated, and the steel was used in the "as-rolled" condition.

A series of tests of large-sized columns was conducted by the Port of New York Authority jointly with the National Bureau of Standards; among them were two of the type of the George Washington Bridge and two of the type of the Bayonne Arch. The strongest column, of carbon manganese, developed an ultimate resistance of 9 653 kips. The ultimate compressive strength of the carbon manganese columns was from 58.6 to 62.3 kips per sq in.[88] Thus, the column strength was found to be the average yield-point strength of the material in the members. It should be added that carbon manganese steel rivets were used successfully for the field connections.

[88] "Tests of Steel Tower Columns for the George Washington Bridge", by Stang and Whittemore, *Journal of Research*, National Bureau of Standards, Vol. 15, September, 1935, and paper in print.

The manufacture of manganese steel has shown that much care must be exercised in the production of the steel and the rolling of the plates and that the heavier plates are likely to encounter difficulties and to develop cracks. Tension tests of large specimens made by the contractor in connection with the Bayonne Arch gave poor results, and he finally decided not to use carbon manganese steel in the tension members of that bridge. In this instance, the reasons for using high-strength steel was due, as stated, to economical considerations. Substitution of carbon manganese steel for nickel steel was due to a saving in cost to the consumer. It is doubtful whether there was an actual saving in cost to the producer.

Summary.—The writer has discussed at length the application of high-strength steel to most of the large bridges in the United States and the reasons which prompted its use. The reason that nickel steel was used in most cases was simply that it was the material available and had been tried out first. Manufacturers were familiar with it and engineers knew it to be dependable and well behaving in finished structures. The reasons that prompted metallurgists and engineers to search for other high-strength steels suitable for structural purposes were those of economy. When used in the Queensboro and Manhattan Bridges in the first decade of the Twentieth Century, nickel steel cost about 3 cents per lb more than carbon steel. This differential in price has varied but little during the succeeding years. For the Delaware River Bridge, in 1924, the average of the bids was 2.25 cents per lb more for nickel steel than for carbon steel; for the Bayonne Arch, in 1928, it was 2.8 cents; and in the San Francisco-Oakland Bay Bridge, in 1933, it was 2.8 cents. The alloying nickel is practically controlled by a monopoly, and its cost to the mills has varied little. Additional cost of rolling and fabricating has kept the price relatively high. For the Harahan Bridge, a cantilever railroad bridge over the Mississippi River, at Memphis, Tenn., in 1914, 700 tons of Mayari steel was used in eye-bars and riveted members, with the evident intent to reduce the cost of high-strength steel and, apparently, good technical results were obtained. Mayari steel, however, has not been in the market for structural purposes in recent years.

History of Silicon Steel

Fortunately for the advance of bridge construction, a new steel was developed about 1916 which took its place in strength above structural carbon steel and below nickel or special steels. This steel, known as silicon steel, has a minimum yield point of 45 kips per sq in. and a tensile strength of 80 to 95 kips per sq in.

Notwithstanding its great popularity, silicon steel is fairly young. More than fifty years ago a silicon steel was proposed by English mills for ship construction. However, not before 1907 did silicon steel make its appearance in ship construction in plates for the S. S. *Mauretania.* Because of the wide use of this steel in recent times, the writer considers it important to discuss what is generally associated with the trade mark, "silicon steel,"

in European countries. The steel used in the *Mauretania* is said to have had the characteristics cited in Table 23.

TABLE 23.—EVOLUTION OF SILICON STEEL

Description	Silicon steel in the S. S. *Mauretania*, in 1907	Silicon steel in George Washington Bridge, in 1928-30
Chemical Analysis (Percentages):		
Carbon	0.27	0.35
Silicon	1.12	0.27
Manganese	0.72	0.78
Physical Properties:		
Yield-point stress, in kips per square inch	65	50.8
Tensile strength, in kips per square inch	92 to 105	88.8
Percentage elongation in 8 in	25 to 30	22
Percentage reduction of area	......	43

In later years, European manufacturers, and especially German mills, after the World War, had adopted a similar grade of steel, usually containing from 1.0 to 1.3% of silicon. This steel gave unsatisfactory results and ultimately was recalled. The greatest trouble was the high percentage of silicon as compared with the practice of American mills which limits it to 0.45 per cent. Because of the troubles experienced with the higher percentage, silicon steels in general acquired a bad reputation in Europe. In discussing steels with European engineers it will be well to explain to them the difference between European and American steel of the same name. As manufactured in the United States, silicon steel has a low percentage of silicon and a medium percentage of manganese. It could properly be named "Mansil" to indicate the ingredients which produce its characteristic qualities, or "Medium Manganese" steel.

It first made its appearance in bridge building in 1915 in the bridge across the Ohio River, at Metropolis, Ill. This bridge has a simple truss span of 720 ft and its long span and weight demanded a higher-strength steel. The demand was well met by silicon steel. So successful was the new material that to date about 350 000 tons of it has been consumed for bridges. It has been used for the towers of the Delaware River Bridge, Ambassador Bridge, Martinez-Benicia Bridge, George Washington Bridge, Golden Gate, New Orleans, Tri-Borough, and San Francisco-Oakland Bay Bridges. It has become a standard steel of to-day.

A fair idea of the quality of silicon steel that is being manufactured in such large tonnage can be had from the results of 895 melts and 1 884 tests of the silicon steel used in the towers of the George Washington Bridge, a total of 23 600 tons (see Table 23).

Economy.—The reason for the extensive use of silicon steel is its economy. Erected, in place, it costs 10 to 15% more than carbon steel. Its specified minimum yield point is 36% higher and a permissible unit stress of one-third higher is generally allowed for it. An elementary example will illus-

trate the economic relation of silicon steel to carbon steel. Assuming that 1 000 tons of carbon steel, in place, will cost \$100 000, the higher allowable unit stress, with practical allowances, will require only 800 tons of silicon steel at, say, \$112.50 per ton, amounting to \$90 000. A saving of \$10 000, or of 10% of the cost, will be realized.

The saving in cost shown in the foregoing example covers the lesser cost of the material in place. It does not take into account the saving in steel effected by virtue of its decreased total weight. Although it is of slight importance in buildings and minor bridges, the reduction in weight becomes a substantial factor in longer bridges where an additional pound of weight may require 3 lb of steel to sustain it. To this factor is due the saving sought by bridge engineers, and it is the determining cause for the selection of higher strength steel.

Practical Advantages and Limitations of High-Strength Steel

From the point of view of the engineering of bridges and structures, a high-strength steel is an alloy that develops a substantially higher yield point and tensile strength than the so-called standard structural steel and is sufficiently ductile to be fabricated by the equipment and procedure in modern shops. It must also be ductile enough to overcome stress concentrations greater than the yield-point stress when they occur and to be capable of distributing the stress more or less over the entire section of the member without impairing its efficiency. The yield point is accepted as one of the measures of the quality of steel, not because it is a better index of quality than the limit of proportionality or the elastic limit, but simply because, for acceptance testing, it is much more feasible. Testing for commercial acceptance of material requires simplicity and speed. Both are obtained by the observation of the yield point or a conventional definition of it. The consumer, therefore, really buys the material on the basis of its yield point and its tensile strength as observed by testing procedures which are established conventionally to meet the exigencies of practical acceptance at the mills and shops. When the engineer specifies a high-strength steel he obtains a product with a higher yield point and higher tensile strength than is ordinarily used.

Criterion for Unit Stresses.—The object of the engineer in introducing a higher strength steel, whether for technical or for economical reasons, is to utilize its strength by applying to it higher permissible unit stresses. The question then arises here as to how much stronger is the new steel when in action in the structure than the common carbon steel. Can the "higher strength" of the new material be utilized by the designer of the structure in direct proportion to its yield point or tensile strength? If so, which of the two should guide the adoption of the unit stress, the yield point or the tensile strength? The engineer thus arrives at the fundamental considerations of what constitutes the resistance of steel when acting in a structure.

Engineering knowledge of the present time has found experimentally that a steel specimen subjected to a static load within its limit of proportionality

will sustain the load indefinitely and when the load is released it will assume its original dimensions. Very little set and scarcely any creep due to time has been observed on specimens. The good behavior and long life of innumerable steel structures bear witness to these facts. Sufficient observations are available, furthermore, to justify the assumption that the variation of the intensity of a load applied in one direction only will not reduce the sustaining qualities of the material. Experiments have not yet established positively that the tensile strength of a specimen will not be reduced by applying a load and then removing it entirely a sufficient number of times to establish faith in the probability that such conditions would not be exceeded during the life of the structure. It has been established, however, that a reversal of stress within certain limits will cause the specimen to fail after many repetitions. The strength of the steel to resist an "infinite" number of stress reversals is known as fatigue strength and is lower than its static strength. Moreover, the fatigue strength depends on the tensile strength and not on the proportional limit or on the yield point. Taking the lowest values commonly set in specifications, the percentages of increase in yield point and tensile strength are indicated by reference to Table 24.

TABLE 24.—Percentage Increase in Yield Point and Tensile Strength

Description	Yield point stress	Tensile strength
Carbon steel to silicon steel	36	33
Carbon steel to special steel	67	50

Although the decrease in percentage of tensile strength is not much for the two varieties of steel in Table 24, attention is called to the fact because several steels recently have come into the market, the main characteristic of which is a higher ratio of yield point to tensile strength. When establishing the permissible unit stresses for the design of the structure, therefore, the engineer must consider the character of the loads to which it will be subjected and must choose the material best fitted for its function. For practically static loads the higher yield point will be the controlling influence, and for frequently reversed stresses the tensile strength will be the controlling influence.

While establishing permissible unit stresses the engineer should keep in mind that the proportional limit and the elastic limit are the limits that should not be exceeded in a structure and that the true margin of safety depends on them. Careful observations have shown that the elastic limit is lower than the yield point and sometimes substantially so. Generally, the elastic limit can be taken at eight-tenths of the yield-point stress and it may be substantially below it.

With the foregoing limitations in mind the engineer can take advantage of the higher strength qualities of the special steels. The recent Specifications for Steel Railway Bridges of the American Railway Engineering

Association call for the following permissible unit stresses in tension (in kips per square inch, net):

Carbon steel	18
Silicon steel	24
Nickel steel	30

It will be noted that the stress allowed for nickel steel is 1.67 times that of carbon steel, and that allowed for silicon steel is 1.33 times that of carbon steel. As a result, smaller sectional areas are required which will require less material. The reduced weight of steel required means less dead load for the structure to sustain and, in turn, reduces the steel tonnage. Where sections of carbon steel are too large, they will become proportionally smaller for the stronger steels and members will become easier to handle. Above all, when properly and judiciously applied, a saving in cost of the structure will be realized.

Limitations Imposed by Flexibility.—There are limitations, however, to the use of higher strength steels for structures which are inherent in all steels and are derived from their basic qualities. The modulus of elasticity of various steels is practically the same within narrow limits. All phenomena of the behavior of steel members and structures which are functions of the modulus of elasticity, therefore, will develop the same degree of deformation. The members of the structure composed of high-strength steel will shorten and elongate in inverse proportion to their sectional area, and the area being smaller, they will develop proportionately greater deformation. The structure as a whole, consisting of all the members, therefore, will be less stiff and will deflect more under load. This is not desirable. The more flexible a structure is the more secondary stresses it will develop in its stiff connections and if the deformation of the structure should become appreciable it will also develop additional stresses due to the distortion of the original geometrical pattern. Thus, very tall structures when exposed to high winds may sway sufficiently to produce additional stresses to an appreciable degree, so also may tall towers of long-span suspension bridges.

Limitations Imposed by Vibration.—Where the rapid application of loads produces vibrations, the intensity of these vibrations will be greater for the stronger steels because the intensity is inversely proportional to the moment of inertia of the structure and the latter value will be smaller for the stronger steel. Trains passing over railroad bridges at high speeds cause much vibration in the structure, and it is of serious importance rather to reduce than to augment these vibrations. Both the greater deformations and the higher vibrations which will be produced in structures built of stronger steels demand the careful thought of the designing engineer. In designing a structure it is important to consider seriously whether the advantage of the reduced cost effected by the use of the stronger steel is not outweighed by the disadvantage of the more flexible structure.

Buckling of Plates and Flanges.—Another phenomenon in the behavior of steel members in which the constancy of the modulus of elasticity plays

an important rôle is that of the buckling of plates and outstanding flanges of steel members in compression. According to Euler's well-known theoretical study of the buckling strength of a deflected column under a compressive load, the column strength is directly proportional to the modulus of elasticity of the material and the moment of inertia of the column. The correctness of the Euler theory has been verified experimentally. The elastic stability or buckling strength of plates subjected to compression and shear has been derived from Euler's theory, and it has been established theoretically and verified experimentally that the critical unit stress at which buckling is imminent is directly proportional to the modulus of elasticity. A concise statement of the practical aspects of the problem has been presented[86] very ably by Otis E. Hovey, M. Am. Soc. C. E., who establishes a table of recommended ratios of the width of a plate to its thickness based on the yield point of the material used. For the purpose of showing that smaller ratios are permissible for higher yield points, three ratios will be quoted:

Yield point stress, in kips per square inch	Ratio of width to thickness
33	48.8
45	41.8
55	37.8

The foregoing data demonstrate vividly that a stronger steel is not proportionately more stable against buckling than common carbon steel and that when high-strength steel is applied it is sometimes penalized where wide plates are used in the structure.

The practical importance of the limitation presented by buckling resistance in design is well illustrated by the case of the towers of the Golden Gate Bridge and the San Francisco-Oakland Bay Bridge. The towers of the Golden Gate Bridge are 690 ft above the piers and each pier must sustain a vertical load of 61 500 tons. About 45 000 tons of carbon and silicon steel were used for both towers. The tower shafts are built as cellular structures with widths of 42 in. The general dimensions of the towers are such that in the lower portion the stability of the steel plates, and not high stresses, is controlling. Carbon steel, therefore, was used in the lower two-thirds of the shaft. In the upper one-third where the increased slimness of the shaft requires higher allowable working stresses and stronger steel, silicon was used. It was found that a number of silicon steel plates, located toward the outer faces, required thickening because the buckling resistance was not equivalent to the permissible unit stress. A number of single web-plates, therefore, were increased in thickness; a total of about 70 tons of steel was thus added.

Similar increases in thickness because of buckling strength were made in some web-plates in the towers of the San Francisco-Oakland Bay Bridge.

Details.—In the building of a steel member many auxiliary parts enter which are commonly known as "details." Designing engineers know that

[86] "Elastic Stability of Plates", by Otis E. Hovey, *Bulletin*, Am. Ry. Eng. Assoc., February, 1935.

such auxiliary parts as lacing-bars, batten-plates, and stiffeners are not highly stressed and do not demand high-strength steel. In order to function well and to fulfill their purpose these parts should be rather stiff than strong. In other words, lacing-bars, batten-plates, and stiffeners should offer high resistance to deformation. To do this it is important that they have more section rather than that they be stronger per unit of area. These parts of high-strength members could very well be made of common carbon steel when they do not carry primary stresses and where there is enough tonnage to warrant the additional care required in sorting in the shop.

Similar considerations hold true for most secondary members in bridge trusses. Hangers and parts in subdivided panels sustain concentrated panel loads only and, as a rule, they do not require heavy sections. Lighter members frequently under-run in size and should be made of carbon steel. The same is true for most lateral and sway-bracing in medium span bridges. Sway-bracing mostly functions to preserve the geometrical pattern of the structure and stiffness more than strength, is of importance. Lateral bracing requires heavy members where the lateral shear becomes high, which generally is in less than one-half the length of the bridge; in the lighter half, the least size of the member controls. If the tonnage of the steel is sufficient to warrant the use of two kinds of steel, carbon steel may be used in at least a part of the lateral system.

Adapting Steels to Parts of a Structure.—In the design of large structures engineers have recognized the value of differentiating between various members according to their functions and of using steels suitable for these functions. For example, the web members and all lateral and sway-bracing members of the Bayonne Arch are of carbon steel, whereas the lower chord is of carbon manganese steel and the top chord of silicon steel. The towers of the Delaware River Bridge are of silicon steel and their transverse bracing, as well as all diaphragms, etc., are of carbon steel; the chords of the stiffening trusses are of nickel steel; the webs, however, are of silicon steel and the lateral system, because of participation stresses, is also of silicon steel. In the towers of the George Washington Bridge the shafts are of silicon steel, the bracing, all secondary parts, and parts in which stiffness rather than strength was desirable, are of carbon steel. The method of differentiating between the various members of a structure in accordance with their function has become general practice on important structures where such a procedure is warranted.

Physical Limitations of Higher Strength Steels

In considering various grades of steel for structural purposes the physical limitations of higher strength steels should be given attention because they will be reflected in the cost of the fabricated and erected steel.

Fabricating Problems.—All shaping and forming of metals is performed either by heating the material to a plastic state, or by exerting force on the cold metal. Within certain limits, structural steel is usually shaped by suitable devices at shop temperature. Cold-shaping is more convenient,

speedier, and more economical. Practically all straightening of plates and bars is done in the cold state. Cold-shaping and straightening of steel are based on the principle of applying force through a motion of the forming device so that the elastic limit is exceeded and the metal enters the plastic state and, therefore, follows the shaping tools into the desired form. Without exceeding the elastic limit, the metal, of course, would spring back into its original form. The fabricator is well aware of the fact that the higher the elastic limit of the material, the more force will have to be exerted to pass it and the stronger the forming equipment will have to be. Shaping and straightening will be more difficult and tools will break more frequently. It will also require more time because the higher elastic limit steel will need to pass through the straightening rolls a greater number of times.

It should also be remembered that the stronger steels require a more careful procedure in the pouring and generally more ingots are discarded. Their rolling temperature has a more limited range, and some, if not all, of the higher steels require protection from cold blasts and drafts during the rolling process. The finer the material the more care it requires; the stronger the steel, the more difficult it is to form.

Distribution of Stress Among the Rivets in a Joint.—Another matter that deserves serious consideration is that of stress distribution in riveted joints. When a relatively wide plate is spliced to another plate by the common riveted connection, the question arises as to whether the stress is distributed uniformly through the rivets from one plate to the other. The phenomenon of splicing steel by a group of rivets is by no means simple. Like most phenomena encountered in practice it has been made simple by an assumption which, although not correct, makes it possible to approximate the facts roughly and to proceed with the task of splicing the members. The assumption is that all parts, the plates and the rivets, are rigid members and that a stress, uniformly or continuously distributed in a plate, will transmit its total force to the connecting rivets and these, when symmetrically arranged, will transmit the force to the second plate in the same symmetrical and uniform distribution. This assumption dates from the time when stresses were low and the elastic properties of metal were ignored. Engineers know that such uniform distribution does not prevail in the plates near the rivets; the originally distributed stresses meet their resistance in the rivets and rush to them to overcome it. Concentrations of stress are formed around the rivets which sometimes exceed the elastic limit. At that time a system of equilibrium establishes itself between the plates and the rivets by the mutual yielding of each; where the intensity of stress is too great for the elastic limit, it passes (for the time being) into the plastic state. The phenomenon of stress distribution through rivets still requires much study. Engineers are aware of the problem and, at present, are devoting their attention to it. One aspect of the problem, however, is quite clear: The higher the elastic limit of the material the greater may become the concentration of stresses and the less uniform will be the distribution of stress in the plates. In fact, too high an elastic limit may lead to such a high concentration of stress as to cause incipient

failure. With the present knowledge of the phenomenon the prognosis may be made that the efficiency of riveted splices is not in direct proportion to the increase in the yield point of the material. The higher yield point, therefore, cannot be fully utilized in proportioning the connection.

What has been stated herein, concerning stress concentration on rivets, of course, holds generally true for all "hard points"; that is, for all places where the material encounters concentrated resistance. The same phenomenon is developed where the shape and area of the material change abruptly and the flow of stress is contracted and "choked." In such cases, the same as in riveted joints, it is desirable that the initial distributed stress be low and that the material should be able to adjust itself to the conditions. The development of photo-elastic studies in recent years has demonstrated, forcefully, the phenomenon of stress concentration.

The writer has dwelt at some length on the physical limitations of higher strength steels with the intent to emphasize the restrictions that may have to be imposed and to dampen the enthusiasm that the stronger material is likely to evoke.

Uses for High-Strength Steels

Modern economic, social, and technical development has brought people closer together in space and time than ever before in human history. The co-ordination of human efforts has brought together Man and mechanism. In the incessant endeavor to satisfy the ever-increasing demand for physical goods and to make the comforts of life accessible to the many, structures of great magnitude and capacity often become desirable as connecting links in production and distribution. Such structures and machines sustain heavier masses, move more freight, cross large rivers and wide bays, and lift up their spires into the skies. Because of their functions and of their magnitude they must sustain great forces, and materials of high strength are required for their construction.

Bridges with long spans require large members and, therefore, weigh more. Their stresses can be sustained by high-strength steel, with less material and at a lower cost. Tall buildings for special purposes, such as the Palace of Soviets, in Moscow, U. S. S. R., are subjected to high wind pressures and stronger steel will find its proper application for the skeletons of such structures. Derricks of large capacity and long-span cranes, and bridge members which are utilized during the erection of the structure and sustain great forces, may profitably be built of steel stronger than the common carbon steel. Wherever the demand for sustaining great forces will appear, necessity will compel the use of stronger steels independent of its economy. Where technical conditions of fabricating shops and facility of erection in the field will demand lighter sections and lighter members, higher strength steels will be applied. Their widest field of application, however, is in the reduced cost of the structure.

Engineering Economy.—In discussing the economy of large structures several interpretations and meanings of the word should be considered.

There is an economy inherent in the design of a structure which is part of the play of forces acting in the structure under load and of the arrangement of the sustaining members and their suitability to perform the functions which the behavior of the structure will demand. This economy is a measure of the mechanical fitness of the structure for its intended purpose. It is independent of the market price of the material and labor required to build it, and may well be designated as structural economy. Structural economy forms only a part of the engineering economy of a structure. The latter consists in utilizing for its various members such materials and shapes as will result in the lowest cost of the completed structure.

There is also another very important aspect of economy, namely, financial economy. In this economy enter considerations of the amount of capital invested in the project and the prospective life of the structure. It depends much on the prevailing rates of interest. It also is based on the economic organization of society in a given country. It is largely, however, through the development of engineering economy that higher strength steels will find their application and the field of stronger steels will be extended. The expansion will depend largely on the cost to the mills of the ingredient alloys which enter into the higher strength steels. It will depend on whether these alloys will be plentiful in the market or will be controlled by monopolies. It will also depend on the available processes of manufacturing and fabricating the stronger metals.

Improper Use of High-Strength Steels.—To realize engineering economy in structures fully, and to produce them at a lower cost, careful consideration must be given to the desired result in each case. Not only the first cost, but also the behavior of the structure under load, and its maintenance, should be weighed carefully.

A number of large bridges have been cited for which higher strength steels have been used, and an attempt has been made to give the reasons that have guided the engineers to adopt these steels. A few telling examples, out of many, will be brought to show instances in which higher strength steel has led to improper or uneconomical design.

In one instance an arch bridge of 140-ft span, of the plate-girder type, was designed. Its total steel weight was less than 200 tons, about one-half of which was of silicon steel. The arch ribs were made of 36 by $\frac{3}{8}$-in. webs and four flange angles, 6 by 6 by $\frac{1}{2}$ in. The ratio of the unsupported depth of plate to its thickness was 65. The web-plate was in compression and was manifestly too thin against buckling; it had to be thickened. Instead of using silicon steel, standard carbon steel should have been used. In general, it is not economical to use silicon steel for a short span of 140 ft. This case illustrates the physical and economical limitations in the use of silicon steel.

In another instance the designers evidently were aware of the buckling limitations of carbon steel and desired a compact section. They designed it, however, in an impractical manner. A highway bridge of the cantilever type was planned with a main span of about 800 ft. The chords were of

silicon steel and of the enclosed box type with angles turned in. The outside dimensions were $18\frac{1}{8}$ by $24\frac{1}{2}$ in. The minimum section carrying stress was composed of one top cover, 18 by $\frac{5}{16}$ in., four angles, 4 by 4 by $\frac{5}{16}$ in., two web-plates, 24 by $\frac{7}{16}$ in., and one bottom cover, 18 by $\frac{3}{8}$ in. In the maximum sections the top cover-plates and the upper angles were thickened to $\frac{5}{8}$ in., the web-plates to $\frac{7}{8}$ in., two side-plates, 15 by $\frac{3}{8}$ in., were added, and the bottom angles were made 4 by 4 by $\frac{3}{4}$ in. For riveting purposes and for painting, manholes, 8 by 24 in., were provided in the bottom cover-plate. The clear inside dimensions were thus about 12 by 20 in. for the heavy section. It is very difficult, if not dangerous, at the large joints, to put a man in these chords to do field riveting. The small box-sections also prove to be expensive both in the shop and in the field. Notwithstanding the constricted section of the chord, the ratios of depth to thickness of the thinner web-plates are somewhat high for silicon steel. In this case larger dimensions of chords would have provided more accessibility for riveting and painting, and the use of carbon steel would have furnished well-designed and economic chord sections at a lower total cost.

A third instance of the uneconomical use of stronger steel consists in using silicon steel indiscriminately at random points in carbon-steel trusses.

In a fairly large bridge of the cantilever type there is a suspended span of 150 ft. All members in this span were designed of carbon steel except one bottom-chord section which was made of silicon steel. It was made of two web-plates, 20 by $\frac{1}{2}$ in., and four angles, 4 by 4 by $\frac{7}{16}$ in. By thickening the material to about $\frac{5}{8}$ in., this section could also have been made of carbon steel and the total cost of the section would have been less. In this case a critical review of the material used would have disclosed to the engineer at once that the introduction of silicon steel in one chord section was not good economy.

It may be well to point out that, although for a large tonnage fabricated silicon steel in place will command a differential of $12 per ton, for smaller tonnage the extra charge will be greater. Where the weight of each individual shape is less than 20 tons, the extra charge is $15 per ton. For plates smaller than 36 in., the differential is $10 and for plates larger than 36 in., it is $15. Silicon-steel bars of various sizes in quantities of less than 1 000 lb will cost $25 to $35 per ton extra. The higher extra charges for the smaller quantities are due to the care required to segregate and follow the small quantity of the special steel and to the difficulty of replacing from stock any items rejected during fabrication.

The foregoing examples of actual practice have been cited not in the spirit of criticism, but with the purpose of calling the attention of engineers to the possibility of errors of judgment and oversight and to establish warning signals.

Conclusion

The progress of the more civilized part of humanity has led to the growth and concentration of population in large cities. At the same time,

it has created an enormous demand for rapid and economical transportation of large masses of freight and of great numbers of passengers. Among other efforts it has created a demand for bridges of large capacity over wide rivers. Engineers in their untiring search to meet the demands of growing communities and industry have successfully made use of a few higher strength steels which they have developed and found available. The field for the application of such steels appears to be extending and standardized specifications have been established for the use of manufacturers and engineers. The varieties of alloy steels of higher strength are by no means limited to the few which have actually been used in structures in the United States. At present, a number of high-strength steels have been developed and are available on the market. Many more will be produced to meet the demand. It is the task of the engineer to follow the development of materials and to utilize them to the best advantage. At the same time, it is incumbent on him to study the physical and economical limitations of the higher strength steels and to determine carefully in each case the best advantage that may be derived from their use.

Much effort is being made at present to increase the pay load on freight-carrying vehicles. While materials are being developed to reduce the dead weight of cars and trucks, the pay load, that is, the weight of the freight carried, will be increased and the tendency is strong to increase the total weight of the loaded vehicle. To be able to compete with freight transportation on highways, railroad officials aim to reduce the cost per ton carried. With the present tendency to higher cost of labor, the cost per ton carried must be held down by mechanical efficiency. The result will be heavier trains pulled by heavy locomotives, for which heavier bridges will be required. This is evidenced by the latest specifications for railway bridges. On the other hand, the growth of automobile traffic has made long-span bridges economically feasible. Engineering science, the art of metallurgy and fabricating technique, and erection skill will make it possible to build them economically in greater numbers. During the two decades, 1916 to 1936, the span of bridges has been more than doubled. Engineers have attained a span of 4 200 ft and will surpass it in the future. The use of stronger steels for structures has been intimately connected with the progress of bridge construction and will so continue.

STRUCTURAL APPLICATIONS OF STEEL AND LIGHT-WEIGHT ALLOYS

A SYMPOSIUM

THE APPLICATION OF STAINLESS STEEL IN LIGHT-WEIGHT CONSTRUCTION

By E. J. W. Ragsdale[87], Esq.

Synopsis

In a broad sense, this paper covers the applicability to light construction of the two major types of stainless steel and then describes briefly the general problems of design, fabrication, and usages. Questions of plate stability, efficiency of spot-welded connections, and the economic phases of a relatively costly material are lightly touched upon. Although these seem to merit a more expansive treatment, the danger of such expansion is always that the paper may be thrown out of balance.

Stainless Steels

The structural engineer need concern himself little about the metallurgy of the materials he uses. His purpose is to define requirement, and then to select the materials best suited to it. That selection is made on the basis of established properties, which become accepted values. The only concern is that these properties be not disturbed by continued use or by the processes of manufacture. So much appreciation of metallurgy must the structural engineer have.

When consideration, however, involves the innumerable alloys listed under the name of stainless steel, a mere appreciation of metallurgy no longer suffices. The structural engineer had then best invite the close co-operation of the metallurgist. No less than a dozen different alloys present themselves. Aside from a pronounced resistance to corrosion, they have little in common. Some owe their strength to heat treatment, others lose it thereby. Some are inherently stainless, whereas others are only stainless under certain conditions.

Fortunately, a structural application of stainless steel has already developed, and, through this, the choice of alloys becomes narrowed. Outstanding is a chrome-nickel alloy (18–8)[88], that has been described in detail by Mr. M. J. R. Morris, in this Symposium[89]. As a poor second is a straight chromium steel with from 12 to 17% chromium content. Requirement and the process of fabrication will determine the applicability of each. The first owes its high physical properties to cold working, and, by the same token, may lose them by welding. The other improves by heat treatment, which treatment automatically corrects the effects of any previous welding operation. Therefore, it becomes quickly apparent that the feasibility of heat treating a finished structure may determine the choice. Further considerations will be cost and strength. The cost of the chrome-nickel steel is about 50% greater than that of the chromium

[87] With Edward G. Budd Mfg. Co., Philadelphia, Pa.

[88] Symbols in parentheses denote the trade designation by which the alloy is commonly recognized.

[89] See Table 4, Items Nos. 5 to 10, inclusive.

steel, and, at the same time, it is cold rolled to a 50% greater strength. An even greater advantage, however, lies in the susceptibility of chrome-nickel steel to good and cheap fabrication.

Perhaps a very general distinction may be made by stating that the chrome-nickel steel is better suited to the requirement of light-weight construction, whereas the chrome iron offers a corrosion-resistant substitute for carbon steels in more conventional design.

Design Problems

Light-weight construction has as its premise a more effective use of a more effective material. This indicates a wider spread of material, and, at the same time, a lesser material requirement. Both result in a reduction of the usual thicknesses, and herein lies a problem.

It is an old and convincing trick to illustrate structural stability by trying to stand a piece of paper on edge and then showing how this same sheet increases in load-carrying capacity as it is rolled into cylinders of smaller and smaller diameter. The limit is finally reached when the tube becomes so small as to lack column stiffness. A compromise position then results in a larger tube and a stiffened wall. This thin wall may be strengthened by structural members, by longitudinal corrugation, or by both. The ultimate effectiveness is reached when the column becomes a series of vertical members, mutually cross-braced. The wall has disappeared.

This question of wall or plate stability, however, has already been investigated, especially in connection with bridge construction. It becomes only more acute as the ultimate strength of metals is raised from 75 kips per sq in. to twice that value, and when thicknesses are measured in thousandths of an inch rather than in quarters of an inch. In this case, the question of relative flatness complicates an already complex mathematical treatment. The obvious solution becomes empirical and toward this end a curve on the so-called "flat pitch ratios", has been developed with which it is possible to compute the stability limit in compression of any closed section that is made up of a series of flat surfaces. The "flat pitch ratio", q, is the relation between the unsupported width of a flat surface and the total wall thickness; that is,

$$q = \frac{b}{d} \quad \text{(5)}$$

Taking this value for the widest face of the section, Fig. 36 will show at what percentage of the ultimate strength of the metal, that particular face begins to undulate under compressive load. (The abscissas are plotted as ratios of ultimate compression stress, T_c, to ultimate tensile stress, T_t.)

Quite obviously, therefore, a metal of high tensile strength must be formed into sections that permit a stressing commensurate with its superior strength. An I-beam, for instance, may develop stresses up to the limit of mild steel, but if made of a steel having a working stress three times greater, the beam might collapse through instability long before that stress was realized. Therefore, the sections suitable for one metal cannot be extended arbitrarily for the use of another. Light-weight construction therefore, has brought into

being a series of new and more efficient sections. These sections are largely of the closed-box type, or efficient open sections which are locally stabilized by stiffeners. Some are formed by rolling from a strip, whereas others are fabricated.

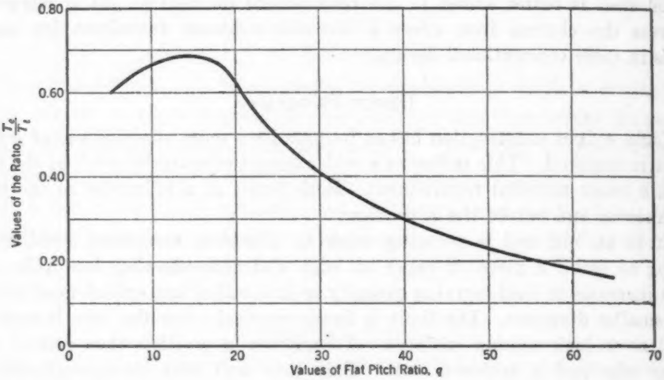

FIG. 36.

Fig. 37(a) and Fig. 37(b) are compression truss members, and Fig. 37(c) and Fig. 37(d) represent floor-beams. All of them (and, in fact, most sections in use) will develop at least 100 kips per sq in. on the compression side;

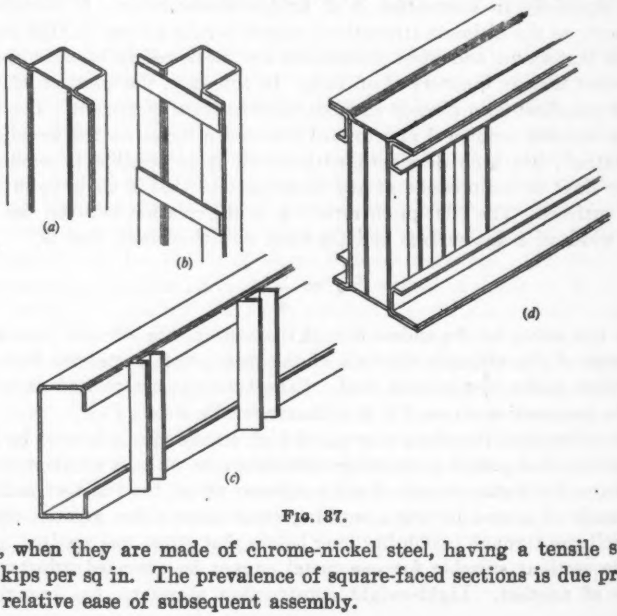

FIG. 37.

that is, when they are made of chrome-nickel steel, having a tensile strength of 150 kips per sq in. The prevalence of square-faced sections is due primarily to the relative ease of subsequent assembly.

Computed on a weight-to-strength ratio, such sections in material of high tensile strength, will be found to be from seven to ten times better than the conventional profiles of mild steel. One-half the advantage comes from the superior metal strength, and the other half from a more effective placement of that metal. Of course, this ratio relates to relatively small sections, such as 6-in. channels or I-beams, and becomes less apparent when compared to the efficient girders, such as obtain in bridge construction.

Efficient and strong as these individual sections may be, however, they are useful only to the extent that their connection, one with another, is equally efficient. Attachment becomes a problem, both as to area and avoidance of eccentricities. In fact, the same care and design exercised in large bridge structures must be interpreted into use for smaller and lighter ones of high-strength metal. Double gusset--plates, nested member ends, and efficient bonding, or joining, become necessary. These requirements again demand close attention to sequence of assembly and to accessibility of welding or riveting. The latter is complicated to the extent that the structure may be small or truly efficient. It is further aggravated often by lack of appreciation of shop procedure. A seemingly simple connection on paper, may baffle a Houdini in assembly.

Even when a type connection may be decided upon, there still remains, however, the question of providing sufficient bond. This bond may be by rivets, or by the fusion of faying surfaces as in welding. In either case, the function of the bond is always to resist straight shear. A definite practice has been established for this function in rivets and mild steel. It is not translatable immediately into high-strength material for the simple reason that rivets of correspondingly stronger physical properties cannot be applied. The requisite increase of shear is more aptly obtained by welding. This offers possibility of a 100% efficient joint. It involves, however, many new considerations of design and shop technique.

Welding

Nothing is simpler than to calculate the strength of a welded connection, and few calculations can be more misleading. The difficulty lies in the assumptions. In the first place, one assumes that the weld is good, and, in the second, that the primary forces still govern. An improved welding technique has done much toward establishing welding certainty, but the relief of heat-induced stress concentrations in and about the welded area remains a problem, the solution of which differs for each individual case.

Although both chrome-nickel steel (18–8) and the chromium steel can be gas welded, arc welding is becoming the more favored of the two processes. It must be recognized, however, that either procedure is a severe heat operation and that these alloys are peculiarly responsive to such treatment. No responsible arc welding should be done, therefore, without subsequent heat treatment. This is not with a view to relieving stresses so much as to correct an impaired metallurgical condition in the weld and the adjacent metal. Since the chrome irons are usually improved by heat treatment, not only is the weld corrected,

but the entire structure becomes benefited. Arc welding is strongly recommended for the straight chrome series, but the limitation of heat treatment also confines the practice to such structural members as may be susceptible to this treatment. These members are usually small and simple pieces, such as will not warp under the application of a high heat.

With chrome-nickel steel there are two difficulties attending arc welding. In cooling through the critical temperature gradient of from 1 200° to 1 600° F, carbides are precipitated. These carbides can only be returned to solution by heating to more than 2 000° and quenching. Then, again, chrome-nickel (18-8) owes its superior physical properties to cold working, and these properties are automatically reduced by either the heat of arc welding or the corrective re-heat treatment. Since this metal in the annealed state only shows an elastic limit of about 34 kips per sq in., its utility in highly stressed members is, therefore, defeated by arc-welded assemblies.

Thus far, the happiest solution for the joining of chrome-nickel steel appears to be found in a special system similar to that of ordinary spot welding. In principle, however, it differs by the establishment of such controls of current, time, and electrode pressure that the metal remains metallurgically unimpaired. This is made possible by the discovery that both carbide precipitation and the annealing of the metal adjacent to the zone of fusion are functions of the time of heat application. With a quick application of heat and a rapid cooling, neither of these undesirable phenomena appear. Welds may be made in as brief a time as one-half cycle, or $\frac{1}{120}$ sec. Rarely does the time of current dwell exceed ten cycles.

However, the process does not correct an inherently insusceptible condition, such as obtains in the chrome irons. In the latter case, regardless of the method of fusion, the bond is coarse-grained and brittle. It can only be corrected by subsequent heat treatment.

Chrome-nickel steel, on the other hand, is strangely susceptible to good welding. Its every property seemingly conspires toward this method of bonding. Recalling that in resistance welding the heat generated is expressed as $I^2R\ t$, the item, R, which is the electrical resistance imposed between the electrodes, assumes basic significance. With corrodible metals, R sums up the resistance of the body of the metal as well as that of the oxided surface. The latter not only varies widely with the extent of oxidation, but is usually many times greater than the resistance of the pure metal itself. Therefore, R is not a constant, and no matter how accurately controlled current and time may be, the resultant heat will vary. With stainless steel, the surface resistance is small and constant. Furthermore, the basic resistance is about six to eight times greater than that of mild steel. Accordingly, the current or time required for a given fusion is less.

Fusion initiates at the inner contacting surfaces of two or more sheets, and progresses outward in proportion to the total heat applied. Such is the heat-conducting property of the electrodes, however, that it can reach the outside surfaces only in the case of a badly burned weld. The shape and depth of the fused button are important. Although the diameter determines the area

in shear, the penetration of the fusion into each adjoining sheet holds these sheets together much the same as the heads of a rivet. A shallow weld lacks tenacity; one that extends entirely through the sheets will invite corrosion. The control of weld shapes lies in the proper setting of the welding machine, which, in turn, is determined as a result of many tests with sectionalized and etched specimen welds.

Having established a proper welding practice, the next step is to insure a strict observance of such practice, because when welding becomes an element in structural procedure, the same standard of reliability is required of it as of the materials to be so bonded together. This seemingly ever-present problem in welding of any kind, has been solved in the special system herein cited, by use of a simple, but unique device for integrating the function, $I^2R\ t$, for each weld made. Any departure from the allowed tolerance rings a bell in the welder, and the result of each weld made or failed is recorded on a tape. Welds cannot be judged from the outside and, without the device mentioned, the operator is really working in the dark and beyond the scope of inspection.

On the other hand, how to make a weld is one thing; what it is worth is another; and therein is found again a remarkable property of chrome-nickel steel. The fused metal has been subjected to the very treatment recommended for annealing to a dead soft condition. Its tensile strength is 90 kips per sq in. More remarkable, however, is the fact that its shear strength is also 90 kips per sq in. This means that one weld has twice the strength of a rivet of like diameter, and since welds can also be placed closer together than rivets, a much more efficient joining results. Single lap-joints can easily show 85% efficiency, against 60% in good riveted connections. Just what stress distribution takes place in and about a welded joint, however, remains a neat problem to engage the ingenuity of some physicist.

When the conventional rivet hole is replaced by a metal softer than the surrounding sheet, and when this soft metal also assumes resisting capacity in tension with the sheet, it is difficult to visualize the proportion and paths of the lines of stress. However, the philosophy of welding is so engaging that one is likely to overlook the only practical consideration which makes this form of welding at all applicable to high-strength chrome-nickel steel (18–8). The point seems never before to have been emphasized; that is, that welding pressures can be used which are sufficient to draw the sheets closely together. In mild steel no such pressure is required because the steel is soft. Were such pressure necessary, the electrodes would break through the surface scale and, in thus reducing the resistance, would make for no weld. This phenomenon is known. With chrome-nickel steel, the electrode pressure is often more than 2 kips for a ¼-in. weld in two 16-gage sheets.

The overlapping of individual spots to form a gas-tight joint is known as seam welding. The same principle applies in this case, but pointed electrodes are usually replaced by rollers. So many considerations are involved, however, that this form of welding must be approached with a full appreciation of the difficulties. The problem is too specialized to be more than mentioned in this paper.

APPLICATIONS

Perhaps the first structural application of chrome-nickel steel was in connection with aircraft. The fact that it could be cold rolled to tensile strengths greater than 200 kips per sq in. and used in thin sheets without fear of corrosion, had a strong appeal. Some research has also been made in connection with bridges. This has been confined mostly to roadways and decorative effects. A much wider application awaits development. Weight reduction also has its place in this connection, not to mention the elimination of the high cost of painting in difficult and inaccessible places.

The development in marine structures has been far wider. It is generally known that warships have become weight conscious almost to an extreme limit and that deck-houses, masts, smoke-stacks, and bulkhead doors constitute only a beginning in the program. Several million pounds of chrome-nickel steel have already been used in this connection and the ultimate is not yet in sight. Nor is the interest confined to naval vessels; the merchant marine has also discovered that stainless steels have their definite uses. The installation of storm windows on the S. S. *Normandie*, for example, is but a modest beginning of the use to which the material can be applied economically and well. Add to the high strength and to the non-corrosive property of chrome-nickel steel a heat resistance almost as remarkable, and it becomes apparent that this type of stainless steel fits into the marine requirement as has no material of the past. Although the cost causes an initial hesitancy, this will be overcome as soon as ideas become adjusted to true economic worth. The present (1936) cost of chrome-nickel steel[20] is about 30 cents per lb. No wonder that structural engineers may hesitate, especially when alloyed steel for bridges is only a fraction more than 1 cent. Translate weight into motion, however, and metal costs become ridiculous. Dirigibles and some heavier-than-air craft cost as much as $20 per lb. Designers of automobile trucks and trailers consider that a pound saved and converted into pay load may be worth $1 per yr. Every extra pound in a Diesel-electric train carries 30 cents for additional power and equipment cost.

Most spectacular have been the developments in the application of chrome-nickel steel to railway cars, and, by the same token, the most publicized. Rarely have the results of research been more timely. With the railroads struggling under the weight of their own rolling stock rather than that of pay loads, and with a depression to emphasize the condition, an improvement was indicated—not just a slight betterment, but a radical one. It was typified by the first *Zephyr* train, the phenomenal performance of which has stimulated efforts not only along this line of construction, but in other directions as well. The field seems wide open for any material superior to mild steel. Ingenuity of design vies with ingenuity of cost argument, and the main objective is often lost from sight. This object in the case of the *Zephyr*, was to reduce the weight of a railway car to substantially one-third that of a heavy passenger coach, and to do so without sacrifice of strength or comfort. The

[20] See "Stainless High-Alloy Structural Steels", by M. J. R. Morris, Table 4, Items Nos. 5 to 10, inclusive, pp. 1258–1259.

three cars of the *Zephyr,* without the power plant, weighed 160 000 lb. Conventional railroad coaches weigh from 130 000 to 160 000 lb. So nearly was that part of the objective attained. Then, with a reduced mass, so were destructive forces also reduced. In a million miles of high-speed operation by these *Zephyr* type trains, and not without exposure to damage, there has been neither structural failure nor weakness. A more severe test of a comparatively new structural metal and a new method of fabrication can scarcely be imagined. It assumes a significance which should be more convincing than the listing of physical properties, or the discussion of welding merits.

Just what share of future railroad building will be enjoyed by stainless steel cannot, of course, be predicted. More certain seems the prediction of a prominent railroad consultant, to the effect that the last heavy railway car has been built. With this great industry becoming weight conscious, and with an inevitable building program ahead, the only limit to the part that can be played by stainless steel appears now to be one of facilities and organizations capable of handling it.

Stainless steel will open other lines of possible utility, as the knowledge of its uses is extended. An excellent book[n] published in 1935, contains a description not only of the properties and methods, but of the width of the fields already attempted. That this field is so sparsely covered reflects merely upon a lack of applied research; for instance, the structural application of chrome-nickel steel owes its development almost entirely to the efforts and enthusiasm of one man. The staff of engineers which he could afford to divert from his normal business in order to prosecute this development was pitifully small. The temptation to follow each new promising lead has been great, for they are promising—all of them. They require development, and this needs only time and enthusiasm, for the foundation work in stainless steels has now been done.

ACKNOWLEDGMENT

The writer is indebted to his employer, The Edward G. Budd Manufacturing Company, for the use of the basic data required for this paper and for permission to present Figs. 36 and 37.

STRUCTURAL APPLICATION OF ALUMINUM ALLOYS

BY E. C. HARTMANN,[92] ASSOC. M. AM. SOC. C. E.

SYNOPSIS

The aluminum alloy most frequently used for structural purposes is described in this paper from the standpoint of the designing engineer. The composition, properties, and forms available are given. Shop fabrication and workmanship are described to show that the practice differs very little from that for ordinary steel fabrication. The recommended design stresses for tension, compression, shear, and bearing are included, and the problem of designing to take advantage of the lighter weight is discussed. The paper is concluded with a brief study of the economics of the use of structural aluminum, indicating the extent of the extra costs and in what fields such extra costs may be justified.

CHARACTERISTICS OF STRUCTURAL ALUMINUM

The engineer interested in minimizing dead weight will find commercially available to-day more than a dozen aluminum alloys which have been used structurally. Each of these alloys, some wrought and some cast, is fitted for some particular field of structural work by virtue of its properties. The selection of the proper alloy to be used in any particular case, involves a number of problems outside the scope of this paper, and, therefore, in order to avoid confusion, the writer will confine himself principally to the wrought aluminum alloy which has been most commonly used in the structural field. This alloy (17S-T)[93] is of the duralumin type.[94]

It contains[95] nominally 95% of aluminum, 4% of copper, and 0.5% each of manganese and magnesium. It is a heat-treatable alloy and is never used structurally except in the heat-treated condition, when it develops the following typical properties:

Weight, in pounds per cubic foot	174
Ultimate tensile strength, in kips per square inch	58
Yield strength, in kips per square inch	35
Percentage elongation in 2 in.	20
Ultimate shearing strength, in kips per square inch	35
Shearing yield strength, in kips per square inch	20

[92] Research Engr., Aluminum Co. of America, New Kensington, Pa.

[93] The symbols in parentheses denote the trade designation by which the alloy is commonly recognized.

[94] Tentative Specifications B78-33T and B89-33T, Am. Soc. for Testing Materials.

[95] "Light-Weight Structural Alloys", by Messrs. Zay Jeffries, C. F. Nagel, Jr., and R. T. Wood, Table 6, Item No. 6, p. 1273, and Table 7, Item No. 6, p. 1279.

Modulus of elasticity in tension and compression, in pounds per square inch........................	10 300 000
Modulus of elasticity in shear, in pounds per square inch	3 800 000
Coefficient of expansion, in degrees per degree Fahrenheit	0.000012
Poisson's ratio	0.33

The yield strength is defined as the stress which produces a permanent set of 0.2% of the initial gage length[86] (see Fig. 38).

The guaranteed minimum properties for this material (in kips per square inch) are, as follows:

Description.	Ultimate tensile strength	Yield point strength.
Plates................	55	32
Structural shapes.......	50	30

Fig. 38 is a typical tensile stress-strain curve for the material.

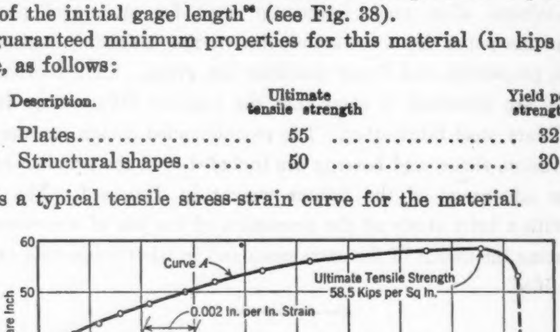

FIG. 38.—TYPICAL STRESS-STRAIN CURVE FOR STRUCTURAL ALUMINUM (DATA TAKEN FROM 0.5-INCH ROUND SPECIMEN.)

Structural aluminum is produced in the form of sheets, plates, structural shapes, rods, bars, rivets, tubing, and forgings. In the form of plates, widths as great as 120 in., thicknesses as much as 1 in., and lengths as great as 35 ft are available, with a weight limitation of 2 kips in any individual piece. In shapes, structural aluminum (17S-T)[86] is available in the form of angles as large as 6 by 6 in., channels as deep as 12 in., I-beams and H-beams as deep as 8 in., and Z-bars as deep as 5 in. Many of the structural shapes are available in lengths as great as 85 ft, but some of them have a length limitation of 35 ft.

FABRICATION OF STRUCTURAL ALUMINUM

Structural aluminum can be fabricated in the ordinary shop with practically no departure from commonly accepted good practice for other

[86] Specification B8-33, Am. Soc. for Testing Materials.

structural metals. The material can be cut by shearing or sawing, the use of the burning torch being prohibited, as it would be for any other heat-treated material. It can be sheared with equipment ordinarily used for steel. Both band and circular saws are used for sawing, and a lubricant or soluble cutting compound is recommended. High-speed metal-cutting band-saws, or heavy-duty wood band-saws with blade speeds of about 5 000 ft per min, are quite satisfactory. Circular saws with hollow ground blades are satisfactory for light work, but for heavy work the teeth should be swaged in order to provide clearance and prevent over-heating. Coarse-toothed blades should be used for both band and circular saws, and the teeth should have no top rake. With circular saws, a peripheral speed of 12 000 ft per min is recommended for the best results.

Structural aluminum can be worked cold to a limited extent. To obtain the best results in cold bending, it is necessary to have all tools in good condition, and to minimize friction between the tools and the metal that is being formed. The metal itself should be free from nicks and scratches, particularly along the edges, and the radii for all bends should be as large as practical.

For difficult forming the metal should be heated, but this should not be undertaken unless equipment for accurate temperature control is available. Heating the metal to a temperature of 300° F improves the cold-forming characteristics somewhat and does not seriously affect the properties of the finished piece, provided the metal is heated less than 30 min. For more difficult forming, however, it is usually necessary to heat the piece to the heat-treating temperature, 930° to 950° F. Such heating, of course, reduces the mechanical properties of the metal unless it is followed immediately by a suitable quench. In the ordinary heat treatment of the metal this quench is provided by immediate immersion in cold water, but since such a quench usually results in objectionable distortion, it is not generally utilized in the fabrication shop unless some means of straightening the finished piece is available. The more common method of providing a quench in the fabricating shop is to transfer the metal quickly from the heating medium to the forming die, which should be cold and of sufficient size to chill the metal thoroughly and suddenly during the forming operation. Since the metal is thoroughly supported and held in alignment by the die, the finished piece is not distorted.

It is clear from the foregoing that, in order that structural aluminum may be hot-formed successfully, it is necessary to have suitable heating equipment with accurate temperature control. Some fabricators of structural aluminum have found it desirable to install such equipment, but in other cases, where only a few pieces require forming, arrangements have been made to have such forming done at the plant of the producer of the metal prior to shipment. The engineer who appreciates the difficulties of forming and bending will make an effort, of course, to minimize the number of pieces that require such treatment, or he will try to limit such pieces to low stressed portions of the structure so that they may be made from one of the lower strength alloys having better forming characteristics than the particular structural aluminum alloy (17S-T), described in this paper.

Rivet holes in structural aluminum may be drilled, punched, or sub-punched and reamed as desired, although drilled or reamed holes are preferable to punched holes. For reaming, the taper bridge reamer with spiral flutes is recommended.

Most aluminum alloy structures, particularly those involving the larger sizes of shapes and plates, are riveted with hot-driven steel rivets. The heating effect of the individual steel rivets is dissipated very quickly by the excellent thermal conductivity of the metal, so that the strength of the aluminum parts adjacent to the rivets is not affected adversely. Some fabricators have adopted the precaution of driving steel rivets at random, particularly in locations where they are closely spaced, to minimize the heating effect.

Aluminum alloy rivets have been used successfully in a number of structures, particularly in sizes smaller than $\frac{3}{8}$ in. which can be cold driven successfully. When it is necessary to use them in the larger sizes, the driving is done hot, and, again, it is necessary to have suitable heating equipment available. The hot-driving of aluminum rivets is very similar to the die-quench hot-forming operation previously described; that is, the rivets are inserted in the hole and driven immediately after removal from the heating medium so that a satisfactory quench is effected by the contact between the rivet and the relatively cold tools and metal around the hole. Some fabricators have successfully adopted the aircraft practice of driving cold rivets of structural aluminum (17S-T) in their semi-soft condition, immediately after heating and quenching, natural aging bringing the strength of the finished rivets up to maximum value over a period of three or four days. In general, however, the additional weight saved by the use of aluminum rivets has not been considered sufficiently important to cause them to be generally adopted instead of steel rivets.

The welding of structural aluminum, like that of most heat-treated materials, has not developed to the stage where it may be utilized to replace rivets. The heat of welding tends to anneal the metal adjacent to the welded area, greatly reducing the strength. When welding is necessary in aluminum construction, one of the lower strength alloys particularly suited for welding is used instead of the standard alloy treated in this paper (17S-T). This applies principally to tanks and light framework rather than to the larger structures.

Aluminum structures should be painted thoroughly, particularly when they are to be used in locations in which the corrosive conditions are severe or uncertain. The procedure generally recommended is to use a priming coat containing a substantial quantity of zinc chromate in a synthetic resin vehicle, applied to all surfaces of the structural parts and allowed to dry before assembly. All parts should be clean and dry, of course, before the application of the priming coat. Following the riveting operation, all rivet heads and adjacent parts should be touched up with the same primer. It is common practice to use at least two protective coatings of aluminum paint over the primer, and care should be taken to work the paint in well around the rivet heads.

No discussion of the fabrication of light-weight structures can be complete without proper consideration of workmanship. When aluminum alloys are

utilized in a structure, it is generally for the specific purpose of reducing dead weight, and, therefore, one may logically assume that great care will be exercised in the design to produce a given result with the least possible material. Any such design deserves and should receive the most careful attention from the standpoint of workmanship. This means, of course, that: (1) Tools should be kept in first-class condition; (2) that holes should be round and no larger than necessary; (3) that edge distances should be carefully maintained and all edges should be well dressed to avoid notches and roughness; and (4) that all material should be handled in the shop work so that surfaces and edges are protected from dents and other injurious accidental defects. It is important that all re-entrant corners be provided with suitable radii to avoid stress concentration, and that rivets shall not be over-driven. In short, the fabricator should observe all the well-known rules of good structural metal practice as set forth in standard specifications in order that the excellence of the shop work may be commensurate with the care exercised in the design, and may contribute to the weight saving expected by the designer.

Designing with Structural Aluminum

In preparing the design of any structure the engineer, of course, must be familiar with the properties of the materials being used and the behavior of those materials under different stress conditions. Unfortunately, it is not always possible for the designing engineer to obtain this knowledge through first-hand experience in actual handling and testing of the materials, and, therefore, he must rely on other sources of information. Generally, he depends for his knowledge of the behavior of any material on some prepared set of specifications which limit the working stresses in the structure to values which are known to be safe on the basis of available test results, theoretical studies, and the experience of those engineers most familiar with the material.

In the case of aluminum alloys, particularly the standard product (17S-T) herein described, a wide variety of tests is available indicative of the structural behavior of the metal, as well as a considerable background of experience in its structural application. Although it is beyond the scope of this paper to go into detail regarding either of these interesting phases of the development of structural aluminum, the writer and his associates have drawn heavily on both in the preparation of the following design stresses. Theoretical studies, such as those by Professor S. Timoshenko[97], have also played an important part in the selection of suitable formulas.

These design stresses represent a factor of safety of at least two against permanent set and buckling, and a factor of safety of at least three against ultimate failure. In each case an attempt has been made to express the allowable stress in such a way that the designer has maximum freedom from arbitrary limitations so that he may exercise his ingenuity to the fullest extent in obtaining maximum weight savings within the limits of safety.

For the basic allowable unit stress on structural aluminum (17S-T) members in direct tension, or on the tension flanges of beams and girders (net section), 15 kips per sq in. is recommended. This value is one-half the

[97] "Strength of Materials", by S. Timoshenko.

guaranteed minimum yield strength for rolled structural shapes, and is less than one-third the guaranteed minimum tensile strength.

For compression on columns and other compression members having an effective slenderness ratio, $\frac{aL}{k}$, equal to or less than 81, an allowable stress (in pounds per square inch) is recommended in accordance with the following straight-line formula:

$$s_a = 15\,000 - 123\,\frac{aL}{k} \quad\text{.....................}(6)$$

In Equation (6), L is defined as the unsupported length of the member, in inches; k is the corresponding least radius of gyration, in inches; and a is a factor describing the end conditions of the member. For both ends fixed, a is equal to 0.5, and for both ends pinned, a is equal to 1.0. Since few if any structural members have completely fixed ends, the value of a should rarely be less than 0.6. In framed construction most compression members have partly fixed ends, and an a-factor should be selected between 0.6 and 1.0, depending upon the end conditions.

For compression on columns and other compression members having an effective slenderness ratio, $\frac{aL}{k}$, greater than 81, the allowable working stress should be in accordance with the following formula:

$$s_a = \frac{33\,000\,000}{\left(\frac{aL}{k}\right)^2} \quad\text{.......................}(7)$$

Equations (6) and (7) for compression are plotted in Fig. 39, and it will be seen that the straight-line portion is tangent to the curved portion, the

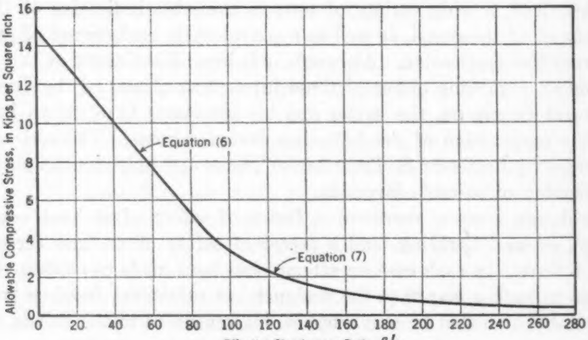

FIG. 39.—ALLOWABLE COMPRESSIVE STRESS IN ALUMINUM ALLOY (17S-T) COLUMNS.

latter being simply the well-known Euler formula with a factor of safety of three applied. This combination of formulas has been found to represent

fairly well the general trend of column tests on a large variety of structural aluminum compression members. It is used in the same manner as most other column formulas, inasmuch as it applies to the average stress on the gross cross-sectional area of the member at or near the center of the unsupported length. It will be noted that there is no rounding off of the column curve as it approaches $\frac{aL}{k} = 0$. In the writer's opinion it is much more logical to accomplish this effect by applying suitable restrictions to the allowable stresses on members which are likely to fail locally.

Flat plates or the legs, webs, and flanges of structural shapes tend to buckle locally when stressed in compression, particularly if such parts are fairly thin with respect to their unsupported widths. Because of the lower modulus of elasticity, aluminum alloys have less resistance to such buckling than steel, and, for this reason, it is more important, perhaps, that the allowable compressive stresses be defined more clearly than in the case of steel. In any event, it is far better to define the safe allowable stresses on such parts than arbitrarily to limit their dimensions because, as previously indicated, the designer should be allowed as much freedom as possible in working toward maximum weight savings.

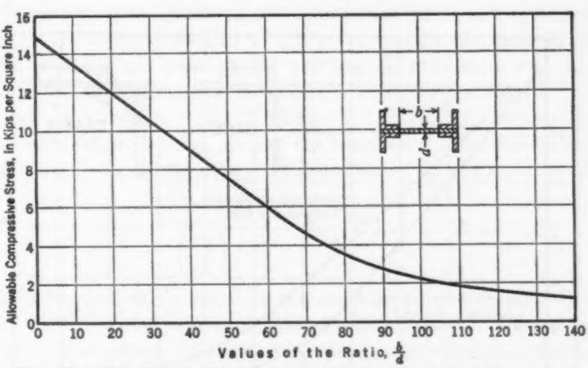

FIG. 40.—ALLOWABLE COMPRESSIVE STRESS ON ALUMINUM ALLOY PLATE SUPPORTED ON TWO EDGES

When flat plates buckle in compression, such buckling occurs in the form of local waves or wrinkles which are practically independent of the length of the member, provided such length is large with respect to the unsupported width of the plate. These local buckling failures in plates may be treated conveniently as local column failures of parts of the plate, using the column formula for the material, provided the proper "equivalent slenderness ratios" are used. From theoretical considerations and available test results the writer and his associates have evaluated these equivalent slenderness ratios for various cases as indicated subsequently.

For flat plates supported along two sides parallel to the direction of stress as in the case of the webs of H-shaped columns, or the compression cover-

plates of double-web box girders, the equivalent slenderness ratio of the plate should be determined, as follows:

$$\frac{aL}{k} = 1.2\,\frac{b}{d} \qquad (8)$$

in which b is the unsupported width, and d, the thickness, both in inches. This equivalent slenderness ratio may be used in the column formulas, Equations (6) and (7), for determining the allowable compressive stress on such plates. The values thus determined are plotted in Fig. 40.

For flat projecting plates supported along one side parallel to the direction of stress, as in the case of the outstanding legs of single-angle, double-angle, T-shaped or star-shaped struts, the equivalent slenderness ratio of the projecting plate should be determined, as follows:

$$\frac{aL}{k} = 4.0\,\frac{b}{d} \qquad (9)$$

in which b is again the unsupported width and d the thickness (see Fig. 41, Case 1). Tests have shown that single-angle, double-angle, T-shaped and star-shaped struts have very little restraint against twisting if any outstanding leg begins to buckle, and the coefficient, 4.0, in Equation (9) is selected on

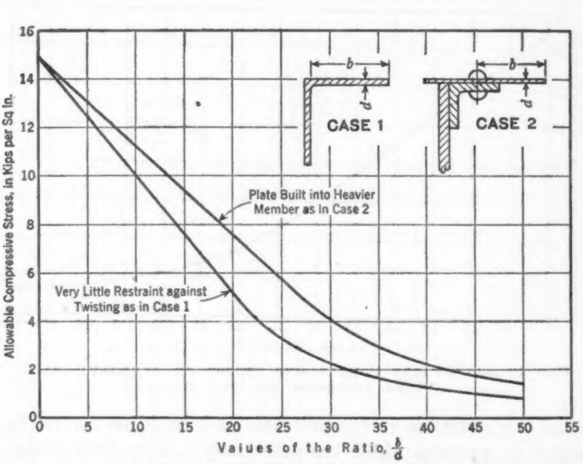

FIG. 41.—ALLOWABLE COMPRESSIVE STRESS ON OUTSTANDING PLATES AND LEGS, OF ANGLES OF ALUMINUM ALLOY

this basis. For projecting plates or legs of angles built into heavier members, as in the case of the flanges of girders or H-shaped columns having relatively thick webs, the coefficient, 4.0, may be reduced to 3.0 because such members offer a much higher degree of restraint against twisting as the outstanding legs or flanges begin to buckle. For intermediate degrees of restraint the coefficient should be selected between the limiting values, 4 and 3, so as to be consistent with the degree of restraint assumed.

When flat plates supported on either one side or on two sides are used as component parts of columns (see Fig. 41, Case 2) they should be investigated for stability in accordance with the foregoing recommendations, independently of the stability of the column as a whole. If it is found that the allowable stress on the plate is less than that for the column as a whole, the former, of course, will control the design of the column, and *vice versa.* The use of equivalent slenderness ratios makes this comparison very simple because it is only necessary to determine whether the equivalent slenderness ratio of the parts is less or greater than the effective slenderness ratio for the column as a whole. In many cases it will be found economical to make the equivalent slenderness ratio of the parts equal to the effective slenderness ratio of the member as a whole, although this cannot be stated as an infallible guide.

For bearing on rivets or on tightly fitted pins and bolts, a working stress of 26 kips per sq in. on the projected area is recommended. Tests have shown that this value represents a factor of safety of at least two against measurable permanent distortion of the hole, and more than three against ultimate failure, provided the edge distance from the center of the hole in the direction of stress is at least twice the hole diameter. For smaller edge distances the foregoing allowable stress (26 kips per sq in.) should be reduced proportionately.

For shear on aluminum (17S-T) rivets or on tightly fitted aluminum (17S-T) pins or bolts, a design stress of 9 kips per sq in. is recommended. This same limiting shear stress applies to the gross section of the webs of beams and girders, provided the shear on the net area on such webs does not exceed 12 kips per sq in., and provided thin webs are adequately stiffened. For shear on steel rivets an allowable stress of 13 kips per sq in. is recommended.

For the webs of beams and girders the maximum shear stress, in pounds per square inch, at the center of any stiffened panel should not exceed:

$$\frac{12\,000\,000}{\left(\frac{h}{d}\right)^2}\left[1 + \left(\frac{h}{l}\right)^2\right] \qquad (10)$$

in which d is the web thickness; h is the clear depth of web between flanges; and l is the clear distance between stiffeners, all in inches. When it is desired to investigate intermediate points in large panels subjected to a varying shear along the length, l may be defined as twice the clear distance to the nearest stiffener. When no stiffeners are used, l becomes very large and the quantity in the brackets approaches unity. Equation (10) not only provides a means of checking girder webs for buckling, but also permits the spacing of stiffeners to be determined to suit any condition of varying shear. It should not be used beyond the limiting value of 9 kips per sq in. Fig. 42 is a set of curves representing Equation (10).

Members which in ordinary service are subject to stress reversal, tension to compression, should be proportioned so that the larger stress plus one-half the smaller stress, does not exceed the basic allowable stress of 15 kips per sq in. This precaution in design will guard against fatigue failures under all ordinary service conditions, because it provides for a million cycles of reversal with an allowance for "stress raisers", such as rivet holes. Of course,

structures that are subject to a considerably larger number of reversals or that have sharp re-entrant corners, and other severe "stress raisers", should receive special treatment in design and cannot be classed with ordinary structures.

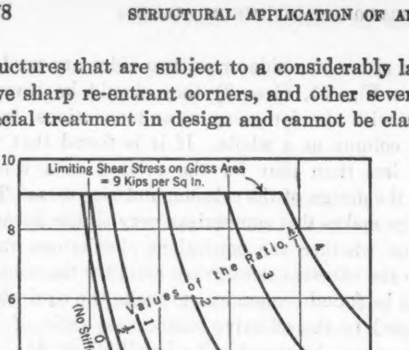

FIG. 42.—ALLOWABLE SHEAR STRESS ON ALUMINUM ALLOY (17S-T) GIRDER WEBS, EQUATION (10)

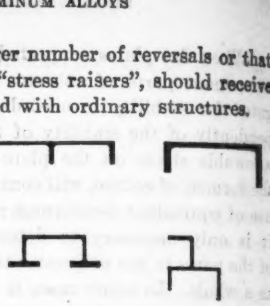

FIG. 43.—EXAMPLES OF ALUMINUM ALLOY SPECIAL SHAPES PRODUCED BY THE EXTRUSION PROCESS

The foregoing safe working stresses are intended to serve as a guide in the design of ordinary structures built of standard structural aluminum, in the same manner that the familiar design specifications for standard steel structures are used. The factors of safety are selected conservatively as indicated. In specialized fields of design these factors of safety may prove to be more conservative than necessary, in view of the exact knowledge of loads and other design conditions, and in such cases the engineer, of course, will use working stresses consistent with the nature of the problem at hand.

Impact allowances on aluminum alloy structures should be the same as those used for comparable steel structures. The entire question of dynamic loadings in ordinary structural design is still on a very unscientific basis, and the mere addition of an arbitrary percentage to the static live load stresses is only a crude attempt to provide a measure of safety against a little understood type of failure. Until a more scientific basis of designing for dynamic loadings comes into general use, there is no point in trying to make adjustments upward or downward in the conventional impact allowances to cover light weight, low modulus materials. Theoretically, of course, the relatively low modulus of elasticity makes aluminum alloys better suited to absorb energy within the elastic range, and this fact is readily demonstrated by tests of simple structural elements. A study of the results of tests and accidents involving more complex built-up structures, however, suggests that the behavior of such structures under dynamic loadings, either in the elastic range or beyond, may be more a function of design than of material, and that aluminum structures may be expected to withstand dynamic loadings at least as well as steel structures of comparable design.

In designing for light weight probably the most important single factor, is the ingenuity of the designer in selecting the best type of structure to carry the loads and meet the other controlling conditions. The designer and detailer must also be adept at arriving at the proper conclusion regarding such questions as the best distribution of metal in various members; when to substitute latticing for solid webs; when to use thin sections with many stiffeners as compared to thicker sections and fewer stiffeners; where to locate splices and connections; and when to use continuity to the best advantage. In all such matters the proper answers change from one structure to the next, depending upon the conditions of the design. The only trustworthy answer to any of these problems is obtained through a careful study of fairly complete comparative designs. Experience gained in the design of steel structures is not always a safe guide in determining how to arrive at the lightest weight in aluminum alloy structures.

The engineer designing in structural aluminum for the first time, is usually intrigued by the possibilities offered by the extrusion process for producing special shapes useful in structural design. In addition to the standard structural shapes, the user of structural aluminum has available an infinite variety of these special shapes, some of which are shown in Fig. 43, and many an aluminum structure owes at least part of its exceptional light weight and lower cost to the intelligent use of such shapes. On the other hand, it cannot be denied that the reverse may easily occur; that is, the novice in aluminum design may be over-enthusiastic about the possibility of extruded shapes, and burden a relatively small job with the cost of several extrusion dies where standard structural shapes might have served practically as well. It should not be difficult in any given case to determine the relative merits of special extrusions and standard shapes if the designer confers with the producer of the special shapes, so that if any extra costs are involved they can be evaluated properly early in the design.

It is a well-known fact that because of the lower modulus of elasticity, aluminum members deflect more than steel members of equal size under the same loading conditions. Occasionally, this fact has been a deterrent for engineers interested in the design of aluminum structures, and almost invariably the reason lies in the fact that the question of deflection is not faced squarely. There is a tendency on the part of some engineers to limit deflections entirely on the basis of their experience with existing steel structures rather than to make an effort to determine the allowable deflection, as an engineering problem. The writer fully appreciates that, in many instances, it is extremely difficult to determine just what the deflection requirements should be, but if minimum weight is to be attained in any structure it is essential for the designer to avoid all unnecessarily severe deflection restrictions.

In general, it is only live load deflections that need concern the designer because excessive dead load deflection can be corrected by proper camber. In addition, in light weight structures the dead load deflections are usually minimized by the weight savings. In members in which deflection becomes a

controlling feature of design it is generally advantageous, of course, to increase the depth, thereby distributing the metal to the best advantage to resist deflections. A simple illustration may help to show the advantages of increased depth; for example, a 5-in. aluminum I-beam for a given span and load will deflect approximately three times as far as the same size of steel I-beam weighing three times as much. If the 5-in. aluminum beam is replaced by a 7-in. aluminum beam, however, the deflection will be reduced to the same as that of the steel beam, whereas the weight is increased to a value which is still only one-half that of the 5-in. steel beam.

Sometimes in striving for the lightest and best possible structure, the engineer will discover that other structural metals, such as the alloy steels, can be used to advantage in some part of what would otherwise be an all-aluminum structure. This is particularly true in the case of highly stressed tension members, shear pins, parts subjected to severe abrasion, shallow beams in which the depth cannot be increased readily, and special high-stressed castings. No special precautions are required in such composite construction, except that the possibility of temperature stresses due to differences in coefficient of expansion, should not be over-looked. Although the magnitude of such temperature stress rarely approaches one-half the design stresses, even where the different metals are riveted together over a considerable length, an attempt should be made to avoid such stresses wherever possible by arranging the different metals in such a way that temperature stresses are minimized. It should also be remembered that when a composite structure is loaded, the stresses in adjacent parts which are riveted securely together will be proportional to the moduli of elasticity. For example, if an aluminum cover-plate is riveted to a steel beam, it will carry only one-third its full share of the load and will not strengthen the beam nearly as much as it would an aluminum beam under the same conditions.

In using various metals in combination in a structure, care should be taken to avoid the possibility of galvanic action which might accelerate corrosion at the points of contact of the different metals, either by breaking the contact with an insulating material, or by excluding all moisture through th use of thoroughly protective paint coatings. The latter precaution is the only one necessary in most cases, and from the excellent condition of existing aluminum structures in which steel rivets have been used, one may readily deduce that this protection is entirely adequate.

The writer would like to emphasize the importance of giving proper attention to non-strength members and secondary strength members in a light-weight structure. Too often when an engineer is studying the possibility of weight saving he is inclined to overlook the fact that a fair percentage of the total weight of his proposed structure lies outside the main strength members. Careful attention given to such items as bracing, walk-ways, walk-way supports, hand-rails, closing sheet, etc., will often be rewarded by surprisingly large additional weight savings, and any structure in which weight saving is important certainly deserves this extra attention. Sometimes it will be found that a study of these structurally unimportant parts will lead

to combining the functions of parts, thereby making possible the elimination of superfluous members and their connections. In any event, it is an important advantage of the light alloys that they permit weight savings in low stressed parts, which are very difficult to obtain in heavier metals that save weight only by virtue of their superior mechanical properties.

Weight Saving Possibilities

The question of when to use structural aluminum is an interesting one, which obviously cannot be treated adequately without going into a detailed and lengthy discussion. The writer will attempt only a brief review of the more important generalities. There are three questions to be answered: (1) What weight savings are possible? (2) What additional expense is incurred to obtain these weight savings? and (3) Can this extra expense be justified? Since structural aluminum weighs 35% as much as steel, a direct substitution, section for section, will lead to a weight saving of 65%, and this margin is often attained through exactly this procedure in actual practice. In most structures, however, the weight savings will range from 50% to 60%, because the designer finds it necessary, in certain members, to use slightly deeper or thicker sections than would be required for equivalent service in steel. The writer has made a study of the weight savings possible in various types of aluminum alloy structural members, tension, bending, and compression, assuming equal conditions of service, and finds that in the average structure in which dead load stresses are relatively small, theoretically, the weight of structural aluminum (17S-T) members should be about 45% that of the same members designed in structural steel for the same loads, a weight saving of 55 per cent.

In larger structures in which the dead load stresses become important in the design of the various members, the weight saved by the use of structural aluminum is greater due to an interesting pyramiding effect. When such a structure is made lighter, the decrease in weight causes a decrease in the dead load stresses which, in turn, permits an additional decrease in size of members, etc. Studies show that in these larger structures weight savings of 65% to 70%, and even greater, should be expected.

In discussing weight savings the use of percentages may lead to a certain degree of confusion. Throughout this paper the writer has used weight-saving percentages defined as follows:

$$\begin{matrix}\text{Percentage of}\\ \text{weight saved}\end{matrix} = 100\left(1 - \frac{\text{Total weight of aluminum members}}{\text{Total weight of equivalent steel members}}\right) \quad ..(11)$$

It does not apply to the over-all weight of structures, except in those instances in which the structural members themselves make up the entire weight of the structure; for example, consider the case of a dragline boom built entirely of structural aluminum and compared with a steel boom of exactly the same length and designed for the same service. The aluminum boom in this case might be expected to weigh 45% of the weight of the steel boom, provided both weights are for the structural parts only, exclusive of cables, sheaves, etc.

If the over-all weight of the dragline unit, including cables, machinery, and sheaves, is used in the comparison, the foregoing weight-saving percentage needs very radical revision. Other complicating factors in the interpretation of weight-saving percentages would be introduced into this same illustration if the aluminum boom was made longer than the steel boom to take advantage of the lower over-turning moment, or if only the outer two-thirds of the boom were constructed of aluminum instead of the entire boom. It is not the writer's purpose to enter into a discussion of these complicating factors, but it is necessary to emphasize that the weight-saving data introduced in this paper are intended to represent the differences in weight between any group of aluminum structural members and the same group of members designed in steel for equivalent service.

The price per pound of structural aluminum plates and shapes will average about fifteen times the corresponding price per pound of structural steel. Reduced to a volume basis instead of a pound basis the structural aluminum plates and shapes will cost about five times as much as those of structural steel. Therefore, comparing two structures having members of identical size throughout, one built of structural aluminum and the other of structural steel, the cost for material alone in the aluminum structure should be about five times that of the steel structure. For structures which in aluminum weigh 45% as much as the same structures designed in steel, the extra cost of the aluminum plates and shapes will be more nearly seven times that of the equivalent steel. If the extra cost is divided by the weight saved, the additional cost for material in the aluminum structures can be

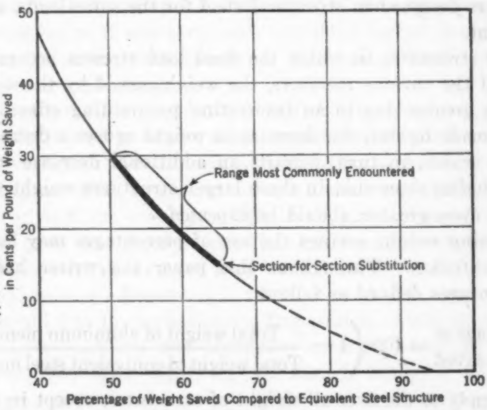

FIG. 44.—EXTRA COST OF STRUCTURAL ALUMINUM STRUCTURES COMPARED TO ORDINARY STEEL

expressed conveniently in terms of extra cost per pound of weight saved. The writer has made a study along these lines, and has plotted the results in Fig. 44 which shows how the extra cost per pound of weight saved decreases as the percentage of weight saved increases, the most common range being from

15 cents to 30 cents extra per lb of weight saved. Of course, there are many factors that may operate to invalidate the values indicated on this curve, but the writer believes that they will be found fairly representative for the ordinary structures encountered to-day.

Although the extra cost values given in Fig. 44 are for material only, they should also represent, quite closely, the over-all difference in cost of fabricated structures because experience has shown that the cost of fabricating any aluminum structure is practically the same as that for fabricating a comparable steel structure. Of course, structural aluminum, because of its light weight, may effect slight savings through lower handling costs, but these savings are frequently offset by the fact that workmen may tend to handle the aluminum more carefully to avoid spoilage.

Since aluminum structures are more expensive than equivalent steel structures, the question of when to use aluminum becomes largely one of justifying the extra cost. Obviously, many structures are built, in which there is no possibility of justifying an extra expenditure of even 10 cents for each pound of weight saved, and for the present these structures are outside the field of structural aluminum. There are many structures, however, in which 15 to 30 cents extra cost per lb of weight saved (and even more) is easily justified. Most of such cases, of course, fall in the classification of moving structures where operating economies are effected. The aircraft and transportation fields have been, and will probably continue to be, the most fertile field for the use of structural aluminum, but engineers are rapidly finding other fields in which the light metals are making a place for themselves in spite of the cost. Such fields include dragline and crane booms, traveling cranes, mine-hoist cages, ship superstructures, etc. One interesting field of use of the light structural metals is in applications where the reduction of dead weight permits the useful life of an existing structure to be extended to accommodate changes in loading conditions not contemplated in the structure as originally designed. Examples are found in the replacement of heavy bridge floors with new light-weight floors, and the use of light-weight traveling cranes in buildings not sturdy enough to support a conventional crane of the required capacity.

As a specific example of the economics of the use of structural aluminum, the writer would like to cite the case of dragline booms, such as are used in levee construction. In this field, the weight saved by the use of aluminum is used most effectively to increase the length of the boom, and, hence, the operating range of the dragline unit. It has been found that a 150-ft steel boom, weighing 33 000 lb, can be replaced with a 175-ft composite aluminum-steel boom weighing about 23 000 lb, the weight saving being accomplished by using 12 000 lb of structural aluminum in the outermost 140 ft of the length. The resulting light-weight boom will handle the same size of bucket as the steel boom, with no greater overturning moment on the machine, and with no decrease in the swing speed. Because of the extra 25 ft in length there is less rehandling of material for the same capacity of bucket so that the speed of the work is increased about 10%, resulting in a saving of about 1 cent per cu yd of earth moved, and, thereby, increasing the earnings by about $1 000

per month per machine. The extra cost of the light-weight boom is thus defrayed in about five months, insuring an adequate return on the additional investment.

No discussion of the costs of aluminum alloy structures is complete without some mention of the scrap price of the metal, which in the case of fabricated structural shapes and plates is about 12 cents per lb at the present time. This high return value of the metal does not affect the extra first cost of structures, of course, and hence has no affect on the values shown in Fig. 44. It should not be overlooked in the general study of the economics of light-weight design, however, particularly on structures having relatively short periods of usefulness due to rapid obsolescence.

Conclusion

Structural aluminum is firmly established in those fields in which it is now being used successfully. Its future in other fields is a matter which lies almost entirely in the hands of designing engineers interested in producing structures which best serve their intended purposes. The writer has tried to indicate that the choice of structural aluminum is almost entirely an economic problem rather than a structural one; that is, structural aluminum may be utilized with confidence in any case where its cost can be justified.

There are many factors, of course, which may affect the future economic status of structural aluminum. Such factors include metallurgical or manufacturing changes which may effect the cost of the metal, the development of new alloys having better mechanical properties, or are otherwise better adapted for structural purposes, new developments in welding, or other fabrication methods, etc. Although some progress is being made at present along many such lines, the writer sees no immediate prospect for any radical change in the status of structural aluminum, and believes that its progress in the structural field in the near future will be simply a continuation of the steady, healthy growth which has marked the development to its present stage of usefulness.

MAGNESIUM ALLOYS AND THEIR STRUCTURAL APPLICATION

By A. W. Winston,[98] Esq.

Synopsis

The combination of light weight with the improved mechanical properties of the newer magnesium alloys makes these materials of increasing interest to the civil engineer. Since 1933 or 1934, production costs have been reduced, and properties have improved to the point where the alloys are finding many successful applications formerly considered impractical for the material.

In this period a number of important applications have developed in the transportation field. As might be expected, because of the necessity for light weight, the airplane industry was the first to adopt these alloys in all types of service. Sand castings of magnesium alloys are used universally in airplane motor and starter castings, in landing wheels and brakes, and as brackets and fittings in the airplane structure. A number of truck and trailer bodies have been built of sheet and structural shapes, resulting in reduced weights and increased operating economy for their owners.

Although they are not used extensively as yet in structural engineering, these alloys give promise of development in this field of application. The purpose of this paper, therefore, is to present the characteristics of the standard magnesium alloys in which the civil engineer is most likely to be interested, in order that he may arrive at a proper appreciation of the possibilities in their use.

Introduction

In changing from one material to another it is very necessary that careful consideration be given to all the factors involved. The success of a design may depend upon the attention given to details which are automatically provided for by the engineer when working in steel, but which may escape attention when he is starting to use a new material.

The metallurgical aspects of magnesium alloys are presented in Part II of this Symposium. Not less important than a knowledge of these fundamental properties and characteristics is a practical knowledge of the performance of actual beams and columns, of correct shop and field methods of fabricating, and of the protective measures to be applied to insure long and satisfactory service.

---

[98] The Dow Chemical Co., Midland, Mich.

The designer contemplating the use of magnesium has available a wide variety of alloys and forms which are adaptable to many specific uses. The manufacture of castings, structural shapes, sheet, and forgings, and the properties obtainable in these forms, have been described in detail in the paper, by Messrs. Zay Jeffries, C. F. Nagel, Jr., and R. T. Wood, entitled "Light-Weight Structural Alloys."[99] On comparing the properties of the standard, cast magnesium alloy with those for cast iron and the cast aluminum alloys (Table 25), it will be observed that the former compare exceptionally well on the basis of unit strength. Although not quite equivalent on a volume basis, the wrought alloys possess very favorable strength-weight ratios. Usually, it is possible to increase the sections slightly to secure the desired stiffness and strength without sacrificing the weight advantage of the magnesium alloys.

DESIGN FACTORS FOR MAGNESIUM ALLOY STRUCTURES

In considering the more important properties of magnesium alloys and their effect upon structural design, reference should be made to Table 25 and Table 26 for details of the comparative properties discussed. The relative bending properties listed in Table 26 are based on the physical properties given in Table 27. The standard formulas for rectangular beams were used in making the calculations.

[99] See p. 1267.

Specific Gravity.—The specific gravity of the present commercial magnesium alloys will average nearly 1.8, which may be compared to 2.8 for aluminum alloys and 7.85 for steel, The weights per cubic foot are, respectively, 112, 175, and 490 lb. For equal volumes the saving in weight by the use of magnesium alloy in place of aluminum would be 63 lb per cu ft, or 36%,

TABLE 27.—PHYSICAL PROPERTIES OF THE ALLOYS COMPARED IN TABLE 26.

Material	Specific gravity	Tensile yield strength, in kips per square inch	Young's modulus of elasticity, in kips per square inch
Steel..............................	7.85	60	29 000
Aluminum alloy..........................	2.79	35	10 000
Magnesium alloy..........................	1.80	30	6 500

and in the case of steel, the saving would be 378 lb per cu ft, or about 77 per cent. In general, not all this theoretical saving can be realized when allowance has been made for differences in strength and modulus of elasticity. With castings, however, these savings are attained frequently. An example of this is found in some large ventilating fans, 12 ft in diameter. When constructed of aluminum alloy, the castings weighed approximately 900 lb. The use of magnesium alloy castings made from the same patterns has lowered the casting weight to less than 600 lb, a net saving of more than 300 lb. The lighter fan has permitted the use of a smaller motor because of the lessened starting load and has reduced, considerably, the cost of the unit. Patterns used for aluminum or cast iron ordinarily may be used for magnesium alloys without modification other than adjustment for shrinkage and increase in the radii of fillets.

Thermal Expansion.—The coefficient of thermal expansion of magnesium alloys is generally accepted to be 0.000016 in. per in. per degree Fahrenheit. This value is slightly greater than that for aluminum alloys (0.000013) and considerably greater than that for steel (0 0000066), or that for cast iron

(0.000006). This difference becomes important when structures subject to temperature changes are being designed, in which magnesium alloy members may be rigidly connected to members of iron or steel; for example, a magnesium alloy floor-plate 10 ft long may be riveted to a steel framework made necessary by space limitations. If such a structure is subjected to a temperature rise of 100° F, the difference in expansion of the two materials will be almost $\frac{1}{8}$ in., an amount sufficient to cause partial shear of the rivets or serious and possibly permanent deformation of the structure. It is important, therefore, that the designer recognize this possibility and provide for it by the elimination of contributing causes. The use of shorter members, expansion joints, and care in the method of attachment will do much to make such composite structures practicable.

Modulus of Elasticity.—The generally accepted value for this constant is 6 500 000 lb per sq in. As this is somewhat lower than the modulus for aluminum (10 000 000), and considerably lower than that for steel (29 000 000), it is necessary to take this fact into consideration in re-designing structures for magnesium alloys.

To secure equal stiffness in bending, which usually is desired, it is necessary to increase the moment of inertia of the section. This may be accomplished with a relatively small increase in dimensions since the moment of inertia varies as the cube of the depth. By designing to equal stiffness, the yield strength will be increased over that of the steel or aluminum member being replaced, retaining very significant weight savings, as indicated in Table 26, and described in greater detail under the heading, "Beams."

The differences in moduli of elasticity must also be considered in designing composite structures to insure correct load-transfer conditions. Thus, if a magnesium alloy tension member is riveted to a steel section, both pieces should be adjusted in size to secure equal elongation between rivets when under operating load. Otherwise, the unequal elongation will throw an excessive load upon certain rivets, possibly resulting in their failure or in the elongation of the rivet holes.

Mechanical Properties.—An appreciation of the possibilities in the use of magnesium alloys is obtained by reference to Table 25 in which the comparative properties of some of the important structural metals are given. As previously noted, cast magnesium alloys have mechanical properties equal to those of the cast aluminum alloys or of cast iron on an equal volume basis. When compared on an equal weight basis, both the cast and wrought magnesium alloys are equal or superior to the other metals in the cast or wrought conditions.

Proportional Limit and Yield Strength.—When magnesium alloys are subjected to the usual tensile tests, there is a gradual breaking away from the modulus line, making determination of tangential proportional limits somewhat difficult. A suggested method is to consider the proportional limit as the stress where the stress-strain curve deviates 0.01% from the modulus line.

Similar to aluminum alloys but unlike steel, magnesium alloys do not exhibit sharp yield points. The yield strength is now accepted as the stress

where the stress-strain curve deviates 0.2% from the modulus line. The usual value obtained for the proportional limit is from 50 to 60% of the yield strength.

A peculiar characteristic of wrought magnesium alloys, recognized by investigators for a number of years, is the low compressive yield strength compared to the tensile yield strength. This value, determined at 0.2% deviation from the modulus line as in the case of the tensile yield strength, is about 75% of the latter value. This ratio is subject to some variation and will be affected by mechanical working, composition, and heat treatment.

* Item numbers corresponding to those in Table 10 (see p. 1288,) and Table 25 (see p. 1386)

In Table 28 are given the properties of the alloys in which wrought shapes are available, showing the progressive development, since 1934, in the direction of securing improved yield strength values. It has been noted that the methods presenting the best prospects for improvement along this line are those involving the heat treatment of wrought sections. The properties given in Table 28 are those obtained on structural sections. The yield strengths of small diameter bar stock as given in Table 25 are slightly higher than those of structural shapes, apparently due to more uniform conditions of flow through the extrusion die.

Fatigue Endurance Limit.—A noteworthy feature of magnesium alloys, particularly in the wrought condition, is the high fatigue endurance limit. Thus, it is not unusual to have an extruded magnesium alloy[100], of the same composition as that given in Item No. 31, Table 25, exhibit a fatigue endurance limit of 19 kips per sq in. with a proportional limit slightly less than this value, and a yield strength of about 33 kips per sq in. Endurance limit data probably will find increasing use in design as experience is obtained with actual service applications.

[100] See p. 1288.

Bearing Strength of Sheet.—The bearing strength of magnesium alloy sheets is rather high compared to the tensile strength of the material, and in the case of a hard-rolled magnesium alloy (Item No. 30, Table 10)[100a] will run from 60 to 70 kips per sq in., whereas the annealed material will be from 55 to 65 kips per sq in. One-fourth of these ultimate values are considered to be safe design values.

Beams.—Magnesium alloy beams deflect appreciably with increasing load above the yield strength until failure finally occurs as stresses approach the ultimate tensile strength. This statement applies to simple beams, such as rectangular sections which fail by yielding of the material. The yield strength of a magnesium alloy beam is considered to be the point at which the outermost fibers are elongated 0.2% beyond the modulus line, and may be determined either by the use of strain-gages or by computing the deflection corresponding to this 0.2% permanent deformation of the outer fibers. This concept applies to the beams the same interpretation of yield strength as that used in the ordinary tensile or compression test on the material. Due to the reinforcing action of the material near the neutral axis, the flexural yield strength as determined in this manner will exceed the tensile or compressive yield strength of the material.

The most important factor that will interfere with the foregoing conclusion is that due to the form of the section. As the sections are made more slender, failure may occur through twisting, buckling, or flange crippling. In such cases, the yield strength of the beam may fall below the yield strength of the material in the outer fibers. Because of this fact, it is suggested that the design values be limited to one-half the flexural yield strengths as determined by actual tests of the sections under consideration. Examples of such tests are given in Table 28 for several typical sections.

Very few data have been obtained on the lateral buckling of compression flanges of beams in the relation of unsupported length to width of flange. Little information is available on the buckling of beam webs and on the crippling of compression flanges. Although most of the I-beam, channel, and plate girder tests conducted to date have failed by lateral buckling, the maximum stresses were about the same as those developed by similar sections which failed by compression yielding of the flanges.

Under the heading, "Modulus of Elasticity," attention was directed to the stiffness characteristics of magnesium alloy sections compared to those of aluminum alloy or steel sections. The relative effects of specific gravity, yield strength, and modulus of elasticity for these three materials on the design of rectangular beams have been computed and are given in Table 26. By reference to this table it will be observed that, on the basis of equal stiffness, the comparison is very favorable to magnesium alloys; for example, for equal stiffness, the magnesium alloy beam will be 65% thicker and 36% stronger than the corresponding steel beam, with a weight saving of 62 per cent. Compared to an aluminum alloy beam of equal stiffness, a magnesium alloy beam will be 15% thicker, 26% lighter, and 14% stronger.

The situation is slightly more complex when one wishes to substitute magnesium alloy structural sections for those of aluminum or steel. If the mem-

[100a] See p. 1288.

ber to be replaced is a steel beam, it is generally desirable to choose a geometrically similar magnesium alloy section having a moment of inertia about four and one-half times as great as that of the steel beam. This rough rule will provide a member of the same stiffness, of considerably greater strength, and of less than one-half the weight.

In like manner, an aluminum section may be replaced by a geometrically similar magnesium section having a moment of inertia about one and two-thirds as great as that of the aluminum section, resulting in a member about 20% lighter, but having the same strength and stiffness.

If wood is to be replaced by magnesium alloy with equal stiffness, the metal section should have a moment of inertia at least one-fifth that of the wood.

The substitution of magnesium alloy beams for steel or aluminum members in composite structures should be made on the basis of equal stiffness, as better load transfer conditions can be maintained with an increase in the strength of the assembly.

Columns.—Magnesium alloy columns act much the same under loads and are as susceptible to design calculations as columns of other materials. The strength of such columns is dependent upon the following factors: (1) Compressive yield strength; (2) ultimate compressive strength; (3) modulus of elasticity; (4) size; (5) shape; (6) end conditions; (7) loading conditions; and (8) length. Perhaps the most important of these factors are the compressive yield strength and the modulus of elasticity.

The compressive yield strength is the governing factor for most short columns used in structural work. As discussed under the heading, "Proportional Limit and Yield Strength," the compressive yield strength of standard magnesium alloy sections has undergone considerable improvement since 1933. Recent determinations for this value during a series of column tests on a variety of sections of magnesium alloy (see Item No. 43, Table 25 and Table 23), have indicated a value of 24 kips per sq in. for the compressive yield strength. It was found that the results of these column tests were closely approximated by a modified Rankine-Ritter formula:

$$\frac{P}{A} = \frac{s_y}{1 + Q\left(\frac{L}{k}\right)^2} + \frac{80\,000}{\frac{L}{k}} \quad \text{.................(12)}$$

in which P = a load, in pounds; A = cross-sectional area, in square inches; s_y = compressive yield strength = 24 000 lb per sq in.; L = length of column, in inches; k = least radius of gyration; and Q = Ritter's constant:

$$Q = \frac{s_y}{C\,\pi^2 E} \quad \text{........................(13)}$$

in which C = a fixation coefficient and E = the modulus of elasticity = 6 500 000 lb per sq in. The results of the tests are plotted in Fig. 45. Although service experience is somewhat lacking in the application of these data, it is suggested that design values should not exceed one-half the unit strength given.

Because of the limited space available in this paper, it will be possible to give only a single example of the column characteristics of magnesium alloys compared to those of aluminum alloys or steel.

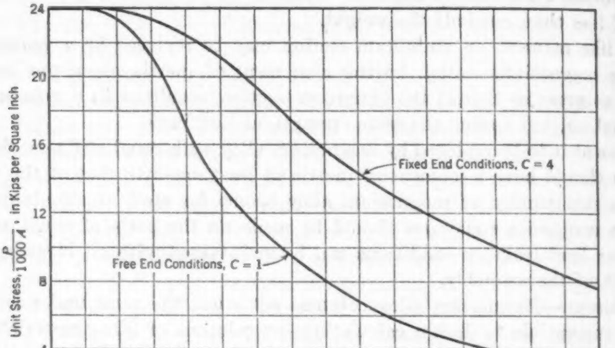

FIG. 45

Assume that a load of 20 000 lb is to be supported by a single fixed-end solid column of round cross-section and a length of 60 in. On computing the necessary diameters, using the published design values for steel and aluminum alloy and one-half the yield strength values for magnesium alloys, as given in Fig. 45, the results given in Table 29 were obtained.

TABLE 29.—COMPUTATION OF COLUMN DIAMETERS

Material	Diameter, in inches	Weight of column, in pounds	Percentage of steel weight saved
Steel	1.72	39.4	..
Aluminum alloy	1.89	17.0	57
Magnesium alloy*	2.10	13.7	65

* Alloy X; see Item No. 43, Table 25.

Some variation from these weight ratios will be experienced when other specific cases are estimated, due to changes in the relative permissible stresses, which will be dependent upon the shape of section, $\frac{L}{k}$-ratios, end conditions, eccentricity of loading, etc. In general, however, the order of weight difference will be similar to that given in Table 29.

FABRICATION METHODS

The successful application of magnesium alloys has been dependent largely upon the development of suitable fabrication methods. Among the important

features of good shop practice are the results and conclusions of many years of experience in the production and use of a wide variety of articles made of magnesium alloys, including castings and built-up assemblies using structural shapes and sheets. As with any other structural material, careful attention to small details has been an important factor in the success of these applications.

Machining.—The machinability of the magnesium alloys is unexcelled by that of any other structural metal. A fine smooth finish is readily secured with no tendency to drag, tear, or chip out. Experience in the average machine shop has proved that practically all machine tools can be run at their maximum speeds with feeds to the full capacity of the machine. High-speed steel or tungsten carbide tools are generally recommended because of the long life between grindings.

Ordinarily, no cutting compound or lubricant is required as heavy cuts and feeds may be taken at high speed without excessive heating of cutting tools or work. A coolant is sometimes advisable on high-speed screw machine operations where a very fine finish is desired.

The power requirement in machining is less than that for any other metal. Comparative tests between magnesium and other alloys show that the power required will be about one-half that for aluminum alloys and brass, one-third that for cast iron, and approximately one-fifth that for steel.

Because of this excellent machinability, manufacturing costs frequently are reduced in spite of a larger cost for the rough casting or forging, particularly where the machining expense is a large proportion of the total cost. Machine production also is increased and, at the same time, operating and maintenance costs are lowered.

Forming.—Magnesium alloy sheet and shapes can be given a moderate amount of cold working, but when sharp bends are required it is necessary to heat the work and the tools. A temperature of 500 to 700° F is best for hot forming. The work may be heated locally with a torch, but a better method is to heat the part in an oven where the temperature can be controlled.

Because of the cold-hardening characteristic of the metal, spinnings, stampings, and drawings are limited to those of liberal bend radii in which only moderate deformation is required. In this case, also, heating of the stock and tools will permit more difficult operations. Tools should be clean, smooth, and well lubricated. Lard oil is generally satisfactory for the purpose.

Although the application of some of these processes may involve slight changes from present practice on other materials, most of these problems are capable of solution with a little expenditure of study and effort.

Riveting.—Rivets made of aluminum alloys, with properties given as Items Nos. 1, 2, and 6, in Table 6[101] (Alloys 2S, 3S, and 17S), may be used in magnesium alloy structures. The first two compositions are soft, are easily headed cold, and can be used where strength is not important. Item No. 6 of Table 6[101] (17S or AM55S), should be used where higher stresses are encountered. Alloy 17S has the higher strength, but must be heat treated just prior

[101] See p. 1273.

to driving. Alloy AM55S is especially recommended for use in magnesium alloy structures as the rivets may be driven cold and have the advantage of minimizing the possibility of galvanic corrosion under certain atmospheric conditions. The design of riveted joints, as with other metals, is based upon the shearing strength of the rivet and on the tensile and bearing strengths of the sheet. The use of steel rivets occasionally may be desirable in locations not subject to weathering where strength requirements or convenience in driving may make them more practical than aluminum alloy rivets. To prevent galvanic action, the steel rivets should be dipped in an insulating primer or compound before driving. One-fourth the bearing strength, or about 15 kips per sq in., may be taken as the safe design value for magnesium alloy (Item No. 30, Table 10).[102]

Welding.—Considerable success has been attained during the past few years in the development of welding processes for magnesium alloys. The methods generally in use at this time are gas welding and electric resistance welding. In oxy-acetylene welding a special flux must be used, while the filler rod should be of approximately the same composition as the part being welded. The presence of traces of flux left in the weld will tend to promote subsequent corrosion, and it is necessary, therefore, that considerable care be exercised during the welding operation to prevent such inclusions. After welding, the parts should be thoroughly cleaned in hot water and treated by immersion in the chrome-pickle solution (described under the heading, "Surface Treatment and Painting"), and then painted. Because of the difficulty in treating large structures, the acetylene welding process should be limited to articles and assemblies that can be cleaned adequately.

Electric spot welding has been used in a number of cases. It offers the advantage of speed and economy, and is applicable to the joining of sheet metal and extruded shapes. The following data give the shear strengths from tension tests of single spot welds joining strips of magnesium alloy sheet (Item No. 30, Table 10)[102]:

Single sheet thickness, in inches	Shear strength, in pounds per spot
$\frac{1}{32}$	500 to 600
$\frac{1}{16}$	900 to 1 000
$\frac{1}{8}$	1 600 to 1 900
$\frac{1}{4}$	1 900 to 2 200

Surface Treatment and Painting.—Under ordinary conditions of atmospheric exposure, magnesium alloys have proved remarkably stable over periods of years. The surface, particularly if polished or buffed, gradually tarnishes and becomes covered with a thin gray oxide film. Some powdering and roughening of the surface occurs in heavy industrial areas or in locations of continuously high humidity. This corrosion is a very slow process, however, being measured in terms of years, and is very much slower than the corresponding rusting of mild steel in the same atmosphere. In saline atmospheres along the sea coast, corrosion may become more serious and necessitate preventive measures.

[102] See p. 1288.

Because of the difficulty in controlling the location and conditions under which an article will be used, it is always recommended that magnesium alloy assemblies or parts be given suitable paint protection. It has been demonstrated that, with proper care, paint systems on magnesium alloys will have a useful life in service as long and as satisfactory as on any other structural metal.

The surface treatment prior to painting is of great importance in the development of a protective paint system. The application of paint coats to the bare metal will result in unsatisfactory adhesion. A chemical treatment known as the chrome-pickle has been developed which, when applied to the metal, imparts to it definite corrosion inhibitive characteristics and a surface etch which promotes satisfactory mechanical bond. The chrome-pickle treatment consists of a dip for 30 sec at room temperature in a bath containing nitric acid and sodium bichromate. The yellowish irridescent coating formed by this treatment possesses good bond to the metal and in conjunction with suitable primers insures lasting adhesion of the paint system.

As a result of thousands of exposure tests, a number of paint schedules have been developed for a variety of service conditions, combining adequate protection with attractive decorative characteristics. A primer is extremely important and must be carefully selected for the particular service to be encountered. For general outdoor exposure, a primer recently developed by the United States Navy (Navy Specification P-27) has been very satisfactory, as it combines excellent adhesion with the desired inhibitive characteristic due to the zinc chromate pigment.

The last few years have seen the development of a number of very superior paint finishes compared to the old oil paints. They possess remarkably good weather resistance and imperviousness to moisture, due largely to the use of synthetic resins in their manufacture. Because of these qualities, they have proved to be very satisfactory for finishes over magnesium alloys. For ordinary atmospheric exposure, two coats of the pigmented enamels are generally satisfactory. For severe exposure conditions, it is recommended that three finish coats be applied, consisting of a varnish developed by the United States Navy (Navy Specification V-10*c*), containing 1½ lb per gal of aluminum powder.

In building assemblies from magnesium alloy structural shapes and sheets which will be exposed to the weather, care should be taken to avoid pockets that could entrap water. Enclosed areas should be provided with drainage and good ventilation, and should be given at least one coat of approved primer. Faying surfaces should be primed and allowed to dry before assembly. In locations where magnesium alloy surfaces will be in contact with wood or dissimilar metals, additional treatment with bituminous paint is recommended. A heavy sealing compound should be used if there is a possibility of water entering the joint.

Numerous structural magnesium parts and assemblies, such as motor castings, airplane wheels, and truck and trailer bodies, have proved that properly applied paint systems will give adequate protection. The use of

magnesium alloys in structural applications now appears practicable (from the protection viewpoint) even in the more severe exposures along the sea coast.

Conclusion

The development of structural applications for magnesium alloys is dependent upon the economy possible through their use. It is a question of balancing initial, fabrication, and maintenance costs against the benefits of saving in weight. Castings of structural magnesium alloys already have demonstrated their ability to compete successfully with older metals and to-day are rendering satisfactory service in hundreds of applications. These castings are of excellent quality and in most cases the cost is very little, if any more than that of the heavier aluminum castings of the same quality.

With the introduction of stronger alloys and improved fabrication processes, the way is now open for the development of additional structural applications. A beginning has been made in the transportation industry, and it is logical to expect interest to continue in this field. On account of the relatively high cost compared to steel, and the lack of need for weight saving, it is improbable that the near future will see much use of magnesium alloys in stationary structures. On the other hand, the civil engineer is most likely to use them in reducing the weight of his equipment, in his crane booms, scaffolds, ladders, and other portable tools, to which magnesium alloys can contribute increased load capacity, strength, and convenience.

DISCUSSION

E. MIRABELLI,[103] M. AM. SOC. C. E. (by letter).—In discussing safety factors and working stress, Mr. Karpov points out that the safety of a design in any redundant construction may be influenced by the fact that weak members can transfer part of their burden to other parts of the structure. In this manner the actual factor of safety is raised above that indicated by a comparison of computed stress with yield point or ultimate strength of material. In a simple beam there occurs a similar transfer of load from over-stressed outer fibers to under-stressed interior fibers, and the calculated stress does not give an exact indication of the margin available to the useful load-carrying capacity of the beam. After the maximum fiber stress has reached the yield point a certain amount of additional load may be applied without causing distress and, within definite limits, the beam deflection will continue nearly in direct proportion to the loading. Ultimately, the useful limit of the beam is reached, and deflection will increase rapidly with little or no increase in loading. The useful limit is affected to a large extent by the type of beam section and also to a small degree by the type of loading. These facts have been known for some time from results of tests and are used to some extent in the structural analysis of airplanes[104]. A process which would lead to a quantitative prediction of the behavior described herein would, to some degree, attain Mr. Karpov's apparent aim which is to diminish the gap between predicted and actual behavior. Such a process for beams of ordinary carbon steel may be based on an idealization of the stress-strain diagram into a series of straight lines, as shown in Fig. 46(*a*). The strain-hardening region to the right of $n_1 \epsilon$ is unimportant because failure takes place in the form of a rapid increase in the rate of vertical deflection before the outer fibers are strained sufficiently to reach this region. (This discussion refers to plastic failure only and not to elastic failure due to lack of lateral support.) The assumptions are made that through the entire range of stress, including the plastic range, a plane section before bending remains plane after bending[105] and also that the stress-strain relation is the same for tension and compression[106]. The stress distribution over a symmetrical beam section then will be as shown in Fig. 46(*b*), with a portion near the neutral axis in a state of elastic stress and the remainder of the section in a plastic state.

To illustrate the method of developing the deflection equations, the rectangular beam shown in Fig. 47 will be considered with a single concentrated load at mid-span of sufficient magnitude to produce a region of plastic stress. The limits of the plastic regions are defined horizontally

by x and vertically by y. Using Fig. 46(b) and Fig. 46(c) and taking moments about the neutral axis, it can be shown that the moment of resistance is,

$$M = \frac{1}{6} s_1 b h^2 \left(\frac{3}{2} - \frac{1}{2 n^2} \right) \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

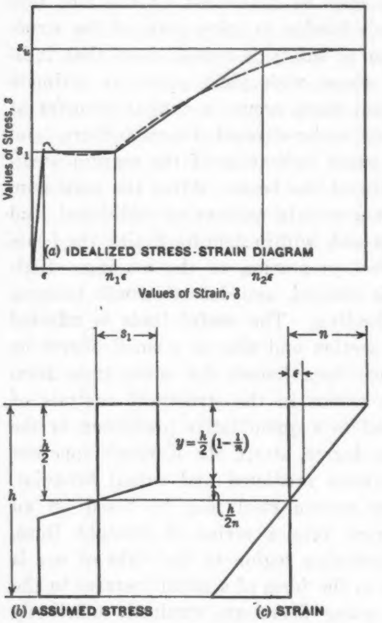

FIG. 46.—STRESS AND STRAIN DIAGRAMS.

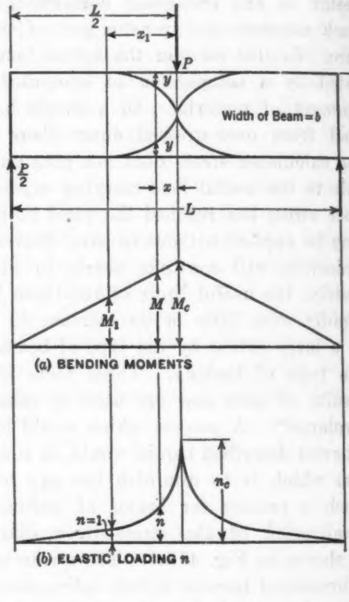

FIG. 47.—RECTANGULAR BEAM WITH A CONCENTRATED LOAD AT THE CENTER.

Now, let P_1 represent the smallest load that would cause a maximum bending stress equal to the yield point stress, and let M_1 represent the corresponding maximum bending moment. Then, from the equality of external and internal moments it is obvious that,

$$M_1 = \frac{1}{4} P_1 L = \frac{1}{6} s_1 b h^2 \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

At the section where $x = x_1$ (see Fig. 47), the bending moment is,

$$\frac{P}{2} \left(\frac{L}{2} - x_1 \right) = \frac{1}{6} s_1 b h^2 = \frac{1}{4} P_1 L \ldots\ldots\ldots\ldots (16)$$

from which,

$$x_1 = \frac{L}{2} \left(1 - \frac{P_1}{P} \right) \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

Equation (17) defines the horizontal limit of the plastic region along the outer fibers.

The strain along the outer fibers at any section which cuts the plastic region is measured by the value of the quantity, n, at that section. To obtain an expression for the strain factor, n, substitute Equation (15) in Equation (14) and equate internal and external moments, thus:

$$\frac{P}{2}\left(\frac{L}{2}-x\right)=\frac{1}{4}\,P_1 L\left(\frac{3}{2}-\frac{1}{2\,n^2}\right)\ldots\ldots\ldots\ldots(18)$$

When solved for n, Equation (18) gives,

$$n=\sqrt{\frac{1}{3-2\left(\frac{P}{P_1}\right)\left(1-2\,\frac{x}{L}\right)}}\ldots\ldots\ldots\ldots(19)$$

When $x = x_1$, it is obvious that $n = 1$, and, since in the purely elastic region the strain is proportional to the bending moment, it follows that in the region, $\frac{L}{2} > x > x_1$, the strain factor is given by the expression,

$$n=\frac{L-2\,x}{L-2\,x_1}\ldots\ldots\ldots\ldots(20)$$

The strain factor, n, may be used now to obtain deflections from the relation,

$$\delta=\int m\,d\theta\ldots\ldots\ldots\ldots(21)$$

in which m is the bending moment at any section due to a unit load applied at the section for which the deflection, δ, is desired, and $d\theta$ is the angular distortion in any element, dx. From Fig. 46(c) it is apparent that the angular distortion is,

$$d\theta=\frac{2\,n\,\epsilon}{h}\,dx\ldots\ldots\ldots\ldots(22)$$

If the deflection at mid-span is to be determined,

$$m=\frac{1}{2}\left(\frac{L}{2}-x\right)\ldots\ldots\ldots\ldots(23)$$

Substituting Equations (22) and (23) in Equation (21) and then performing the integration with the help of Equations (17), (19), and (20), and simplifying:

$$\delta_c=\frac{\epsilon\,L^2}{h}\left\{\left(\frac{P_1}{P}\right)^2\left[\frac{5}{6}-\left(\frac{3}{4}-\frac{1}{12\,n_c^2}\right)\frac{1}{n_c}\right]\right\}\ldots\ldots(24)$$

in which n_c is the strain factor at mid-span and may be calculated by use of Equation (19). If the quantity within the braces is given a substitution value, u, Equation (24) may be simplified thus:

$$\delta_c=\frac{u\,\epsilon\,L^2}{h}\ldots\ldots\ldots\ldots(25)$$

An alternative method for calculating deflections is by using quantities, $d\theta$, as "elastic weights." From Equation (22), it is seen that for a beam of uniform height the only variable is the quantity, n. This quantity may be used alone as an "elastic loading" if the results are corrected by multiplying by the constant, $2\frac{\epsilon_1}{h}$. The deflection at any point of the beam is the "bending moment" resulting from the application of the "elastic loading."

The foregoing method may be extended to beams with other types of cross-section. The loading-deflection curves shown in Fig. 48 were plotted from calculated deflections. The I-sections were assumed to have a ratio of flange thickness to depth of beam equal to 0.05 and a ratio of web thickness to width of flange equal to 0.10. These are average values for standard I-beams. The diamond-shaped section is a square with loading in the plane of a diagonal. In all calculations it was assumed that $n_1 = 12$ (see Fig. 46(*a*)) and that the slopes of the two inclined lines of the idealized diagram are in the ratio, 1:80. These are average values for medium carbon steel.

From the definition of P_1, it follows that the ordinate, $\frac{P}{P_1} = 1.0$ (Fig. 48), shows when yield point stress begins in the most stressed material. These curves indicate a yield point in flexure which differs from the yield point in direct stress and which varies widely with the shape of the beam section. These curves also indicate a possible exception to Mr. Karpov's statement that the stress-strain curves of Fig. 2 demonstrate the non-applicability of Hooke's law to low-strength steel stressed above the yield point. If Hooke's law may be interpreted as meaning that deflections are proportional to the forces which produce them, it is evident that sometimes the law is applicable with close approximation even when the steel is stressed above the yield point because the deflections continue very nearly in proportion to the loading for a considerable distance. The calculated curves are in good agreement with the published results of a number of experiments[107]. If the yield point in flexure is to be taken as the limit of the useful carrying capacity of a beam (that is, the point on which the factor of safety is to be based), it is evident that such a factor will vary with the shape of the beam. For example, using a working stress of 18 kips per sq in. for steel having a yield point of 36 kips per sq in., the factor of safety in flexure for the square section on edge is 4, for the rectangular section, 3, and for the typical I-section, 2.4. To obtain a uniform safety factor of 2.4, for example, the working stresses should be 30 kips per sq in. for the square section on edge, 22.5 kips per sq in. for the rectangular section, and 18 kips per sq in. for the typical I-section.

[107] Test data may be found in the following publications: "Experiments on the Yield Point of Steel under Transverse Tests", by Sir A. B. W. Kennedy, *Engineering*, London, June, 1923, Vol. 115, p. 736: "The Strength of I-Beams in Flexure", by H. F. Moore, *Bulletin No. 68*, Eng. Experiment Station, Univ. of Illinois; "Strength of Light I-Beams", by the late Milo S. Ketchum, Hon. M. Am. Soc. C. E., and J. O. Draffin, M. Am. Soc. C. E., *Bulletin No. 241*, Eng. Experiment Station, Univ. of Illinois; "Beitrag zur Frage der tatsächlichen Tragfähigkeit einfacher und durchlaufender Balkenträger", von Maier-Leibnitz, *Die Bautechnik*, Berlin, 1928, Vol. 6, pp. 11, 27; and "Versuche mit eingespannten und einfachen Balken von I-Form", von Maier-Leibnitz, *Die Bautechnik*, Berlin, 1929, Vol. 7, p. 313.

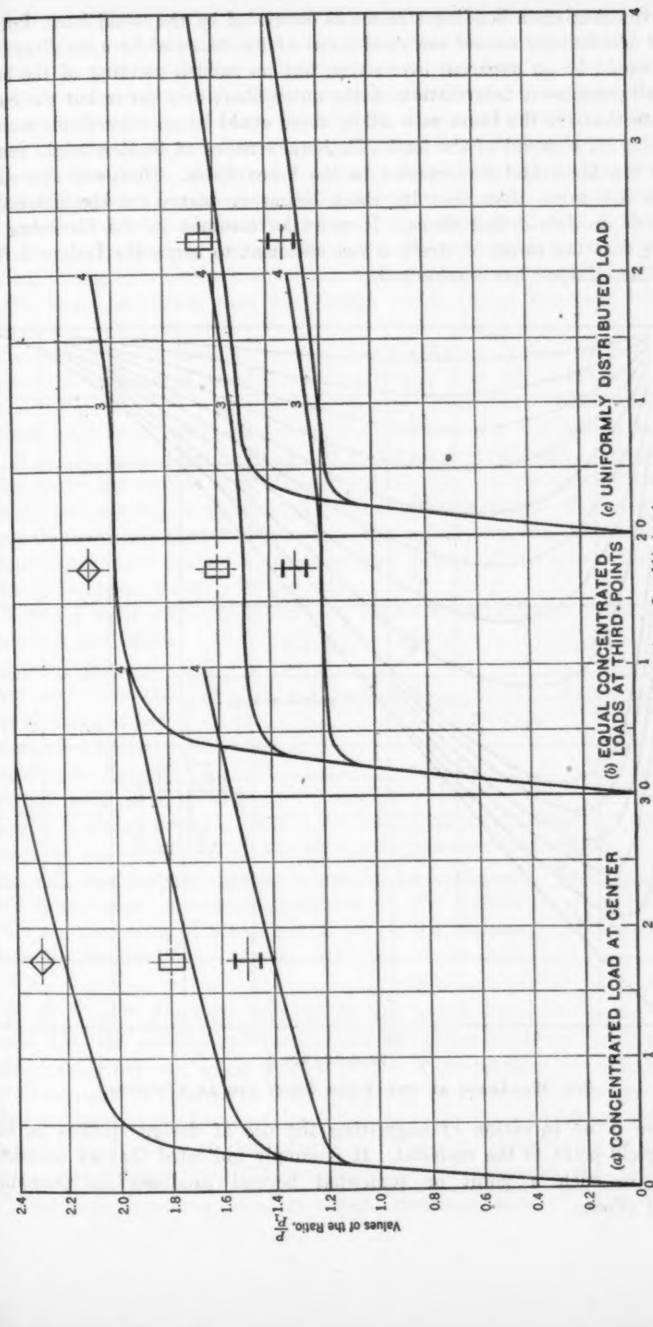

FIG. 48.—LOAD DEFLECTION CURVES (SEE EQUATIONS (24) AND (25)).

If the maximum bending stresses as computed by the usual beam formula should accidentally exceed the yield point of the material by a small amount, there would be an apparent over-stress, but no sudden yielding of the beam. A small permanent deformation of the outer fibers may occur but the curves indicate that for the beam as a whole there could be no appreciable residual deflection on removal of the load. Residual stresses of tension might remain in the top fibers and compression in the lower fibers. However, this condition is not worse than that in which beams or plates are straightened or bent cold in fabricating shops. It must be assumed in the foregoing discussion that the range of stress is not sufficient to cause the fatigue failure, which Mr. Karpov has emphasized.

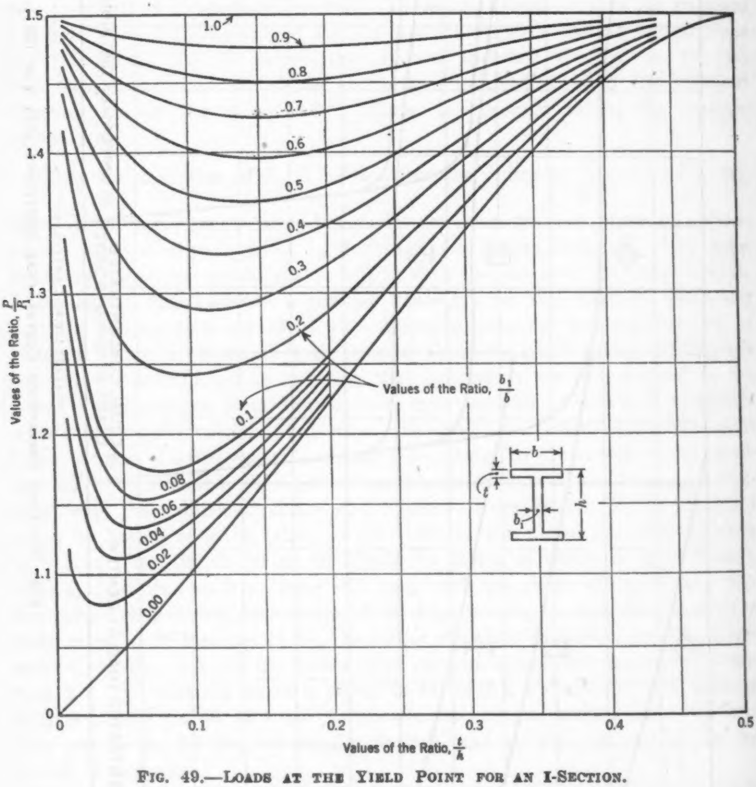

FIG. 49.—LOADS AT THE YIELD POINT FOR AN I-SECTION.

There is no intention of suggesting the use of design stresses as high as the yield point of the material. It is simply indicated that an occasional loading to such a point or somewhat beyond produces no permanent harmful effect.

There is still a question as to the effect of plastic flow or creep whereby long-continued, excessive loading may cause progressive increase in deflection. It appears reasonable to believe that plastic flow of an appreciable magnitude occurs only if the plastic region extends over a considerable part of the cross-section of the beam. Otherwise, the resistance of the elastically stressed portion of the section prevents further deformation.

The yield point in flexure for I-beams varies with the proportions of flanges and webs. The curves of Fig. 49 show the effect of variations in such proportions. It is interesting to note that keeping the flange thickness constant and increasing the web thickness always results in an increased ultimate strength, whereas keeping the web thickness constant and increasing the flange thickness does not always result in an increased ultimate strength.

The foregoing methods for simple beams may be applied to continuous beams with interesting results. For example, for the rectangular beam shown in Fig. 50, P_1 is one of a pair of equal loads which when applied at mid-span will start yield-point stress at a section over the middle support, and P is the corresponding load which will start yield-point stress at a section under the applied load. It is found that the loading may be increased from P_1 to 1.198 P_1, or about 20% without causing plastic stress anywhere except in the small shaded region over the middle support. With a group of four equal loads applied at the one-third points of the spans, the corresponding increase is nearly 50 per cent.

It would seem that any modern or future stress theories which aim at economical and efficient use of materials should recognize the effect of shape of section on the ultimate strength in flexure, and that some parts of a structure may be stressed to the yield point, and even beyond, without impairing its usefulness. Such recognition would tend toward the accomplishment of Mr. Karpov's purpose which is "* * * the designing of structures in which the evaluated and actual safety factors are identical."

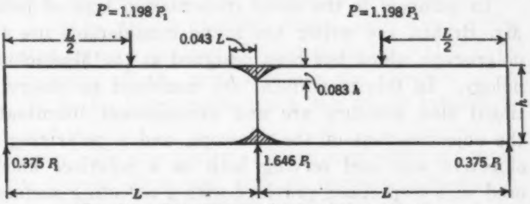

FIG. 50.—CONTINUOUS RECTANGULAR BEAM.

R. W. VOSE,[108] JUN. AM. SOC. C. E. (by letter).—The statement by Mr. Brahtz that "the photo-elastic method is a two-dimensional analysis", must be taken to apply not only to the general nature of the problem, but also to every individual point of interest in the structure to be investigated by the method. It has not been generally appreciated that in many cases which are nominally two-dimensional—such as the bearing of rollers, the distribution of stress in riveted gusset-plates, and the concentrations of stress in the vicinity of

[108] Instructor, Mech. Eng., Mass. Inst. Tech., Cambridge, Mass.

sharp corners—third-dimensional stresses arise in the flat model, due to surface distortions and to methods of load application in the actual model. These stresses inevitably balk the investigator, since they affect his tool—the light ray—in an indeterminate manner, and force him to avoid many localized regions of high stress which may be critical in certain types of design involving repeated stress.

The same limitation is encountered when an attempt is made to analyze the surface stresses in a three-dimensional structure by means of any of the "surface photo-elasticity" methods, of which Mr. Brahtz mentions one. A sheet of any of the photo-elastically active materials may be conveniently examined from one side only, if the other side is provided with a reflecting layer to return the polarized light to the analyzing apparatus. If the reflecting side of this sheet is attached to, or inserted in, a loaded model of any material, the sheet will partake of the strains in the model, and the stresses induced in it may then be determined photo-elastically and used as an indication of the stresses in the model. The method fails in the general case, however, due to the three-dimensional nature of the stresses induced in the surface sheet by the model, and it is found to give accurate results only in regions where the stress is not changing rapidly, in which case strain-gages might equally well be applied. Further limitations in this particular application come from the low stresses induced in the photo-elastic model due to their unusually low moduli of elasticity as compared with engineering materials, and from the present inability of the method to give other than the shearing stress at a point.

In addition to the usual transmission type of polariscope as described by Mr. Brahtz, the writer has found considerable use for a portable reflecting polariscope which has been designed at the Massachusetts Institute of Technology. In this instrument are combined an observing telescope of conventional size, mercury arc and incandescent illuminators projecting through the objective lens of the telescope, and a polarizing unit mounted over the objective lens and serving both as a polarizer and an analyzer. This is used with a specimen provided with a reflecting surface or a separate reflector, as mentioned previously, and owing to its small size may be carried to a model loaded in any suitable testing machine and moved from point to point around a model of any complexity. With its small size goes a correspondingly small field and low illumination, so that the instrument is not suited for projection work and must be used visually over small areas.

The same portable polariscope can be converted from the usual type of differential interferometer to an interferometer of the Fabry type with which the individual principal stresses can be determined. The principle of this interferometer and the equations for the solution of its indications are the same as those of the Mach-Zehnder interferometer which Mr. Brahtz describes, but instead of the expensive reflecting apparatus described by him the two surfaces of the model itself, polished to high reflecting power and parallelism, are substituted. This method promises to be an inexpensive supplement to other photo-elastic methods.

In connection with the determination of the individual principal stresses from the shear stress pattern furnished by the usual differential polariscope, it should be mentioned that each method has its own field of applicability. The point-to-point integration methods of Filon and of Neuber are dependent on having a number of free boundary points, or other points at which the complete stress conditions are accurately known; but on the other hand they are the only methods that can be applied to models which have flowed plastically. Such models are of importance in the fields of mechanical processing and soil mechanics where the possibilities of "photo-plasticity" have only been touched. On the other hand, the lateral extensometer methods, the Mach-Zehnder and Fabry interferometric methods, and the membrane methods all depend upon elasticity in the model.

In reviewing the past applications of photo-elasticity it seems that the field of mechanical engineering has been rather thoroughly covered by the present methods, and the designer in this field now has available sufficient data on stress concentrations and similar effects to enable him to handle, satisfactorily, most questions dealing purely with stress The overshadowing influence of fatigue, surface conditions, vibration, residual stresses, and many other factors, lessens the importance of accurate stress estimation. In contrast, the structural engineer is faced with problems in which stress calculations are of major importance in the design, and here it is that photo-elasticity may find increasing fields of usefulness in its present form.

Raymond H. Hobrock,[109] Esq. (by letter).—Considerable information on the mechanical and physical properties of the aluminum and magnesium alloys is presented in the paper by Messrs. Jeffries, Nagel, and Wood. The authors have wisely indicated quite a number of conditions for which it is best to consult the manufacturer of the metals before the selection of a particular alloy is made. It is the latter point which the writer intends to emphasize.

Civil engineers, in common with a majority of other engineers, are probably most familiar with the ferrous alloys and, through training and association, have become familiar with the interpretation of data on mechanical properties with the ferrous alloys in mind. The familiar mechanical properties for which values are usually given are the modulus of elasticity, the yield stress, the ultimate stress, the percentage elongation, percentage reduction of area, and, more recently, the endurance limit. If the engineer proceeds, by the same testing methods, to gain numerical values for these quantities for an aluminum alloy and for an iron-carbon alloy, the question arises, first, as to the legitimacy of a comparison of such numerical quantities as a basis for the determination of the general useful characteristics of the materials for specific applications. Secondly, one may inquire as to what other information is required for a reasonably complete analysis, providing a comparison of the measured numerical quantities of the mechanical properties are admitted as a legitimate first approximation for an estimation of usefulness.

[109] Director, Research Laboratory, Bundy Tubing Co., Detroit, Mich.

In order to gain some idea of the co-relation between the usual measured mechanical properties and the information which might be required by a civil engineer, it is important first to understand what the quantities determined for the mechanical properties actually measure, and then to examine whether or not the properties so measured are pertinent in the design of a successful structure.

Of the mechanical properties usually measured:

(1) The elongation, the reduction of area, and the contraction measure the capacity to flow; that is, they measure the plastic characteristics;

(2) The elastic limit and the yield stress give values at which the plastic characteristics begin; that is, they give numerical values for forces required for the material to deform or to flow some small amount fixed by general agreement;

(3) The ultimate strength is a specific stress value measured during the course of the plastic deformation; it measures the force required for plastic flow at the point where the flow presents the greatest resistance; and,

(4) The endurance limit is a value for a specific stress which may be applied any number of times in complete reversal without causing failure.

Perhaps the most striking fact about an examination of these mechanical properties is that, with the exception of the endurance limit, they are all associated with the plastic characteristics of the material. Since few structures are designed with the intention of causing the structure to undergo a plastic deformation, some doubt may arise as to the value of such quantities in the design of rigid structures. The value does lie chiefly in that these measured properties define a region that must surely be avoided. The yield stress or the elastic limit stands at the indefinite portal to this region —they reveal that at this point the material "flows a little"—how little is a matter that must be further investigated.

Nevertheless, the engineer has learned to make use of these quantities, and he learned them, perhaps, very largely in association with the ferrous alloys. He may express his doubt of the exact location of the beginning of the region in which the material "flows a little" by being on the safe side and assuming that that stress value is 20% too high; and he usually makes his structure two to ten times as strong as his best calculations (based upon the expected load and the yield stress of the material) indicate that it need be—he uses a safety factor. That safety factor can, and is, properly intended to compensate for more than accidental or uncontemplated excess loadings, or the imperfect state of current knowledge of stress analysis. It attempts to take into account a great many of the characteristics of the material that are unknown to the engineer or that are not quantitatively defined and subject to mathematical treatment.

With this in mind the first question may be expanded and restated as follows: If it is conceded that behavior characteristics are usually taken into account in structures of familiar ferrous alloys by the introduction of safety factors learned through much experience, are all these characteristics

so inter-related in the case of the light structural alloys that the same safety factors might be used as in the ferrous alloys? If not, are there safety factors that will serve such purpose? Or do the light alloys have some characteristics quite different in relative importance from the same characteristics for a ferrous alloy that should receive special consideration in the design of structures?

It may be of value to examine a few of the conditions that are normally imposed upon a structure, or that might reasonably be expected to be imposed upon a structure during the course of its life, and then inquire into what behavioristic characteristics are indicated for determining the relative value of materials in respect to these requirements.

Anticipated Loadings.—Anticipated loadings of both a static and dynamic nature may be approached in the manner described by Mr. Karpov, making use of the best methods of computing stresses and based primarily upon the modulus of elasticity, the yield stress, and the fatigue properties.

Accidental Localized Overloads.—Such an accidental overload may result, for example, from the impact of an automobile or other vehicle upon a structural element of a bridge. Under such conditions it is valuable to know how the material of the structure, and, finally, how the structure itself, will re-act toward the redistribution of stresses. Will the structural element fail readily under an impact load? How sensitive is the structural material to boundary conditions, to stress concentrations, such as rivet holes, surface injuries, corrosion cracks, etc? Will the sudden application of a load cause failure at loads much less than if slowly applied? The answers are dependent upon the capacity of the material to undergo a plastic deformation quickly and, therefore, to redistribute the stresses. Some idea of the relative values of different materials in this respect is to be gained from impact testing, especially at various impact velocities. A more fundamental material property which perhaps serves as a measure of dynamic ductility is the damping capacity, that is, a measure of the capacity of the material to absorb energy.

Much work still needs to be done in the correlation and interpretation of values for damping capacities directly in terms useful to the design engineer. Indeed, the first need is to devise experimental means for measuring the damping capacity as a function of applied stress. At present, values for damping capacity are usually correlated with the maximum stress in the specimen only, except for very small stresses, as in the case of a free bar subjected to small longitudinal vibrations.

Relaxation or Creep.—If a sheet of metal contains a small hole at a distance of at least three times the diameter from the edge of the sheet, and if this sheet is subjected to tension forces, a stress concentration occurs on the circumference of the hole and on an axis of the sheet perpendicular to the direction of tension which is three times as large as the stress in the undisturbed part of the sheet. However, if the hole is filled tightly with a rivet, in such a manner that radial forces are exerted on the circumference of the hole, these stress concentrations may be eliminated. Suppose that a

rivet is properly driven or squeezed in a hole and then exerts the radial force necessary to avoid the stress concentration, the question arises as to how long this condition can be maintained; that is, will the material relax after a certain length of time and relieve the radial forces? If it does, it will result in re-establishment of the stress concentrations. Obviously, information on relaxation and of creep, as well as the results of practical experiments, would be of value in this important case.

Properties at Elevated Temperatures.—These properties are of importance to bridges, buildings, and structures of this type in so far as they aid in predicting the behavior of the structures under unusual conditions as, for example, in the case of a local conflagration in a building. If the strength properties of a structural material decrease rapidly with increase in temperature, it may happen that a purely local fire will endanger the entire structure. It would seem that, because of their relatively low melting points, the aluminum alloys should show a much more rapid decrease in such strength properties with increasing temperature than a ferrous alloy. Furthermore, those aluminum alloys dependent upon precipitation-hardening effects for a goodly portion of their strength, might be expected to decline in strength rapidly at relatively low temperatures. On the other hand, the aluminum alloys possess a great advantage in their high heat conductivity, this being about 4.5 times as great as for low carbon steel at 100° C. It would be of considerable interest, however, to have comparative data on structures of the two materials designed for the same loading and subjected to identical conditions of local heating.

The Course of Destruction of a Structure.—One type of destruction, obviously, is started as a structure is built; that is, the natural deterioration. For a proper consideration of this factor, it is necessary to consider the corrosion properties in relation to the corrosive agents likely to act upon the material of the structure, the fatigue properties, the creep, the influence of the expected atmospheric temperature variations, and, in the case of precipitation-hardened materials, the influence of time itself. Since the acquisition of the highest strength properties in the case of some of the precipitation-hardened materials is a function of time after the solution heat treatment, one might expect that deterioration in properties might also be a function of time. This can be shown to be true in tests at elevated temperatures. From theoretical considerations one might expect a precipitation-hardened material to be thermodynamically more unstable at room temperatures than at elevated temperatures so that the tendency for a decrease in strength properties is greater at room temperatures. However, it is quite certain that the rate of approach to the condition of a thermodynamically lower energy level (and, consequently, to decreased strength properties) is much less at the room temperature. Information regarding strength properties of the light alloys after long times, under stress, and subject to the usual temperature variations of the atmosphere, would do much toward deciding whether or not this is a consideration of any practical importance.

In the event that a structure does fail by overloading, or a part of it fails in fatigue, and that this local failure leads to failure of the entire structure, how will it fail? Will it fail suddenly or will there be some warning, such as an apparent slow deformation of the structure? Obviously, some clue of this is to be gained by comparison of the plastic characteristics of the material—exactly those properties most often measured and listed.

Let no one gain the impression that all this desirable information is available about structural steel and is not available about the light alloys. This is certainly not the case; but engineers have used structural steel for a long time, and there is incorporated in the safety factors which they apply, some estimation of many of these unknown characteristics. The future will undoubtedly see a considerable use of the light alloys for civil engineering, and it has been the writer's intention to indicate that values for the ordinarily measured behavioristic characteristics, coupled with the usual safety factors—or perhaps with any one or two safety factors—will very likely not be sufficient to produce a good design.

At the present state of knowledge and in consideration of the relative unfamiliarity of structural engineers with the light alloys, the advice of Messrs. Jeffries, Nagel, and Wood to "consult the manufacturers" should be strongly emphasized.

William F. Clapp,[110] Esq. (by letter).—The money spent in the effort to solve the various angles of the corrosion problem, with the ultimate object of producing superior metals, is staggering. Enormous numbers of long-time exposure tests are being conducted in many parts of the world under all conceivable conditions. On the other hand it seems that intensive studies of service records either have not been equally stressed, or the results have not been published or made available to the interested student. Therefore, it is to suggest that additional effort be made to analyze carefully the various factors that have resulted in the innumerable examples of exceptionally good and exceedingly poor service records of the various metals. Is it not within reason to anticipate that findings of value, comparable to those obtained from exposure tests, might result from the equally intensive laboratory studies of service records?

Although deeply interested in the various factors connected with the problems of corrosion, the writer's observations have been entirely confined to the study of a limited number of examples of metal deterioration, in which one or more of a large group of marine organisms has been designated as either directly responsible for, or as producing indirectly the conditions favorable for, accelerated corrosion. To read in recent engineering reports that the "marine borers" were responsible for excessive deterioration in certain steel structures in California; and in other reports that probably certain species of *Balanus* accomplished the same results by means of some powerful secretion, is certainly sufficient to arouse one's curiosity. Although the destructive powers of the marine borers should not be under-estimated, it is scarcely fair,

[110] Cons. Biologist, Duxbury, Mass.

when causes are difficult to find, nonchalantly to blame the "bugs." Some effort should be made either to prove or to remove the implication that marine organisms, particularly marine borers, are contributing factors of major importance. To prove them entirely innocent of this particular outrage is not as simple a matter as at first anticipated. Dr. F. N. Speller and others have indicated[111] some very insidious methods by means of which the marine organisms may after all contribute their share to metal corrosion. However, actual proof seems still to be lacking.

An accumulation of records of the biological, chemical, and electrical conditions surrounding outstanding examples of excellent and poor service, together with the analyses of the metal involved, would not be an appalling program of research, particularly when the annual losses due to corrosion, as described and tabulated by Mr. Aston and others, are taken into consideration.

J. C. Hunsaker,[112] Esq. (by letter).—Three stimulating papers on the application of stainless steels, aluminum alloys, and magnesium alloys have been presented by Messrs. Ragsdale, Hartmann, and Winston, respectively. The three papers will be considered together by an engineer faced with the necessity for making a decision as to the materials for his design. He will appreciate Mr. Hartmann's paper best, perhaps, because it gives him practical design data rather than physical properties and generalities which, although significant, may not bear on his specific problems. Obviously, there are other criteria than strength, weight, and cost of the metal involved in structural or mechanical design. The engineer responsible for a decision must be assured of durability and maintenance, procurability in quantity without sacrifice of uniformity, shop and erection tooling and practice, and other factors which bear on over-all safety. There is less information offered concerning the latter factors, as applied to stainless steels and magnesium alloys.

The engineer, for example, may be interested in the possibility of light-weight floors for existing bridges, if the substitution of such a floor will prolong the life of the bridge; but he is loathe to abandon conventional materials. It is possible that such floors could be built of stainless steel with satisfactory weight, life, and durability, but the cost of material and fabrication would be high. Since neither rolled nor extruded sections are available, all beams, stringers, and secondary members must be built up. They could not be welded to the existing structure, in all probability, since torch-welding affects the stainless steel and shot-welding is out of the question on thick members of mild steel. It would be difficult to drill them in the field so that they could be riveted, and riveted-joint design of thin members is uncertain and complicated. Repairs to existing stainless steel structures would appear to be difficult. Moreover, for bridge loads, substantial sheets would be required instead of the light gages used in rail cars and deck houses. These sheets are well-nigh impossible to shear and are difficult to form as they have considerable "spring-back." If bent too sharply there seems to be an effect on

[111] "Corrosion—Causes and Prevention", by F. N. Speller, *Transactions*, A. S. M. E., June, 1935.

[112] Prof. of Mech. Eng., Mass. Inst. Tech., Cambridge, Mass.

the grain structure due to the excessive cold working, with the result that the corners corrode. From these considerations one might conclude that stainless steel, as utilized at present, would not be economical, although its durability and low maintenance costs tend to offset the higher costs of the material itself.

A real virtue of stainless steel lies in the indirect savings it makes possible for low-weight, high-speed means of transportation. The light-weight train operating at 90 miles per hr can do so on lighter rails and bridges than is possible with standard equipment. Duralumin or magnesium can be considered as equal to stainless steel from this point of view, although one may question both from the standpoint of fire hazard, particularly the magnesium alloys. The latter are also questionable from the standpoint of corrosion, especially in climates burdened with salt moisture or chemicals.

From what the writer has observed of the corrosion of duralumin in contact with steel in airplanes, he would question Mr. Hartmann's recommendation that steel rivets and pins be used for connections on structural aluminum. With adequate paint, corrosion can doubtless be prevented, but all one has to do is to look around at bridges these days to see how little paint they get. Such connections are questionable, particularly near the coast where the fogs are salt, or over railways where the blast from a locomotive blows sulfurous gases against the structure.

In buildings, the criterion for stiffness may be the plastered ceiling which has a definite deflection limit if cracks are to be avoided. It is true that aluminum beams can be made deeper so that they will have the required stiffness, and yet be lighter than steel; but when fireproofing is added, the total weight is as great as, or greater than, that of the steel. Little or nothing may be saved in the weight of the building. Magnesium or stainless beams would probably suffer from the same lack of stiffness; the one due to a low value of E, the other due to the use of deep, thin-walled elements carrying high unit stresses.

The engineer needs to know the limits of available standard elements of construction for stainless steel and magnesium. Stainless sheets seem to be limited in width because of the difficulty of rolling a hard metal to a constant thickness. The writer does not know what the limits are for the various gages; he assumes that magnesium is not available in long extruded sections having larger areas. Aluminum alloy was in this condition before 1926. Stainless steel can be formed through rolls so that long sections are available, but they are limited in width. It is difficult to know what can be done with tubes but the structural engineer considers this section an impossible one in any case, since he cannot fasten other members to it conveniently.

In general, the three materials—stainless steel, aluminum, and magnesium—are clearly of great interest both to the structural, and to the mechanical, engineer; but the specific applications will be approached with caution and step by step. It is fortunate that development of the three types of metal is in such competent hands, but it will require both experience and opportunity before engineers are able to proceed with confidence to the special application of each to uses in which it has a real advantage.

HORACE C. KNERR,[113] ESQ. (by letter).—A symposium on light-weight structural design seems incomplete without including that class of material which affords the lightest possible construction, namely, heat-treated alloy steel, in the range of 150 to 200 kips per sq in.

Considered in terms of load-carrying capacity for a given weight of material, metals may be compared on the basis of a strength-weight factor obtained by dividing the design strength value (that is, ultimate strength or yield strength), in kips per square inch, by specific gravity.[114]

Taking representative strength values for magnesium and aluminum alloys, respectively, and comparing them with steel on this basis:

$$\text{Magnesium} = \text{Duralumin} = \text{Alloy Steel} = \text{Strength-Weight Factor}$$

$$\frac{35}{1.8} = \frac{55}{2.8} = \frac{150}{7.8} = 19$$

If the foregoing strength values are taken as ultimate, they are conservative for the metals indicated. If they are regarded as yield values, the factors for magnesium and duralumin are extreme, but that for steel can be exceeded. Steel, therefore, as a material, may equal or exceed in lightness the so-called light alloys.

Steel lends itself admirably to assembly by any of the welding processes—acetylene, electric arc, electric resistance, etc.—whereas the magnesium and aluminum alloys do not.

The autogenous welded joint is more efficient as regards material than the riveted joint and, therefore, it is lighter, thus contributing further to the lightness advantage of steel.

Comparison of the high-grade, heat-treatable alloy steels with the stainless steels, such as Alloy 18:8 (which derive their strength from cold work), shows certain advantages for the less costly material.

Stainless steels can be welded only by a proprietary process without sacrificing strength and corrosion resistance. They can be given high strength (150 kips per sq in., or more) only in the form of thin ribbons or strips and must be formed and fabricated in this hard, springy condition—a difficult feat.

Their necessarily thin structural sections and the relatively low elastic modulus of the material tend to result in flimsiness and excessive deflection under load.

Their costliness is somewhat offset by their corrosion resistance and attractive appearance, and, in some cases, by their non-magnetic character.

Heat-treatable alloy steels, such as chrome-nickel, chrome-vanadium, chrome-molybdenum, and others of moderate cost, can be used as forgings, rolled or pressed shapes, or, desirably, as seamless or welded tubing which possesses outstanding engineering advantages. These steels are easily worked, hot or cold, and some are better adapted to welding than others.

Parts may be heat-treated prior to assembly by means of bolts or rivets; or, units of moderate size, after assembly by welding, provided necessary precau-

[113] Cons. Metallurgical Engr.; Pres., Metlab Co., Philadelphia, Pa.

[114] "Material Selection on Strength-Weight Factors", by H. C. Knerr, *Automotive Industries*, April 19, 1923.

tions are taken to avoid distortion. The weld is strengthened by the heat treatment.

Magnesium, aluminum, and stainless steels have all been brought to their highest point of development in the construction of aircraft. The same is true of heat-treatable alloy steels. These steels, in tubular form, assembled by acetylene welding and then heat-treated, have been used successfully for many years in the most vital parts of aircraft, such as the landing gear, wing beams, and heavily stressed structural members where great strength, toughness, reliability, and resistance to shock and fatigue, combined with lightness, are essential. They are still unequalled by the more recently developed materials for these locations.

The three types of metal discussed in this Symposium are all more or less subject to proprietary interest. Their engineering and industrial applications have been promoted vigorously by their sponsors, chiefly in competition with the ordinary steels of low strength.

The heat-treatable alloy steels of high strength, being common property, have lacked this sponsorship and, consequently, have been rather neglected in the rush of new developments. They offer advantages of great importance in the field of light-weight construction, advantages to which the Engineering Profession may well give careful attention.

F. T. SISCO,[115] ESQ. (by letter).—Such a clear and comprehensive picture of the alloy steels and the light non-ferrous alloys has been presented in this Symposium that it seems impossible to add anything of interest on the properties and applications of these materials. There is one point, however, which was neglected by all the authors, which should be mentioned. That is, the rôle played by the research laboratories in developing these alloys so that the engineer will have readily available, at a reasonable cost, a material with certain distinctive properties or combination of properties. Although the writer will confine his remarks to alloy steel they are, perhaps, equally applicable to the non-ferrous alloys.

The history of alloy steels goes back scarcely fifty years, but in that short time splendid results have been attained and some remarkable materials have been produced. Considering the vastness of the field, it is quite astounding that the research laboratories have produced steels which meet almost every present industrial demand. The vastness of the alloy-steel field may be realized when it is remembered that of the alloys of iron with carbon and the eight common alloying elements about 50 000 000 combinations are possible.

Broadly, there are two kinds of research on alloy steels. It is difficult to give them names. They might be called scientific and practical; or if one wishes to be as cynical as a certain physicist, one might call them planned and "hit-or-miss", or "machine-gun" research. Under the research which the writer has tentatively termed "scientific" or "planned" is included work on constitutional diagrams and its ramifications. There are many outstanding examples of such work by American metallurgists. This type of research

[115] Metallurgist and Editor, Alloys of Iron Research, The Eng. Foundation, New York, N. Y.

has as its object the addition of basic knowledge on alloy systems and may or may not have practical consequences. No metallurgist will deny, however, that it is important that the gaps in basic knowledge be filled as soon as possible, even if nothing practical results.

Practical or "hit-or-miss" research is essentially carried on by using as a base material a commercial carbon steel or cast iron, and adding special alloys, or treating the material in special ways, to note what happens. For many years most of the research on alloy steels was conducted in this manner, and most of the common alloy steels are the result of such work. There is much justification for it, because the effect of combinations of alloying elements can rarely be predicted from the known effects of these alloys when used singly. Much of the research at the present time is a combination of planned and "hit-or-miss" methods.

One of the important essentials in beginning research work on alloy steels, whether it is to fill a gap in basic knowledge or to develop a new low-alloy steel, is for the metallurgist to be sure that he is not repeating work already done by some one else. Despite the fact that only a few hundred, or at most a few thousand, of the 50 000 000 possible combinations of alloys have been investigated, the literature on alloy steels is enormous. Reports of such research are scattered through thousands of journals and books in many languages. Reviewing this literature is time-consuming and, except where large libraries are available, practically impossible. Consequently it has frequently happened in the past that, after a metallurgist had completed his research, he found that similar work had been done previously by some one else.

To avoid such unnecessary duplication of effort "Alloys of Iron Research" was founded in 1929 by The Engineering Foundation. Its object is to review this vast literature, "weed out" the clearly erratic work, correlate and summarize the remainder, call attention to conflicts in data, and recommend research to fill gaps in basic knowledge. The results of this critical review of the world's research are correlated in a series of monographs which give to the metallurgist all the essential known data on alloy steels, thus enabling him to plan his research and development work with no loss of time and effort. They also give to the engineer an unbiased summary of the properties of all the alloy steels known to-day.

What will be the future of alloy steels is any one's guess. It has been said that the world is entering an alloy-steel age. No one knows now how many of the 50 000 000 possible alloy steels will be worthless commercially or at least no better than the ones available to-day. No one knows how many of them will have remarkable properties, so remarkable perhaps that a veritable revolution in construction may occur when they are developed. The most that can be said is that good alloy steels are available to-day (steels which are entirely satisfactory for many commercial applications) but that more research is needed to develop new steels, to improve the properties and reduce the cost of the older ones. That the iron and steel industry recognizes this is plain from the speed with which its laboratories are working, from the rapidly expanding literature reporting the results of research, from its splendid

co-operation in the basic research to fill the gaps in the knowledge of alloy systems, and from the new alloy steels which are made available each year.

J. CHARLES RATHBUN,[116] M. AM. SOC. C. E., AND D. M. MACALPINE,[117] JUN. AM. SOC. C. E. (by letter).—The field of photo-elasticity has been covered by Mr. Brahtz in a most creditable manner. It does not, however, mention the multi-material use of the photo-elastic method. The idea has been suggested before, but the writers know of no attempt being made to use it. This type of model differs in several important respects from those described in the paper. At the College of the City of New York the photo-elasticity equipment is composed of a standard polariscope, with Nicol prisms and a carbon light source. Although this apparatus is equipped with a specially designed hydraulic loading device, it was considered more satisfactory to apply the loads as weights attached to the lower end of the models.

The advantage of this arrangement can be visualized best in the solution of the problem of determining the partition of a load among the rivets in a butt-joint connection. The model for this case consisted of three plates riveted together, the load being applied to the center plate and the reaction being furnished by the two outer plates.

An attempt was made to coat the inner surface of one of the outer plates with a reflecting material, with the intention of obtaining the patterns after the polarized light had passed through the same plate twice. The results were not satisfactory and the idea was abandoned. A mirror was then inserted between the plates to take the place of the reflecting coating. This appears to be unsatisfactory for several reasons, among them being the effect of the mirror on the stress distribution and also the effect of the distortion of the mirror when stress was applied to the model. Tin foil, aluminum foil, and silvered glass were all tried.

Models were then made which consisted of a central plate of marblette and two outer plates of celluloid, the idea being that, since marblette is much more sensitive than celluloid, the error due to the effect of the less sensitive material could be neglected in the first approximation to the solution. This error may possibly be evaluated and allowed for, if it is considered necessary, by using two sets of models alike in every respect except that different materials are used for the outer plates. There would then be two solutions of the same problem, each containing a set of errors. With the properties of the two materials, and the ratio between the errors known, the absolute value of the error might be computed or estimated, and the correction made.

The first model tested consisted of two strips of celluloid, 1 in. wide and 0.1 in. thick, riveted on either side to a strip of marblette 1 in. wide and 0.25 in. thick. Five rivets, 0.25 in. in diameter and spaced at 0.75-in. centers, were used, the rivets being in line. The value of two 0.1-in. plates of celluloid, when multiplied by the value of E (350 000 lb per sq in.) for celluloid, is approximately the same as that of one 0.25-in. plate when multiplied by the value of E (250 000 lb per sq in.) for marblette, so that the model repre-

[116] Assoc. Prof., Civ. Eng., Coll. of the City of New York, New York, N. Y.
[117] Instructor, Coll. of the City of New York, School of Technology, New York, N. Y.

sented three plates of approximately equal thickness riveted together. Furthermore, since the rivets were made of marblette, the plates had an effective thickness equal to the diameters of the rivets.

The problem of using rivets having a snug fit, but at the same time not introducing any initial stress in the sensitive marblette, was solved by using rivets having a loose fit and coating them with liquid marblette; that is, cementing the rivet into place with a very thin coat of marblette.

This design of model was used because both experimental and mathematical checks on the results were available. Although common practice assumes the partition of load as uniform between the rivets, it is easily shown that the outer rivets carry much more load than the inner ones. The partition obtained by the photo-elastic analysis of the multi-material model checked those obtained analytically within less than 2% in all cases and within less than 1% in most cases.

This experience has encouraged the writer to run a series of tests on rivet groups (not in a line) of five and six rivets when the load applied is eccentric to the grouping and also when the eccentricity is zero. That the results differ materially from those obtained using the assumption made in practice when designing the rivet groups, is quite obvious. It is hoped that a series of these investigations will yield very useful data. This same multi-materials method can be applied to the partition of the load among the rivets in the standard connection between beams and columns in building construction.

For the purpose of experimental study, models were made in which the three plates were of the same material. The resulting confused pattern could not be separated into the separate patterns of the inner and outer plates. This same tendency ensued when high loads were used with the multi-materials models. If the loads used were great enough to produce isochromatics and isoclinics in the celluloid, some confusion was found in interpreting the results. When an isoclinic from the celluloid crossed one from the marblette they destroyed each other, producing a light spot and not a dark spot. This confusion was avoided by using stresses so low that the effect on the celluloid was not visible whereas the isoclinics of the marblette were quite definite. A further advantage encountered in the use of low loads on marblette models is the reduction of creep to a negligible amount. The investigations found little evidence of creep under these loading conditions. This multi-material use of the photo-elastic method is worthy of further study.

FRED L. PLUMMER,[118] M. AM. SOC. C. E. (by letter).—The design of any part of a machine or structure, the size of which is determined by the stresses or deformations which may be imposed upon that part, represents a structural problem which deserves the attention of a competent structural engineer. Too many structural engineers think of fixed structures—buildings and bridges—as the only proper field for their activities. The design of the side frame or the truck of a railway car, the structural frame of an airplane or of a bus, and the hull and deck structures of boats are also structural

[118] Cons. Engr.; Associate Prof., Structural Eng., Case School of Applied Science, Cleveland, Ohio.

problems. They sometimes present very difficult design problems which challenge the talents of the best engineers.

Only a few years ago, many structures of this type were built by processes which placed definite limitations on the choice of sizes and shapes of the various parts. As a consequence, much of the analysis and design was reduced to an arbitrary "rule-of-thumb" or "cut-and-try" process. The introduction of high-strength and light-weight metals, together with the use of new fabrication processes, has caused such methods of design to become quite inadequate and has created a wide and comparatively new field of activity for the structural engineer. New problems are involved; however, structural engineers are better trained than any others to analyze and design these mobile structures properly. It will be unfortunate if through neglect the manufacturers of such structures and machines are forced to re-train men who are now trained primarily to design mechanisms and not structures.

The design of any structure involves first an attempt to predict what forces will act upon the completed structure and the conditions under which those forces will be active. It is then necessary to determine as accurately as possible (and the degree of precision is seldom even close to perfect) the stresses and distortions that will probably be created in the structure by the applied forces, whether those forces be applied loads or destructive agencies of entirely different character. Finally, the material must be selected, and the proper quantity and shape of that material must be determined, which will provide most efficiently a safe and useful service life for the projected structure. Included in this final step is the selection and design of proper connections so that the parts of the structure may be assembled and act as a unit. This problem, which is perhaps the most difficult of the group, frequently receives too little study.

High-strength steels and the light-weight alloys are usually selected for use in a given structure because of superior corrosion resistance properties or because the weight of the structure can be decreased by the use of such metals. This Symposium is devoted to a consideration of light-weight structures. Since these metals cost more than the materials now in common use, their selection can only be justified if the resulting structure is safer, if a longer service life can be expected, or if the extra cost can be balanced by lower maintenance and operation costs, or by greater income-producing possibilities.

The papers presented by Messrs. Ragsdale, Hartmann, and Winston have outlined the economical use of such metals in buildings, bridges, and erection equipment; excavating and materials-handling equipment, including cranes, trucks, etc.; in transportation equipment, including trains, buses, airplanes, and airships; on boats; and for a number of other miscellaneous uses.

The structural designer must re-study the fundamentals and not assume blindly that the principles followed in the analysis and design of structures built of materials now in common use must necessarily hold if similar structures are built of these newer metals.

In presenting these papers, the various authors of this Symposium have called attention to such factors as: (1) The non-linear distribution of unit

stresses; (2) the effect of surface conditions on the strength of metal parts; (3) the effect of pulsating stresses "which may result in fatigue failures"; (4) the possible results of a small margin between yield point and ultimate strength, making less probable the relief of stress concentrations by the yielding of some of the over-stressed parts; (5) the difficulties of obtaining satisfactory joints of high-strength materials; (6) the problems created by the heat of welding if that method of fabrication is used; (7) the stress distribution between rivets in joints involving large plates and a great number of rivets; (8) the thin sections which frequently result when high-strength materials are used, give rise to a number of problems (corrosion may have a much greater relative effect; and failure by buckling becomes a greater possibility); and, (9) low moduli of elasticity and thin sections both contributed to greater distortions, more flexibility, and possible serious vibrations.

Not many years ago, few structural engineering organizations included on their staffs men capable of analyzing a highly redundant structure. It was common practice, in so far as possible, to design and construct all structures as simple non-continuous elements. Now, every large design staff includes a number of men trained in the analysis and design of statically indeterminate structures. Engineers are trained to meet and solve new and difficult situations, and they would be false indeed to the traditions of their profession if they were to allow the foregoing difficulties to prevent the use of these new metals. On the other hand, they must not use them without making a most careful study of the probable performance of the resulting structure as well as a thorough investigation of the economic factors involved.

The papers by Messrs. Ragsdale, Hartmann, and Winston contain a wealth of accurate design data. The authors have discussed in detail the proper treatment of many of the difficulties which accompany the use of these metals. Very briefly, they have indicated some of the economic factors that determine whether such metals should or should not be used. Each author might well amplify this part of his paper.

The increased use of these newer metals seems inevitable. Every structural engineer should study for himself the comparative design of at least one structure so that he can more fully appreciate the possibilities that lie in the development of these metals.

C. F. GOODRICH,[119] M. AM. SOC. C. E. (by letter).—All structural engineers who are faced with the problem of designing any large steel structure should read carefully the paper by Mr. Moisseiff because, although it contains no new technical formulas or data, it presents facts which, if studied and followed, will lead to better and more economical designs. There are two points, especially, which might well be more strongly emphasized:

(1) The very rapid development of the high-strength steels in the last decade and the contrastingly slow previous development; and,

(2) The note of caution against the promiscuous use of the various high-strength steels for structures, or for parts of structures, where ordinary standard carbon steels would have been more economical.

[119] Chf. Engr., Am. Bridge Co., Pittsburgh, Pa.

Prior to 1927 there were only two high-strength, low-alloy, structural steels in use: Nickel steel and silicon steel. Since the introduction of the so-called manganese steel used in the Bayonne (N. J.) Arch, high-strength steels of various chemical content and heat treatment have appeared on the market. It took ten or fifteen years for silicon steel to come into such general use that it could be obtained from any rolling-mill or from stock, or could be fabricated in any shop and at a cost only \$10 or \$15 per ton greater than that of medium structural steel. The high-strength steels that have been produced since 1927 are far from standard at present. There is a tendency among many engineers to seize upon one or another of these newer steels, which exhibit desirable physical qualities, and apply them to structures, without much knowledge of their cost, simply because their use results in a lighter structure.

Mr. Moisseiff cautions against the use of high-strength steels in a small percentage of the members of a structure. The designer must realize that quantity is a large factor in the production cost of steel. Three or four members of high-strength steel in a structure, built generally of medium carbon steel, will cost far more per pound than this same steel in a structure built almost entirely of it.

The condition, pointed out by Mr. Moisseiff, which has existed in the last two decades (wherein the engineer is continually demanding a higher grade of steel from the producer) is a very healthy one. The laboratory, the mills, and the shops need this stimulus if the art of steel-making is to advance, but this growth must not be of the mushroom kind. The engineer must determine how his demands affect the producer: Whether they can be met at reasonable cost, or whether they will defeat the purpose for which they were made—economy and ultimate low cost to his client. Interruptions to continuous production, at the mills, of one grade of steel in order to introduce a special grade, cost money and the engineer's client pays for that extra cost. Unfortunately, the client, being a layman, does not always know that, but must depend upon his engineers for proper economy. Even the engineer sometimes makes the mistake of thinking that his case may be a "special one", that the mills will be glad to get his order and so will absorb the extra cost. There is no need to point out that this is false economy, but it happens constantly.

Very short deliveries are now being specified. The standard structural steels lend themselves to these short deliveries far better than the special steels, because they are standard product.

The economical problems placed before the designer and the producer by the introduction of these many new high-strength steels are not simple. Their solution will take time and study even if the demand for stronger and better steel is ever pressing.

G. K. Herzog,[120] Esq. (by letter).—The tremendous increase in the use of the stainless, high-alloy steels for structural purposes should make the paper by Mr. Morris of particular interest to civil engineers who are, perhaps, as

[120] With Electro Metallurgical Co., New York, N. Y.

yet not quite as familiar with their advantages as are mechanical and chemical engineers. For the latter they are the solution of many a heretofore insoluble problem. As Mr. Morris states, the method of manufacture and the production of these steels are in a state of flux and rapid progress is being made. The same is true of the modifications of the compositions of the various types of steel to increase their strength or corrosion resistance, or to improve their fabricating properties. He has briefly touched upon some of these modifications in composition, but has perhaps not emphasized their importance quite enough.

The addition of 2 to 4% molybdenum to the 18–8 (18% chromium and 8% nickel) type of steel not only increases its resistance to corrosion, but also has a marked favorable effect on its creep strength at elevated temperatures. The increased resistance to corrosion is such that in a number of applications for which ordinary or plain 18–8 steels cannot be used, the grade containing molybdenum is entirely satisfactory; that is, the addition of molybdenum so enhances the corrosion-resisting properties of this type of steel that it opens up entirely new fields of application.

The same is true of the use of columbium. The ordinary grade of Alloy 18–8 cannot be used satisfactorily in certain temperature ranges because of the structural changes which this steel undergoes when exposed for any length of time to temperatures within this range. This may result in premature failure of parts operating at these temperatures. The addition of ten times as much columbium as the carbon content stabilizes the steel and entirely prevents these structural changes. This improvement is brought about without in any way impairing any of the desirable physical or chemical properties of the steel.

In discussing the plain chromium, or ferritic type of stainless steel, Mr. Morris mentions briefly the addition of small quantities of nickel, molybdenum, and silicon to improve the physical properties and the corrosion resistance of this type. A very interesting and important development in these steels is the addition of nitrogen to improve their physical properties and workability. In the form of castings or ingots these steels, without nitrogen, possess a coarse grain structure which makes them relatively brittle and difficult to forge, roll, or otherwise hot work. The addition of a quantity of nitrogen equivalent to about 1 part per 120 parts of chromium greatly refines the grain, improves ductility and strength, and makes it much easier to hot work the steels.

Another important new development in the plain chromium steels is the addition of columbium to prevent so-called "air-hardening." When some of these steels are heated above a critical temperature (as, for example, in welding), and are then allowed to cool normally in air, they become brittle. This disadvantage is entirely eliminated by the use of the proper quantity of columbium. Furthermore, these improved properties are obtained without any sacrifice of resistance to corrosion at ordinary or elevated temperatures.

These improvements in physical and chemical properties are perhaps of greatest interest to the chemical and mechanical engineer who must design

equipment to operate at higher temperatures and under more corrosive conditions than are in general encountered by civil engineers. However, the writer believes the latter will be interested in these developments.

JOHN H. MEURSINGE,[121] Assoc. M. Am. Soc. C. E. (by letter).—This Symposium happens to be of unusual interest for the Civil Engineering Profession, because it calls attention to the fact that structural engineering has entered into the third phase of its existence, the period called "neotechnics" by the late Patrick Geddes.

As many civil engineers will not be familiar with the symptoms which accompany this event, it will be necessary to dwell for a moment on the philosophy of that great Scotchman. His ideas have recently been worked over and broadened by Lewis Mumford[122] whose work has furnished most of the information which will be used for this discussion.

Mumford has shown[122] how everything on earth grows or develops according to the same pattern. This phenomenon holds true for Man and beast, for machines, architecture, political science, etc.—and also for structural engineering. The pattern distinguishes three periods that fade out in each other. For human beings one may refer to babyhood, childhood, and manhood or womanhood. For machinery, utilities, etc., Mumford calls these phases: Eotechnics, paleotechnics and neotechnics. In the eotechnic stage, the object is still close to Nature; it is poorly developed, but nevertheless it is at most times still attractive to the eye. In the paleotechnic stage, the object increases its speed (if it has any) and it grows quickly, quite often out of proportion; it becomes ugly. In the neotechnic stage, it becomes more efficient, it improves its appearance, and it adapts itself to its surroundings.

Each phase utilizes its own power and materials. According to Mumford: "The eotechnic phase is a water and wood complex, the paleotechnic phase is a coal and iron complex, and the neotechnic phase is an electricity and alloy complex."

If the structural engineer wishes to use the alloys to their fullest advantage he must understand the characteristics of the "neotechnic" period. As a matter of fact he has already obtained results that suit the demands of the neotechnique. Where in the paleotechnic area the cost of a refined design was often greater than that of the materials that could be saved, in the "neotechnic" area, due to the more expensive alloys, the refined design has become a profitable item. This change has been emphasized by most of the authors of the Symposium. Mr. Karpov states: "More refined designs will involve additional engineering work." In the "Synopsis" of his paper, Mr. Brahtz states: "The more expensive alloys make it imperative to the designer, that he avail himself of every possible means of refined stress analysis"; and Mr. Winston states: "* * * careful attention to small details has been an important factor in the success of these applications." Mumford also has stressed the importance of the same fact:

"The lightness of aluminum is a challenge to the more careful and more accurate designer in such machines [and utilities] as still use iron and steel.

[121] Reinforced Concrete Designer, Gen. Petroleum Co., Vernon, Calif.

[122] "Technics and Civilization", by Lewis Mumford.

The gross over sizing of standard dimensions with an excessive factor of safety based upon a judicious allowance for ignorance, is intolerable in the finer designs of airplanes; and the calculations of the airplane engineer must in the end react back upon the design of bridges, cranes, steel buildings; in fact, such a reaction is already in evidence. Instead of bigness and heaviness being a happy distinction, these qualities are now recognized as handicaps; lightness and compactness are the emergent qualities of the 'neotechnic' area."

The technical philosopher and the structural engineer have reached the same conclusion. The importance of this fact should not be under-estimated, for it proves that they can work together. The structural engineer can profit by this in regard to his future.

What can he expect? To sum up the characteristics of the neotechnic area: It does not call for bigger structures, but for more efficient, better looking, edifices which adapt themselves to their surroundings. Whereas the paleotechnic complex (which, for many structures, is still in existence), called for a centralization of the population, the neotechnic complex tends toward decentralization. Subsequently, modern demands will be for structures the sizes of which are within the present scope. Therefore, it is interesting to note that Messrs. Moisseiff and Hartmann call attention to the limitations of the alloys. Mr. Winston calls for shorter members, at the same time mentioning the high fatigue endurance of this alloy.

This last characteristic means higher efficiency, a typical requirement of the neotechnic phase. This higher efficiency goes also with all the noncorrosive alloys. To quote Mr. Aston: "* * * the tangible depreciation of the cost of abandoning structures is exceeded in a monetary sense by the more intangible effects of designing structures heavier than the requirements of working stresses * * *." Stronger and lighter bridges, earthquake-proof buildings, and better homes will call for the application of the new alloys. The structural engineer and the architect should find the world waiting for the application of these new materials.

The demands for the architect's services should increase as shape (appearance) plays an important rôle in the neotechnic complex. In certain areas where high wind pressures are the rule, stream-lined buildings may have a future. Shape will not be less important for the earthquake-proof structures. A material equally distributed throughout the entire building will keep the earthquake stresses low, not to mention the advantages already obtained by the use of the lighter material.

The average structural engineer should have no difficulties in adapting himself to those first two requirements of the neotechnic phase. The third requirement, adaptation to its surroundings, may cause more difficulties, because this means a better place in present-day society or, better stated, the neotechnic society. Although many people cannot see it, the fact remains that pecuniary differences will disappear. To quote Mumford:

"There is no qualitative difference between a poor man's electric bulb of a given candle power and a rich man's, to indicate their differing pecuniary status in society, although there was an enormous difference between the rush or stinking tallow of the peasant and the wax candles or sperm oil used by the upper classes before the coming of gas or electricity."

The structural engineer should understand that the improvements of the neotechnic phase tend toward a classless society. Those who disagree should not waste their efforts on the design and the application of the new materials, for only a mind freed from all the traditions, prejudices, and superstitions of the present era can expect to be successful in this kind of work. Hence, fiction writers, whose imagination is not kept within certain limits by tradition, cost estimates, or conservative employers, have often been able to encroach into the structural engineer's territory.

In the Nineteenth Century the French writer, Jules Verne, visualized a modern submarine long before any engineer had given thought to it. To-day, history is ready to repeat itself. Writers such as H. G. Wells and others indicate that the structural engineer is lagging behind in imagination and application. Is he going to take up the challenge?

If he wants to, he should prepare himself for a struggle. The structural engineer will have to adapt himself to the new circumstances he has brought forth by his own efforts. Many of them soon will find themselves in "no man's land." On one side neotechnics will call for an elaborate design at a high engineering cost, and on the other side will be the employer who is still firmly submerged in the paleotechnic ideas of the profit system. The last one, no doubt, will insist on keeping the engineering cost down to the lowest possible level. The structural engineer, by the use of a great diplomacy, will have to make the best of it, so that he may continue his services to mankind. To succeed he will have to study his technical heritage.

P. G. Lang, Jr.,[123] M. Am. Soc. C. E. (by letter).—A scholarly and illuminating treatment of this subject, Mr. Moisseiff's paper merits careful study by all whose duties concern the design, construction, or maintenance of steel structures. The statements made therein concerning mass and automotive transportation, long-span bridges, and highway bridges for motor traffic are most appropriate, and are complete in a degree which leaves no margin for elaboration or criticism. The paper epitomizes in concise and logical form the present status and prevailing trends of the structural steel industry, especially in its relation to bridges.

In forecasting tendencies in railroad bridge design, a factor of major importance must necessarily be the anticipated developments in railroad equipment, and the present indications are, and have been for some time, that the average weight of such equipment and the consequent severity of its effect on railroad structures is likely to undergo little if any increase in the near future. The demand for increased speed on railroads, however, is continuous and unabated, and it is impossible to surmise any limit to developments in this field. Increasing speeds are inevitably accompanied by increased vibration in the bridges carrying such traffic, and this, in turn, calls attention to questions of impact and fatigue. Apropos of this phase of the matter, it is worthy of note that Mr. Moisseiff establishes a clear distinction between bridge and building work, on the basis of the primary difference that impact and stress reversal, characteristic of the former, are absent in the latter.

[123] Engr. of Bridges, B. & O. R. R., Baltimore, Md.

Specific research objectives, designed to benefit producer and consumer, alike, may well include enhancement of the corrosive-resistant properties of structural metal. This is of obvious importance from a maintenance standpoint. In an effort to improve the corrosive-resistant quality of steel, some specifications were amended to provide for a copper content of 0.2 per cent.

Considering the fact that present-day, ordinary, carbon steel has been in use for forty years or more, and that its reliability has been well tested in practice, when alloy steels are used some consideration should be given to temperature effects, particularly the effects produced by comparatively low temperatures. Structures are frequently built in locations where temperatures range well below zero Fahrenheit, 40° to 50° below being not uncommon in the United States.

Since steel is a mass production commodity, economy of manufacture, in a major degree, is predicated upon uniformity of requirement on the part of the consumers. Any deviation from established practice is expensive and disruptive, and it is probable that in the steel industry the conflict between scientific and economic justification of new processes is most sharply defined. Each producing unit represents a vast investment, and changes in procedure involve alterations in equipment and accessories which are admitted only when absolutely unavoidable. Thus, the development of appliances and processes tends to stagnate. From the standpoint of the consumer, it is necessary that the material be purchasable at a moderate price, and, if it possesses the qualities that fit it for structural use, there is little incentive to assume the additional cost necessary to procure a steel of improved quality, unless this improvement is so great as to leave no room for doubt of economic justification. It is only natural that any specification which provides for material differing from the standard product should meet with some opposition.

Steel of the quality in common use for structural purposes at this time was specified and manufactured as early as 1889, nearly fifty years ago. During this long period, although there have been occasional demands for quantities of high-strength steel for large and important bridges, the demand which composes the major volume of the steel business, and determines its policies and practices, has been for material to be used in ordinary bridges, of moderate size. The actual need as to material for structural work, at this time, is for an improved quality of steel to be used in structures of this latter character, and the inability to produce material of more desirable characteristics seems more apparent than real.

Until 1926, structural steel for use on the Baltimore and Ohio Railroad was purchased to a minimum specification requirement of 30 kips per sq in. A review of test reports covering the actual properties of about 14 000 tons of steel used in bridges on that railroad, and bought to the specification named, indicated that more than 99% of the tonnage represented possessed an elastic limit of 35 kips per sq in., or more, and the specification was changed accordingly to establish that value as the minimum. This change was followed by prompt and vigorous protest, which subsided as soon as it was

demonstrated that for a long time steel had actually been furnished which met or exceeded the new specification requirement, and that, obviously, no increase of cost was involved.

Within the recent past, welding has achieved recognition—and, for work of certain classes, or work situated in certain localities it has received preference—as an articulative process for metal structures. The stability of structures with such connections is necessarily conditioned upon the strength and homogeneity of the jointure welds, and, in devising procedure and materials to insure this condition, the character of steel work becomes a factor of much greater importance than in the case of a structure with riveted or bolted connections.

For many years no attempt has been made to impose a specification requirement limiting the carbon content of structural steel, and, at present, only a small proportion of the structural steel produced and used is subjected to a formal carbon limitation. With the introduction and extensive adoption of structural welding, this phase of the problem has become accentuated, and research indicates that for steel structures thus connected it is highly desirable that carbon be limited to 0.25% on check analysis. The difficulties of production largely vanish when the pertinent facts are ascertained and considered. Although little attempt has been made to impose a definite limitation on carbon for many years, tests of ordinary steel have included ladle and check analyses of carbon content, and a review of test reports covering a very large tonnage of steel work actually furnished for structures of various kinds, principally railroad bridges, clearly shows that only approximately 1% would have been rejected on the basis of carbon content had the 0.25% maximum been stipulated. Hence, no economic grounds exist for objection to such a requirement.

To-day's apparent tendency in the development of specifications for steel construction is toward precision and exactitude, taking cognizance in the design of every ascertainable element, and reducing to the minimum the factor of safety or, as it is sometimes denominated, the "factor of ignorance." Continued progress in this direction is dependent upon the accumulation of exact knowledge concerning the characteristics of structural steel. With respect to the economic phase in its relation to design, as stated by Mr. Moisseiff, it is necessary to balance carefully, the advantages of reduced cost arising from the adoption of stronger steel and, consequently, lighter sections against possible objectionable flexibility in the structure.

In the case of certain alloy steels the cost increment is unquestionably a factor of considerable importance, requiring economic justification. The prices of nickel and silicon steel exceed that of ordinary carbon steel by about 3 cents and 1 cent per lb, respectively. Furthermore, the use in any structure of a steel differing materially from that readily procurable on the market, or the use of steels of different characteristics in the same structure, should be admitted with caution, in view of complications which are likely to arise incident to repairs or partial replacements in the future.

Apart from those portions of Mr. Moisseiff's paper which relate to abstract physical characteristics of the steel, the discussion concerning the necessity

for considering deflections and buckling of plates develops a topic which it is impossible to emphasize too strongly.

With the growing importance of welding in connection with steel construction, the distribution of stress at joints acquires new importance. Questions of this character have arisen on numerous occasions in connection with riveted work, and their recurrence in connection with welded joints does not constitute a new problem; it merely represents a novel phase of one which has existed since the beginning of steel construction.

In conclusion, it may be remarked, as a matter of actual experience, that it is possible without increased cost to manufacture steel in conformity with Specifications A-7-34 of the American Society for Testing Materials, which form the basis of the Specifications for Steel Railway Bridges of the American Railway Engineering Association. At best, laboratory tests are only approximate indications of quality and behavior. As a final thought, it seems fitting to state that, all other factors being equal, the best structure is that having the greatest mass. This final observation applies to the usual structure, and does not, of course, apply to movable bridges or to bridges of extremely long spans.

W. L. WARNER,[124] ESQ. (by letter).—Because of the fundamental metallurgical welding principles which are stated therein, the paper by Messrs. Bain and Llewellyn is of interest not only to the structural engineer and designer, but also to the welding engineer and metallurgist. From the welding standpoint it is believed that no criticism can be made. However, there are several statements in the paper to which attention should be directed.

In discussing the effect of carbon it is stated (see heading, "Characteristics of Individual Alloying Elements: Carbon") that "long experience indicates that at about 0.20% to 0.25% (with comparatively low content of other elements), a broadly applicable optimum is reached for structural carbon steels." This value of 0.25% carbon is the limit which has been set for alloy steel plate material used at the Watertown Arsenal, at Watertown, Mass., in building welded structures for gun carriages as determined experimentally from welding tests.

In the same discussion, the following statements should be emphasized as of particular interest to those concerned with the fabrication of welded structures:

> "Furthermore, even with a minor content of other elements, carbon exerts a definite influence toward hardenability; only in its presence, and in proportion to its concentration, are other elements able to exert substantial influences toward hardenability. * * * However, where welding is to be utilized, the usual structural steel derives about all the strength that carbon alone can provide without excessively restricting other valuable properties."

The latter statement means simply that higher strength should be obtained by adding alloy elements rather than carbon when a weldable higher tensile steel is desired.

[124] Welding Engr., Watertown Arsenal, Watertown, Mass.

Another point in connection with the composition of weldable structural alloy steels is brought out by the following statement in the paper by Messrs. Bain and Llewellyn (see heading, "Complex Steels: Simultaneous Addition of Several Elements"): "A fortunate circumstance is that the concurrent use of moderate quantities of several elements appears to produce a more favorable combination of properties than would result from a single element in an amount sufficient to produce an equivalent strength increase." At Watertown Arsenal, it has been found, for example, that in welding structural nickel steel plate containing approximately 3½% of nickel, better physical properties are obtained by using a combination of nickel and molybdenum in the electrode than by using even larger percentages of either of these two elements alone.

In the discussion of carbon content of the steels shown in Table 3, the following statement is made: "At the same time wherever welding is not used, or in cases amenable to stress-relief annealing following welding, the higher carbon steels are applicable, and they may possess still higher strength." In this connection, it is desired to inject a word of caution that, even when stress-relief annealing is used, this treatment cannot prevent trouble from cracks due to hardness adjacent to the weld during the period between the time when the welding is done and the moment when the heat is turned on in the annealing furnace. Sometimes, this interval may be as much as ten days or two weeks. Therefore, even if the heat treatment is practiced, a carbon content of more than 0.25% in an alloy steel makes the freedom from cracks an uncertain proposition unless some preheating is done before welding.

ELMER K. TIMBY,[128] ASSOC. M. AM. SOC. C. E. (by letter).—The types of tests which may confront the designer of structures, the test methods and materials which he may use, and the technique necessary for the correct design of the model and interpretation of experimental data are outlined clearly in Mr. Templin's excellent paper. It is the purpose of this discussion to show to what extent models are actually used by the profession in the advancement of structural design methods.

Every useful structure develops a definite stress system under a given load condition. The determination of this stress system is the concern of the designing engineer. A simple structure may be solved by the well known equations of equilibrium; hyperstatic structures require a greater number of equations than can be written from the condition of equilibrium, and the sources usually drawn from are the principle of least work and the theory of consistent elastic distortions. The formation of these equations frequently involves assumptions of important magnitude—assumptions that may be so far in error, if improperly made, as to vitiate completely the results of the solution. The model, on the other hand, automatically solves the problem, avoiding the use of equations and the assumptions on which they are based.

The summaries and illustrations that follow are an attempt to review briefly the results of past work in this field in the hope that those who have not had an intimate connection with the development of this line of attack

[128] Asst. Prof. of Civ. Eng., Princeton Univ., Princeton, N. J.

may have a better conception of the true amount of work done and of the effectiveness of the method. The results presented have been assembled partly by circularizing engineers known to be interested in this work. The response to these inquiries was most gratifying, and it is hoped that the summary represents a typical cross-section of the opinions of the profession. It is pointed out that these examples by no means represent all the work which has been done. Many very important studies have been omitted because of lack of space.

One classification includes those models which have formed the basis of research projects sponsored by technical societies, universities, or industrial organizations for the purpose of promoting the progress of engineering. One of the most outstanding examples of this type of work was the extensive use of models by the Committee on Arch Dam Investigation.

The Stevenson Creek Test Dam, studied by this Committee, might be called a full-sized model. It was constructed at a particularly favorable location along Stevenson Creek, in California, where a deep reservoir having a very small capacity was possible. A large source of water, the flow of which could be controlled, was available up stream. The dam was 60 ft high, 2 ft thick at the top, and thickened along a curve on the down-stream side for the lower half of its height.

This dam was loaded and unloaded repeatedly and many observations were taken in an effort to determine its stress distribution. The results obtained have been published in several volumes by the Engineering Foundation[126]. Many organizations and individuals co-operated in making the tests and the results were of sufficient importance to warrant the Committee to make certain general recommendations helpful in designing, constructing, and testing future arch dams, and in testing existing dams to establish their safety, or to determine the feasibility of increasing the height or making other alterations.

The cost of conducting a test on such a large scale was necessarily very great and for this reason the Committee decided to investigate the same structure by use of a celluloid model. This was done at Princeton University under the direction of George E. Beggs, M. Am. Soc. C. E. The model was made of amber celluloid, placed in a concrete valley and loaded with mercury. The results obtained agreed so well with the tests on the full-sized model that future studies to determine the effect of increasing the height of the dam were completed by use of additional celluloid models at a cost much less than would have been required to raise the concrete dam.

It is interesting to note one point brought out by the model studies. Under certain conditions of loading, a part of the dam deflected up stream against a uniformly varying water load. After the model had demonstrated that this was true, a theory was promptly furnished which would lead to this result. Theory had previously erred in assumptions made; experiment corrected the error, and, consequently, improved the theory.

---

[126] Rept of the Committee on Arch Dam Investigation, Engineering Foundation, Vol. 1, 2, and 3.

The particular usefulness of the tests on the model of the Calderwood Dam[127], together with the tests of the structure itself, was that they emphasized the inadequacy of considering an arch dam as a simple series of arches and indicated definitely that some more complete method of analysis, such as the "trial-load", method is necessary. They further emphasized that in any analysis the character and deformation of the foundation must be considered.

Supporting these observations relative to model studies of dams are the following conclusions which are quoted from a paper by J. L. Savage, M. Am. Soc. C. E., presented at the 1934 Annual Meeting of the Society for the Promotion of Engineering Education[128]:

"The careful testing of accurately constructed model dams furnishes a satisfactory and reliable basis for checking the action and safety of concrete arch, arch-gravity, and gravity type dams as well as a satisfactory means of verifying analytical methods used in designing such structures."

* * * * * * * * *

"Plaster-celite models of maximum sections of arch, arched-gravity, and gravity dams are useful in determining load deflections, general stress conditions, special stress conditions at corners, stresses around galleries, and so forth; but may give misleading stress curves in the foundation material due to the necessity of using rigid boundary conditions."

* * * * * * * * *

"The experimental analysis of dams offers an unusually fertile field for further research and for the instruction of students."

Models also have been extremely useful in the construction of huge dams, as well as of assistance in design. The use of models in connection with the construction of the Bonneville Dam (Oregon) will serve as a timely illustration. Of this project, J. C. Stevens, M. Am. Soc. C. E., has stated[129]:

"Hydraulic models of the Bonneville Dam have saved many times their cost and have substantially accelerated the construction schedule of the project. The experiments have been carried on in an outdoor hydraulic laboratory built especially for the purpose at Government Moorings, in Portland."

In describing a model type of baffle adopted to prevent scour and consisting essentially of blocks staggered in two rows, Mr. Stevens stated[130]:

"It was a surprise to find that the downstream sloping face of the baffle block was very effective in preventing scour, but once the fact was established a theory to account for it was discovered in the phenomena of turbulence and stray currents."

The coffer-dam design and installation were studied thoroughly by models.

The Special Committee of the Society on Concrete and Reinforced Concrete Arches made many model studies in connection with concrete arch bridges, on rigid abutments, on elastic piers, with and without high and low superstructure, and with and without expansion joints. A number of both concrete and celluloid models were used in these tests. The experimental

[129] *Civil Engineering*, October, 1936, p. 674.

[130] *Loc. cit.*, p. 675.

work on the concrete arches was conducted at the University of Illinois under the supervision of W. M. Wilson, M. Am. Soc. C. E.[16] Celluloid model studies of some of the same arches were made at Ohio State University under the direction of Clyde T. Morris, M. Am. Soc. C. E., and at Princeton University, by Professor Beggs[131]. As a result of these and other tests conducted by it, the Committee has made definite recommendations for design practice.

Cases of the use of models to improve theory have been cited by Mr. Templin. It might be well to consider a case in which a model was used to verify a new theoretical approach. The geometric properties of the Williot diagram were used to express moments in terms of angular displacement and thus furnish a sufficient number of equations for the stress analysis of the tower of the Golden Gate Suspension Bridge. This was a large and unusual cellular structure combining set-backs with portal construction above the roadway. Below the roadway cross-bracing connected the two legs of the tower. It was considered desirable to verify the theoretical design by means of an independent study. Professor Beggs constructed a structural model and made strain and deflection measurements at many points. Then he computed the model, using the theory which was being applied in the design in the full-sized tower.

This model was fabricated from stainless steel by shot-welding to a scale of 1 to 56. Tensometers were used to measure strains; deflections were measured with dials; and rotations were measured by the use of mirrors and reflected light. Structurally, the model was a duplicate of the tower as regards area of members, distances to extreme fibers, and moments of inertia. However, the entire comparative theoretical work was based on a calculation of the model. The results of the experiment were in excellent agreement with the results of the theoretical calculations. The model was used in this case to verify a method. There could be no question of lack of similarity since the identical structure was used in each of the two methods. The theoretical method can now be applied with confidence to structures of a similar nature.

In addition to the verification of a particular method this model represented a new type of model construction. Stainless steel is a material of exceptional quality and when fabricated properly, produces a structure in which there is no question as to the rigidity of joints. Some engineers may question the use of welding to represent structures which in practice are assembled by riveting. It is the general practice, however, for designers to consider the gross area and moment of inertia of either riveted or reinforced concrete members during the calculations of resultant forces, and to make allowance for net sections, or cracked sections, only when the point at which the unit stresses are to be evaluated has been reached. For this reason it is thought that the use of welding is entirely justified. Allowance for net sections may be made when interpreting the observed strains. Theoretical deflection calculations are also generally based upon gross sections and, therefore, need no correction when welding is used instead of riveting.

[131] Final Report of the Special Committee on Concrete and Reinforced Concrete Arches, *Transactions*, Am. Soc. C. E. Vol. 100 (1935), p. 1427.

It seems entirely reasonable that the use of gross sections should give results close to the actual even when a structure is assembled with rivets. The rivet holes form such a small part of the structure that their total effect in any case would be slight. Furthermore, the irregularity of stress around a rivet hole argues against too great refinement when considering the over-all action of a structure using theories postulating uniform stress variation.

Another example of the use of models is in connection with suspension bridges. In the final report[132] on the Delaware River Bridge, Leon S. Moisseiff, M. Am. Soc. C. E., presented a treatise on suspension bridge theory. D. B. Steinman, M. Am. Soc. C. E., applied this theory to the Mt. Hope Suspension Bridge, in Rhode Island, and furnished rather complete theoretical calculations for this structure[133]. Since such complete data were available, Professor Beggs selected this structure as the prototype for a model study to determine whether a model of a suspension bridge would yield satisfactory design information.

The results of this study were in excellent agreement with the available theoretical data, and it was evident that a vast amount of information could be obtained from such a model in a relatively short time. Slight but consistent differences between experimental and theoretical values were explained by the fact that the theory assumed the application of uniform suspender loads, as a matter of convenience, whereas the model showed definitely (as was expected) a non-uniform distribution of load[134].

Although the model of the Mt. Hope Suspension Bridge was made and tested purely as a research problem, it did prove so practical that Professor Beggs later undertook preliminary studies of the San Francisco-Oakland Bay Bridge, using models of the type developed in the Mt. Hope studies. The models, three in number, followed preliminary designs of the full-sized structure and were made from the following data furnished by these designs: (1) Principal dimensions of the structure; (2) cross-sectional areas and elastic moduli of cables and suspenders; (3) moments of inertia of the stiffening trusses and the elastic modulus of their material; (4) elastic constants of the towers; (5) magnitudes of the various loads; (6) general proportions of certain parts, such as the tower saddles and cable anchorages; and (7) range of temperature conditions.

Information obtained from the tests included tower deflections, cable deflections (both lateral and vertical), truss deflections (both lateral and vertical), cable stresses, grade changes on the roadway, and lateral and vertical truss moments. Instrument readings were converted directly into values for the prototype by means of properly constructed charts based upon elastic constants, scale factors, and calibration factors. The results[135] were most useful, both from a research and from a design point of view. One of the models con-

[134] "Suspension Bridge Stresses Determined by Model", by George E. Beggs, M. Am. Soc. C. E., Elmer K. Timby, Assoc. M. Am. Soc. C. E., and Blair Birdsall, Jun. Am. Soc. C. E., *Engineering News-Record*, June 9, 1932.

[135] "Tests on Structural Models of Proposed San-Francisco-Oakland Suspension Bridge," by Messrs. Beggs, Davis, and Davis, Univ. of California Press, 1933.

formed very closely to the design finally adopted and was partly dismantled, during the construction of the prototype, and used to plan the sequence for erecting stiffening-truss sections without producing excessive tower deflections, and to determine the order of erecting the floor steel, and the order of placing concrete paving.

The model furnished a means of providing easier, quicker, cheaper, and probably more reliable information than could have been obtained analytically. Early measurements of tower deflection varied 10% or more from those measured on the prototype. The variation, however, was uniform and after the law of variation was established, proper allowance was made and subsequent behavior predicted with satisfactory accuracy. Construction operations were expedited to an extent that made the mechanical analysis more than self-supporting. No accurate costs of this test are available, but it is estimated that it was less than 0.1% of the contract. The tests were made jointly by the engineer and the contractor and were accepted by the engineer as a basis for the approval of the erection program.

Another interesting experiment which led from the Mt. Hope model was the model which was used during the erection of the George Washington Bridge across the Hudson River, at New York City. During the erection of this bridge some of the junior engineers in the field had witnessed a demonstration of the Mt. Hope model. Upon returning to the job, one of them, Mr. A. O. Bergholm, decided that it would be comparatively easy and extremely interesting to construct a model of the partly completed bridge and have a private check for his own use of the erection data furnished by the design office. Accordingly, at his own expense, he began the construction of a model in the basement of the building being occupied as the Field Office. His project was discovered, however, by the Resident Engineer who was so favorably impressed by the possibilities that he authorized the necessary expenditures for constructing the model.

In this model the cable and suspenders were made from piano wire, the dead weights from cloth bags and shot, and the towers and foundation from wood. Dials were utilized to measure saddle motions and a vertical scale was used to determine the position of each panel point. In addition to being used many times, the model saved its cost by solving one particular problem.

Steel for the roadway was delivered to the structure by barge. On one day the steel arriving on the barge was different from that called for on the erection schedule. The question arose as to whether the erection schedule could be altered safely and the erection of the steel which was on the barge permitted. The engineers went to the model, applied an amount of lead shot which corresponded to the steel in question and observed the deflections. The results indicated that the steel could be erected safely at that time and the erection proceeded without delay.

The rapid determination of an erection schedule is always extremely vital to the bridge fabricator. Years may have been spent by the promoters of a project before arriving at a decision to construct, in smoothing out legal difficulties, and in actually undertaking the contract; but, when the fabricator

comes "into the picture", time is at such a premium that the fabricator may be liable to a late penalty of as much as $1 000 per day on a large project. The fabricator, therefore, is anxious to use a reliable means of determining his erection schedule quickly because upon this hinges the sequence of his mill and equipment orders, and the profitable completion of his contract.

The use of models of suspension bridges by bridge companies for the determination of erection data is one of the notable examples of the practical application of models in the field of bridge construction. One company has constructed models of four bridges, in each case for the primary purpose of determining definite erection data for the trusses and roadway. The first such model used by this company was utilized in determining the erection schedule for the reconstruction of the Ambassador Bridge, at Detroit, Mich. This bridge has an 1 850-ft main span and unloaded side spans.

The model was ingeniously designed, of inexpensive material, in such a manner as to be quickly fabricated. Nominal ⅛-in. bead chains, similar to pull-chains for electric lamps, were used for the cable. This was flexible, permitted easy location of the suspenders, and had a weight which gave a practical scale reduction factor. The saddles of the prototype were mounted on rollers during erection and, to simulate this freedom of motion in the model, the tower was replaced with a hinged tension member that could be made vertical by adjustment and comparison with a plumb-bob. Being vertical it exerted no horizontal component, and thus simulated the rollers. For that part of the span with suspenders only hanging from the cables, narrow strips of paper simulated the weight of the suspenders. Pieces of soft iron wire were used to represent the weight of the suspender plus the truss and floor system. One man spent two weeks in designing and erecting the model.

Information obtained from this model consisted of the shape of the cable under unsymmetrical or partial erection loads with particular reference to kinks at cable bands and at the edges of the saddles, vertical deflections of the cable, horizontal movements of the saddles, and the allowable or necessary sequence of closing the joints in the trusses. This information was determined for successive conditions of erection and for various numbers of travelers and the total time required to obtain all this information was one man's time for one week. As a result of the studies, the eight floor-beams at mid-span were suspended from the cable before the travelers left the towers. This pre-loading eliminated excessive cable kinks.

The results obtained from this simple model were entirely satisfactory for field use and were subsequently checked by available and well established, but nevertheless time-consuming, analytic methods. The agreement between experiment and theory was also entirely satisfactory.

The fact that the aforementioned model was practical and economical as well as rapid is best established by noting that the same company has since used three similar models in the determination of erection data.

A model was made for the Triborough Bridge in New York City. The engineer for this bridge had fixed definite limits for the tower deflections. Therefore, it was essential to have material arrive on the job in an order which would insure freedom from delays caused by revision of the erection

schedule, which might be necessary should the adopted plan of erection produce excessive tower deflections. Model studies furnished a theoretically ideal erection schedule and allowable variations therefrom. This schedule was used during the actual erection of the bridge and proved to be entirely satisfactory.

The Triborough Bridge was chosen as a test bridge for the comparison of erection data obtained from a model, from observation of the bridge during erection, and by calculation. Comparisons have been entirely satisfactory for erection purposes and the model has shown itself to be superior to computation even when the erection schedule had been definitely predetermined and, therefore, all trial calculations eliminated.

Since 1928 another bridge company has used two models to determine the dampening effect of various types of storm systems. Any one familiar with suspension bridge erection will know of the complicated nature of these systems on long-span bridges and will be able to appreciate the effectiveness of a model in studying their action. Other models have been made so that spinning equipment could be operated in miniature. The rapid strides made in the art of spinning parallel wire cables is ample proof that the models have been useful. The equipment used and the spinning speed attained during the spinning of the cables for the Golden Gate Bridge mark another milestone in suspension-bridge construction. By the use of triple spinning wheels and double tramways, twenty-four wires were placed with each trip of the wheels as compared with only four wires on the George Washington Bridge, the cables of which were erected only about eight years before. Models have played no small part in this rapid progress. All the models used by the company have either reduced the cost of the construction or the time required for design to such an extent as to be more than self-supporting. As a matter of interest, where records are available, these various model studies cost from 0.05% to a maximum of 2.5% of the cable contract.

Other models have been used by the company to study erection equipment for foot-bridges, cables during the erection of the roadway, and suspended cable-car transportation systems. All materials used have been inexpensive, and the models have been fabricated in an exceedingly practical manner. The erection procedures for the cables of the George Washington Bridge, the "Sky-ride" at the Chicago World's Fair (1933), and the Golden Gate Bridge have all been determined by model studies. These models have proved to be such a great aid in facilitating design and solving erection procedure problems that the company considers them indispensable on any major project.

Models have other uses, however, than those cited by Mr. Templin and in this discussion. Many structures have been designed either as a whole or in part as a result of stress analyses made with models. Probably the most extensively used system of model analysis is the deformeter method[190], which is particularly popular with State Highway, County and City Engineering Departments. The engineers in these departments are frequently charged with the design of relatively large and complicated, continuous, reinforced concrete structures.

---

[190] "Indeterminate Structures Mechanically Analyzed", by George Erle Beggs, M. Am. Soc. C. E., *Proceedings*, Am. Concrete Inst., Vol. 18, 1922.

The deformeter was used to advantage by Arthur G. Hayden, M. Am. Soc. C. E., in developing methods of design for the rigid frame bridge which was perfected by Mr. Hayden for use in grade separations in an extensive parkway system[187]. Six single-span, concrete, rigid-frame bridges of about 60-ft span, and two double-span, concrete, rigid-frame bridges were analyzed by this method. Each span of the double-span bridges was about 42 ft. After the construction program was well under way for this system of bridges, quick analytical methods were developed, which replaced the model studies. The model studies pointed the way to the efficient analytical method, and the accuracy of the method was established by comparison with the mechanical analyses.

The Missouri State Highway Department has made mechanical analyses as a part of its regular design procedure. The deformeter was applied in the Department's design of a self-anchored suspension bridge tower of the Vierendeel type. The tower was about 60 ft high and had all diagonal bracing omitted. This stress analysis was considered by the designing engineer of the State Highway Department to be more reliable than the tedious mathematical analysis. The results were very satisfactory, the cost being 0.1% of the cost of the structure. The latter was reduced by reason of the mechanical analysis to an extent which made the model study more than self-supporting.

The Missouri State Highway Department also used the deformeter in the analysis of a structure which consists of five reinforced concrete open-spandrel arches of 195-ft span with the deck structure continuous over each span. The two end spans were unsymmetrical. The purpose of the mechanical analysis was to show the effect of the deck structure. This deck structure was not considered in the mathematical analysis because the arches were on high piers and it would have been necessary to solve 285 simultaneous equations. The model was constructed of celluloid to represent the full length of the bridge. The scale chosen made the model about 14 ft long. Again, the results were satisfactory, the cost in this case being 0.2% of the cost of the structure, and the model was more than self-supporting.

Citation of other and varied examples of the usefulness of this device could be continued indefinitely.

Because it could be easily fabricated for the purpose, bronze was selected as the material for a model of the Bayonne Arch (Kill van Kull), the longest two-hinged spandrel-braced steel arch bridge in the world[188]. The model was built in 1929 under the direction of the consulting engineer and was used partly to check the results derived from theoretical investigations and partly to determine more specifically the importance of sway-bracing for distributing unsymmetrical loads between the two arch ribs, and the behavior of the portals in transmitting wind stresses. This model falls in a class mentioned by Mr. Templin as being different in some details from the prototype, but nevertheless very useful, and emphasizes the point which he made that models do not need to be exact scale reproductions, nor do they need to satisfy every theo-

[187] "The Rigid Frame Bridge," by Arthur G. Hayden, John Wiley and Sons, 1931.

[188] "Design, Materials and Erection of the Kill van Kull (Bayonne Arch)," by Leon S. Moisseiff, M. Am. Soc. C. E., *Journal*, Franklin Inst., May, 1932.

retical requirement for exact similitude. Built-up sections of the full-sized structure were represented by solid members in the model. It was not possible, therefore, to reduce the area in the required proportion and, at the same time, assure equivalent stiffness against buckling. Areas of all members were reduced in the same ratio. The proportional behavior of the two structures was not affected by the departures from strict similitude. Static loads were applied to the model and the resulting strains and deflections were read with commercial instruments. The results obtained from this study were entirely satisfactory.

Welding, a method of fabrication which is increasing in popularity, has had a distinct effect in revealing and improving poor designs in some fields of construction. The newer designs have often presented difficult stress problems due to the shapes made possible by flame-cutting and the greater thicknesses which can be joined by welding. The safety of these new structures has been determined mainly by one of the following experimental methods: Testing of full-sized structures to destruction; non-destructive tests of full-sized structures in which the overstressed points are detected by the cracking of rosin or the flaking of a lime wash applied to the surface before testing; non-destructive tests in which strain-gage measurements are taken over the surface; and testing miniature models of like or of different material.

Many engineers feel that the use of miniature models in this field is not particularly fruitful. The departure of stress variation from the usually assumed straight-line distribution, the variable ability of ductility to adjust overstress in plates of different thicknesses, the relatively small size of the completed units, the residual stresses caused by the welding, and the new shop technique necessary to make a scalar reproduction, all tend to convince the producer of welded structures that he obtains more reliable information from a full-sized test.

In 1930, H. V. Spurr, M. Am. Soc. C. E., published[139] a method of design for wind bents in which he utilized a direct and rational method of design in contradistinction to the approximate-investigate-re-distribute-re-analyze methods common prior to that time.

As a check upon the Spurr method, a steel model was constructed and tested at the Experiment Station of Ohio State University[140]. The results of this investigation have been published as an authoritative study on the reliability of the Spurr method of design. The conclusions and recommendations are too numerous to mention herein, but the investigation serves as an excellent illustration of the usefulness of model studies in establishing the validity, or in making desirable revisions of practical, and somewhat approximate, design methods, so that they can be used with confidence by the profession. Without doubt this model, and the information obtained therefrom, will have a marked effect on the design of many of the buildings of the future.

The knowledge of wind pressures and velocities at surfaces of exposed structures is necessary to the successful application of any theory for the cal-

[139] "Wind Bracing," by Henry V. Spurr, McGraw-Hill Book Co., 1930.

[140] "Tests and Design of Steel Wind Bents for Tall Buildings," by G. E. Large, Assoc. M. Am. Soc. C. E., Samuel T. Carpenter, Jun. Am. Soc. C. E., and Clyde T. Morris, M. Am. Soc. C. E., Eng. Experiment Station, *Bulletin No. 93*, Ohio State University.

culation of wind stresses in members within the structure. In general, more thought must be given to necessary violation of the laws of similitude when dealing with dynamic or moving loads than when considering a static system. For this reason tests on the airship hangar at Lakehurst, N. J., conducted under the joint sponsorship of the Bureau of Yards and Docks of the U. S. Navy Department, The National Advisory Committee for Aeronautics, and Rensselaer Polytechnic Institute, should be of particular value.

Wind-tunnel tests were made on 1 to 800, 1 to 400, 1 to 200, and 1 to 40-scale models and actual pressure measurements are now (1936) being made on the full-sized hangar itself. The measurements on the full-sized hangar plus those made on the models will serve to provide a more reliable basis than has been available in the past for the evaluation of wind-tunnel tests on small models. The science of fluid dynamics, applied as it is at present, to problems involving all kinds of motion in any medium, owes much of its progress to the results of model studies.

Mention will be made of one type of test which is in the field of the Mechanical Engineer, but which also has a real interest for the Civil Engineer. Most of the monumental dams recently built and now under construction would have been impractical had it not been that equipment was being developed to utilize the hydraulic power which they made available. Elaborate equipment has been perfected for testing new designs of turbine rotors[141]. Models are made to include new features and are tested to determine their ability to resist fatigue stresses. The effective operation of the rotor requires irregularities of shape which make analytical calculations extremely difficult. On the other hand, the unit as a whole must meet continuous operating requirements. Failure of a rotor, revolving at present high speeds, cannot be contemplated—the design must be good. Inexpensive models may be allowed to fail without danger or inconvenience and the designer, in this way, is at liberty to try new and perhaps novel ideas. The publications of men interested in this field have repeatedly pointed out the usefulness of models of this type used in an extremely practical manner to determine fatigue limits of new materials or new designs.

Still another method of model investigation which should not go unmentioned is the method of testing underground structures which has been developed by Philip B. Bucky, Professor of Mining at Columbia University, in New York City. In this method the model is made an exact duplicate of the structure and strained by placing it in a centrifuge which, with the revolutions per minute properly regulated, produces centrifugal forces equivalent to the gravitational forces encountered in a sub-surface structure. The cost of an experimental analysis is small. Safe spans for flat and arched roofs, and the stress distribution within pillars, have been determined successfully in this manner by the combined use of stroboscopic and photo-elastic equipment. The practical application of this method requires a rather complete geological knowledge of the strata in which the proposed structure is to

---

[141] "Fatigue Tests of Model Turbo-Generator Rotors", by R. E. Peterson, *Mechanical Engineering*, March, 1931.

be built, together with a comprehensive and thorough understanding of theory and experimental technique.

Considerable experimental research work has been done by the faculty and graduate students of the universities. The Beggs deformeter, photo-elasticity, and loaded models have all been used extensively and from reports which have been gathered, it would appear that much effort has been wasted because many men have studied the same problem, only to have the results filed away and lost to the profession. These efforts, however, are not entirely wasted. A student will gain an understanding of structural action from working with models which might take years of study to acquire. Models, without doubt, serve a useful purpose when used to supplement class-room instruction. It is regrettable, nevertheless, that more co-ordinated and continued studies cannot be made. That this is possible is demonstrated by the tests which have been conducted on a miniature building frame by various students at Iowa State College under the direction of R. A. Caughey, M. Am. Soc. C. E. This miniature model has been revised and used repeatedly to solve various problems.

Illustrations of successful model studies could continue at great length, but the effort seems unnecessary. Mr. Templin has indicated the possibilities of making experimental studies; this discussion has attempted to show by means of actual illustration that experimental studies are more than possible. They are a much used tool of many present-day designers.

Models, however, are not just built. There are strict requirements of similitude. A real danger exists in that some designers may be led, by reports of startling results obtained with models, to believe that the model is a substitute for analytical ability. Such is definitely not the case. The successful model investigations have been made by engineers skilled in theoretical analysis, capable of designing a model, recognizing its limitations, and interpreting the experimental data. An engineer who has mastered the technique of using models has the ability to construct calculating machines which will assist him to design structures of unprecedented magnitude and importance. Mr. Templin has made a valuable contribution to engineering literature.

In an exceedingly vivid description of the photo-elastic method of determining stress, Mr. Brahtz raises an old point, which attains new importance in the design of the larger present-day structures, when he states that it is not always a simple matter to keep the probable error as low as 10 per cent. The writer is of the opinion that the results are very acceptable in the majority of cases if no greater discrepancies exist.

Engineers have always used a factor of safety. With loading conditions as unknown and variable as they are, this seems essential. However, the factor of safety has cared for three uncertainties: (1) Unknown loading conditions; (2) variability of the material which carries the loads; and (3) approximations in the design method. Human nature, and Nature herself, being what they are, there seems to be little hope of decreasing the factor of safety by reducing therein the requirements of Item (1). Much has been done to eliminate uncertainties in structural materials. and a conse-

quent increase in working stresses has resulted, thus reducing the requirements for Item (2). The "factor of ignorance" (Item (3)), seems to be the most vulnerable point of attack.

Many structures, costing millions of dollars each, have been built recently, and the designers, almost without exception, have been using to advantage the newly perfected methods offered by experimental analyses. In some cases, errors of appreciable magnitude have been discovered in accepted theoretical methods—in particular, those dealing with hyperstatic structures. In almost all cases the experimental results have furnished a confidence which fostered a more efficient design.

The writer doubts whether results are in general within 10% of the actual, even if they may be within a small percentage of that required by the assumed loads. Mr. Brahtz is to be commended for calling attention to the difficulties of technique involved in a reliable mechanical analysis. The photo-elastic method, as a practical tool, is both new and fascinating. As such, it is subject to both incorrect and too frequent use. The results obtained from the polariscope and other auxiliary devices certainly must be judged in the light of all factors, and not merely by the inherent accuracy of the method.

Werner Lehman,[142] Esq. (by letter).—Many phases of applications of aluminum alloys in the field of excavating machinery have been investigated by the writer, in which light weight structures are desirable in long booms, buckets, and other parts that must be counterbalanced and revolved at long radii. A reduction in weight of such parts is easily found to be economical through an increase in output or an increase in reach or working radius of the machines. The selling of such a benefit is often more difficult than the proof of economy.

Engineers are mostly interested in the capacity of a finished product to perform the intended purpose and for that reason the writer agrees with the importance of the questions presented by Messrs. Jeffries, Nagel, and Wood (see heading, "Effect of Cold Working"): (1) Will the new structure possess adequate strength? and (2) will it retain that strength under the anticipated service conditions?

The first question can be well defined by the engineer using the proper proportions for the characteristic of the building material. Structural Aluminum 17ST can be trusted as close to the values given in the data books as steel structures, provided the material is handled correctly in the process of manufacture so that no parts are changed in their characteristic properties by excess heat or local over-stress. With the proper instructions one can rely on the manufacturing department so that no deductions are made for improper handling. The aluminum alloys are not more difficult to handle than high-strength heat-treated steels. To avoid errors, the writer does not advocate any heating of aluminum in manufacturing processes.

[142] Chf. Engr., Bucyrus-Erie Co., South Milwaukee, Wis.

Closely spaced rivets are driven at random to prevent local over-heating. Riveting with hot steel rivets has shown little ill effect on the heat-treated alloy, 17ST, used in long dragline booms. Most holes for bolts and rivets are drilled.

The second question is not so easily answered, because experience is not available over long periods as with steel. On an average, aluminum alloys can be trusted as well as steel. Concerning the structures of excavating machinery with their constant shock, vibrations, rapidly changing loads, and often occurring unforeseen strains, there is not enough knowledge of the long-time fatigue factor. It seems that occasional rest periods have the same healthy effect of aging and normalizing as in steel structures.

The writer agrees with Mr. Hartmann concerning the need for careful study of slenderness in compression members as a composite strut as well as the detail of the sections. Considerable test data are available. His statements concerning savings on long dragline booms agree with the writer's experience. The resistance factor of aluminum to corrosion does not enter into the designs and uses for excavation machinery. Abrasion resistance is more important in the design of buckets for excavators where it may be a deciding factor in the selection of material. The coefficient of expansion and the modulus of elasticity are both unsuitable to combine aluminum with steel in the same section.

Probably the strongest competitor to light weight alloys is the progress in the art of welding of steel and the recently developed weldable steel alloys of great strength and resistance to abrasion. The peculiar shapes of dippers and drag-buckets does not lend itself to extensive economical use of aluminum mainly because the resistance to abrasion and shock is all important and the use of wearing plates defeats the benefit derived from light weight alloys.

When saving of weight is important, any designer of machinery should keep the excellent properties of structural heat-treated aluminum alloys in mind and should weigh their possibilities not only in the detail, but as to their effect on the complete structure.

Otis E. Hovey,[148] M. Am. Soc. C. E. (by letter).—In the Specifications for Steel Railway Bridges of the American Railway Engineering Association, dated August, 1935 (in Part III, "Alloy Steels, Foreword", p. 49, Article 9), it is stated that "no steel should be considered satisfactory for bridge construction if its yield point exceeds 70 per cent of the ultimate strength." In some cases, this rule has been quoted as an authoritative requirement for all structural alloy steels and particularly with reference to the low-alloy steel the chemical and physical properties of which are given by Messrs. Bain and Llewellyn (see heading, "Complex Steels: Simultaneous Addition of Several Elements"). It will be interesting to trace the origin and application of the limiting yield point ratio of 70 per cent.

During an extensive research into the properties of heat-treated carbon-steel eye-bars, in 1914, the late C. G. Emil Larsson, M. Am. Soc. C. E., and

[148] Cons. Engr., New York, N. Y.

the writer studied the results of many tests with respect to physical properties developed and with particular reference to ductility. The suggestion to limit the yield point ratios to 70% of the ultimate tensile strength was made for the purpose of insuring the desired ductility in the finished product. It should be remembered that carbon steel, and not alloy steel, was under investigation at that time. At a later date the same limiting yield point ratio was inserted in the Specifications of the American Railway Engineering Association for alloy steels.

The paper by Messrs. Bain and Llewellyn shows that there are several combinations of low-carbon steel with various alloying elements that produce low-alloy steels which have satisfactory ductile properties, even if their yield points in some cases are greater than 70% of their ultimate tensile strengths.

The writer believes that arbitrary rules limiting the yield point ratio should not be made, but that attention should be given to the ductile properties, the endurance limits, and to the impact properties, in order to be sure that a particular steel will be suitable for bridges and other structures.

Mr. Moisseiff has presented a paper of much interest and great value at a time when many engineers are keenly interested in the development of high-strength steels appropriate for use in heavy and long-span bridges and in other structures in which a stronger steel is needed.

The presentation of this paper brought to mind a matter of some historic interest, since it deals with the evolution of what may be termed low-alloy high-strength steels. As a matter of fact the steel first used in the principal truss members of a long-span bridge was an alloy. This refers to the trussed arches of the first Mississippi River Bridge, at St. Louis, Mo., commonly known as the Eads Bridge. The main members of the arches are hollow cylinders about 18 in. in diameter, in panel lengths, and each section is made up of six steel staves bound together by outside cylindrically formed plates. The material in the staves is a chrome alloy steel.

The contract for the superstructure, erected in place, was signed on February 26, 1870. The celebration of the completion of the bridge occurred on July 4, 1874. During 1870 and 1871 an investigation was made of various steels, which resulted in the choice of the chrome alloy steel. A study of the specifications reveals that the modulus of elasticity was considered to be one of the most important physical properties of the steel. A few quotations are given herewith:

"The modulus of elasticity of the steel in the staves shall not be less than 26 000 000 nor more than 30 000 000 pounds. This variation should be avoided if possible, in which case the lower amount will be preferable. Each bar will be tested by the contractor, and the modulus stamped on it by the inspector. * * *."

"Each tube is to be composed of six staves having, as near as possible, the same modulus of elasticity."

"One specimen bolt from each twenty staves will be made by which to test their limits of elasticity and ultimate strengths in tension."

"The specimen bolts must be able to sustain a tensile strain of 40 000 pounds per square inch, without permanent set, and must have an ultimate strength of 90 000 pounds per square inch of section."

Elsewhere, it is stated that "should some of the sections of a tube when under compression yield more than others, it is obvious that those others would be forced to bear more than their share of the load." Furthermore, "small specimens of the steel were, however, continually tested to destruction to ascertain both the modulus of elasticity and the ultimate strength. The modulus was kept at about 27 000 000 and the ultimate strength at about 120 000 pounds per square inch." The stress-strain line of a full-sized test of a stave was nearly straight up to a compressive unit stress of 50 321 lb per sq in. "In compression almost any degree can be obtained by the addition of chrome. To avoid difficulty, however, in finishing the steel in the lathes, it is only made sufficiently hard to meet the requirements of the specifications." A supplementary contract provided that "the staves composing the tubes shall not be required to stand a compressive strain exceeding 50 000 pounds, or a tensile strain exceeding 40 000 pounds, per square inch of section, without permanent set."

At a time when there is so much interest in the development of alloy steels, particularly adapted to special applications, the writer deems it proper to call attention to the attitude of Captain Eads and his staff, 66 yr ago, toward the use of alloy steel in the first long-span bridge, which now carries live loads far in excess of those for which it was designed. Much additional interesting data may be found in "A History of the St. Louis Bridge", by Professor Calvin Milton Woodward, published in 1881.

R. G. Sturm,[144] Assoc. M. Am. Soc. C. E. (by letter).—In the various papers presented in this Symposium many problems confronting the users of new materials in structures have been presented. Special emphasis should be given to a consideration of the stability problem, several phases of which have been treated in the Symposium. The writer wishes to connote a conception of stability in the more general sense; that is, stability against buckling, stability against vibration, stability against shock, and stability against excessive deformation with time. In connection with this general definition of stability, it is proposed to consider the actual volume of the metal (without relation to weight) that goes to make up a given member of any structure, and the effect of that volume on each of the aforementioned types of stability.

Stability against buckling is influenced not only by the modulus of elasticity of the material, but also by the shape and proportions of the cross-section of the member. The member must be strong enough not only to carry its load as a whole, but each component part must also be able to carry its share of the load without local buckling. Since the stress at which local buckling occurs varies as the square of the thickness, it is possible that the thickness of the material may influence the stability more than the modulus of elasticity. Structural members often fail by twisting, in which case the torsional rigidity of the member plays an important part in its stability.

[144] Research Engr. Physicist, Aluminum Co. of America, New Kensington, Pa.

The torsional rigidity of thin open members varies as the cube of the thickness of the material. It may be concluded from these considerations that in some cases the actual volume of the member might have a greater effect than the modulus of elasticity.

Stability against vibration is achieved by two means: First, the natural frequency of vibration may be made so high that resonance or near resonance will not occur in practice; and, second, if resonance is approached, the damping effect of the system may be made great enough to prevent excessive amplitudes of vibration. The frequency of vibration of any member is greatly increased by the rigidity of its end connections, and the rigidity of a connection is influenced greatly by the torsional rigidity of the members framing into the joint. Therefore, in this case also, the actual thickness or the volume of the material is an important factor in stability against vibration.

In general, the natural frequency of vibration of a given structure may be fairly well approximated by the equation:

$$\text{Frequency} = \frac{3.13}{\sqrt{\text{Static deflection}}} \quad \ldots\ldots\ldots\ldots\ldots (26)$$

One finds that the weight and modulus included with the design control the static deflection of the structure under its own weight and, hence, its natural frequency. Resonance between applied impulses and the natural frequency of a structure is one of the greatest factors causing dynamic effects of high-speed traffic on large bridges.

Stability against shock is a difficult quantity to measure. Elastic resistance to shock is greatly increased by lowering the natural frequency of vibration, which is just the opposite of the condition sought for to provide stability against vibration. Therefore, a balance between these two conditions must be sought. In general, it is desirable to have members that will withstand emergency shocks without complete fracture even if they do take a permanent set. Very thin sections generally tend to tear or buckle, whereas heavier sections can deform plastically and take considerable permanent set without a complete fracture Therefore, the stability against shock will be influenced greatly by the volume of the material in the member as well as by other factors. Another factor very significant in resisting shock is the ductility of the material considered. Ductility is intended herein to connote the capacity of the material to become elongated over relatively long lengths rather than to "neck down" at a local point.

The stability against excessive deformation with time requires a balance between the beneficial effects and the deleterious effects of creep. High concentrated stresses are unavoidable at some localities in structures. If, by virtue of a slight amount of creep, the metal can adjust itself, these concentrated stresses are distributed, and the danger of failure at that point is greatly reduced. If the material at the point of concentrated stresses is not thick enough to permit such a redistribution of stress, minute buckling or tearing through local instability may occur before creep has an opportunity to take place. In such event, the actual volume of the material at the point of

highly stressed concentration is of a great significance. In general, over-all deformation of structural members under stress can be controlled by a proper choice of design stresses for the material considered, whereas the local deformations around joints cannot be so controlled.

Many of the foregoing factors have been considered in the Symposium but is seems well to emphasize the fact that the general stability of a structure may be influenced greatly by the thickness of the material in the members of the structure and that with materials of low specific gravity it is possible to obtain a lighter dead weight and still maintain adequate thickness to provide stability.

E. Robert deLuccia,[145] Esq. (by letter).—In the popular mind structural aluminum alloy is known only as duralumin, the material from which is fabricated the framework of large rigid airships, such as the *Akron* and the *Macon*; and even in the average engineering mind the thought of using structural aluminum is associated with such special structures as airships and airplanes. In his excellent paper, Mr. Hartmann indicates other uses for this material. He states that but little difference exists in the methods of shop fabrication between aluminum and other structural metals. However, he does state that the workmanship should be of a high quality. It is doubtful whether the average practice for structural steel, say, would be at all suitable for aluminum alloys. The difference does not lie so much in the use of the proper tools but in the care that the shop personnel is willing to exercise in the fabrication of the structure. This does not belong so much in the category of workmanship as it does in the proper appreciation of a new and useful material and in the will to assist the designer to the fullest in his attempt to produce a fine, closely designed structure. Certain lapses, which occur even in the best shops, such as occasional rough handling and nicking of material, over-driving and over-heating of rivets, accidental bending of plates and shapes, and consequent straightening, although possibly tolerated without danger to structural steel, would probably damage aluminum material and, therefore, should not be allowed. The rejection of even a small quantity of aluminum material rapidly mounts into a considerable sum of money and, therefore, it is important to the fabricator that he understand clearly the requirements necessary for successful fabrication in this metal. It would appear to be better to stress the proper fabrication of aluminum as such than to compare it to some other material, such as steel. Of course, steel has been used so long as the standard structural metal that it is a temptation to point out the similarity of other metals to its advantages. Nevertheless, it seems important to think in aluminum while working with it, if satisfactory results are to be obtained.

Although the thought of treating aluminum as a sovereign metal is important to the fabricator, it is of the utmost importance to the designer. Mr. Hartmann indicates this somewhat, but it should be emphasized that, due to properties which are peculiarly its own, aluminum should be considered as a quite different material, the various properties of which are subject to

[145] Chf. Designing Engr., U. S. Engr. Office, Huntington, W. Va.

successful exploitation in design only when they are thoroughly understood and appreciated. As an illustration, there is the relatively low modulus of elasticity of aluminum which produces deflections that generally would be considered excessive in structural steel. The first thought of the designer, newly introduced to aluminum, is to deepen or thicken the member under consideration in an attempt to reduce the deflection. Such a procedure, of course, subtracts from the property which probably had most to do with the selection of the aluminum, namely, its relatively light weight. The designer, therefore, should understand, and expect fully, that relatively excessive deflection will occur and he should be willing to face this fact squarely, accepting it as proper and usual, and designing his structure accordingly.

A short description of the dam across the Ohio River 9 miles below Gallipolis, Ohio, is given to demonstrate the type of problems that can arise in connection with the design of an up-stream emergency bulkhead for the roller-gates, and their satisfactory solution by the use of a light-weight alloy. The dam consists principally of nine concrete piers (16 ft wide and about 135 ft high) eight gate-hoists, eight steel roller-gates (each with a clear opening of 125.5 ft and a damming height of 29.5 ft) and a concrete sill upon which the roller-gates are seated. The pool above the dam is maintained during increasing flows in the river by raising the gates. In times of flood, the gates are raised completely above the water; as the flow decreases, they are lowered. In the event that a gate is prevented from being lowered due to some accident, the pool is saved by lowering a bulkhead in specially constructed recesses in the piers up stream from the gates. The bulkhead is also used for unwatering the gates for routine inspection, painting, and repairing.

The studies for the design of the dam indicated that the aforementioned size of roller-gates, although unprecedented, would be the most feasible. It was realized, however, that the relatively long span and high head would require a special solution for the up-stream emergency bulkhead. The problem was further complicated by the fact that the bulkhead would have to be capable of being placed across an opening with the gate raised and passing water through the full 125.5-ft width, under a head of more than 20 ft.

A further consideration in the design of the bulkhead was the method of handling it. It was desired to place it by the use of a whirler derrick-boat. In order that this could be done without endangering the boat, it was necessary that its boom be of sufficient length to enable the boat to lay against an undamaged gate while placing the bulkhead across the opening of the damaged gate. This would result in a boom more than 125 ft long, with the load being lifted at a radius of about 117 ft. It will be readily seen, therefore, that the weight of the bulkhead was a prime consideration.

Various designs for the bulkhead fabricated from structural steel, alloy steel, or structural aluminum alloy were considered. It was found that the structure fabricated from an aluminum alloy would be by far the lightest in weight and, therefore, this material was selected. To facilitate handling, the bulkhead was separated into seven units of equal size and weight. The

weights of the bulkhead, fabricated from the various materials considered, are as follows:

Material	Weight, in Tons Each unit	Weight, in Tons Total bulkhead
Structural steel	78	546
Alloy steel	44	308
Structural aluminum alloy	28	196

As constructed the bulkhead has a total damming height of 30.33 ft, each unit having a damming height of 4.33 ft. Fig. 51 (submitted through the courtesy of the Huntington District, U. S. Engineer Office, Huntington, W. Va.) shows the seven units as stored temporarily. These units are built from two, simple trusses of the Pratt type, which are held apart by channel and angle struts between the chord members. On the inside of the lower chord and extending between the two trusses is a $\frac{3}{8}$-in. skin-plate which serves to make the unit water-tight. Each truss is 127.5 ft long and 12.5 ft deep (measured between working centers). On the outsides of the lower chord of

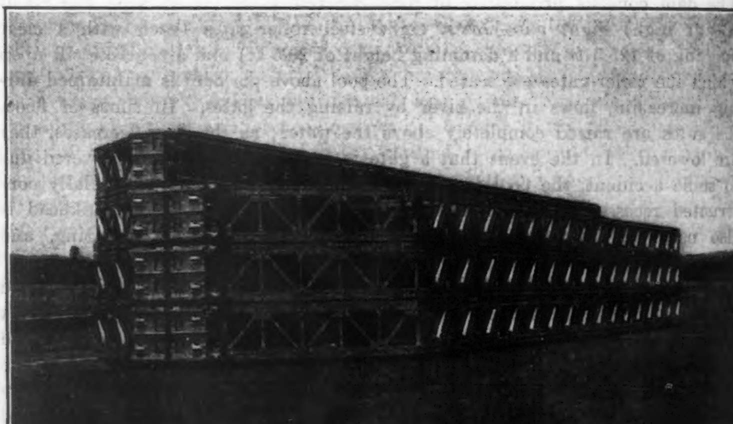

FIG. 51.—SEVEN UNITS, AS TEMPORARILY STORED, OF GALLIPOLIS DAM, OHIO RIVER.

each truss are 4 by 4-in. oak timbers, running the full length of the unit, which effect a seal between the units, and between the lowest unit and the sill, when placed in the dam. Timbers are also provided at the panel points of the top chords to serve as buffer-blocks between the units. On each end of each unit is a housing containing a roller nest which, in turn, contains two rollers $18\frac{1}{2}$ in. in diameter which bear on a steel plate embedded in the down-stream face of the recesses in the piers. The rollers are placed on the down-stream side of the unit and the roller nest is arranged to swivel about trunnion pins so that as the trusses deflect the rollers remain in full contact with the plate in the recess.

Guide rollers are provided on the ends and up-stream side of the housing to prevent binding in the recess in the event that the unit tips in raising or lowering. A specially designed pick-up beam, from which hooks are suspended to engage pins at approximately the third points of each unit, is used to pick up the units.

The truss is fabricated from Aluminum Alloy 27 S-T (see Table 7, Item No. 10) with the exception of the bent hip plates and the rivets which are of structural grade steel. The aluminum alloy has the following chemical composition: Aluminum (minimum) 92%; copper, 3.9% to 4.9%; manganese, 0.5% to 1.1%; silicon, 0.5% to 1.1%; tin, 0.03% to 0.07%; iron (maximum), 0.9%; magnesium (maximum) 0.03%; and, other elements (maximum), 0.03 per cent. It is used structurally in the heat-treated condition and has the following physical characteristics: Ultimate tensile strength, 58 kips per sq in.; yield strength (permanent set of 0.2% of the initial gage length), 45 kips per sq in.; and, elongation in 2 in. (minimum), 8 per cent.

The following are the maximum stresses, in pounds per square inch, allowed in the design of the Gallipolis bulkhead:

(1) Tension, on net section = 22 000; (2) compression, axial loads, on gross section for $\frac{a\,L}{k}$ less than 67, $= 22\,000 - 219\,\frac{a\,L}{k}$; $\frac{a\,L}{k}$ more than 67, $= 33\,000\,000\left(\frac{k}{a\,L}\right)^2$; and, for truss members, the riveted connections, $a = 0.75$; (3) compression in beam and girder flanges $= 20\,000 - 230\,\frac{L}{b'}$; (4) maximum shear on gross area = 10 000; and, on net area = 13 000, limited always, however, by the formula:

$$s = 12\,000\,000\ t^2\left(\frac{1}{d^2}+\frac{1}{l^2}\right)\qquad(27)$$

in which d = clear depth of web, in inches; and l = clear stiffener spacing, in inches; and (5) bearing = 26 000. In Items (1) to (3) L = unsupported length of flange, in inches; $b' = b\left(c+\frac{t}{d}\right)$; b = width of compression flange, in inches; t = web thickness, in inches; d = over-all depth of beam or girder, in inches; $c = 1.0$ for symmetrical members, with web and flange rolled or extruded integrally; $c = 0.7$ for symmetrical members with cover-plate, flanges and web not integral; $c = 0.5$ for symmetrical members with no cover-plate, flanges and web not integral; and, the value of $\frac{L}{b'}$ was kept less than 40.

The top chord of each truss consists of four 6 by 4 by $\frac{9}{16}$-in. angles, one 16 by $\frac{3}{4}$-in. web-plate, and one $8\frac{3}{4}$ by $\frac{5}{8}$-in. cover-plate arranged in the form of an I-section. The cover-plate extends over the four center panels only. The web-plate is cut at the gussets for the diagonals and milled for bear-

ing. The angles are continuous over the gussets. The bottom chord is similar to the top chord, except that the web-plates are not milled at the gussets. Splice-plates are used on the web-plates to transmit the tension in the web across the gussets and are carried a sufficient distance beyond the gusset to take care of the negative moment resulting from the water load on the skin-plate. The diagonals are all rolled or extruded shapes, and range in size from two 8-in. channels weighing 5.78 lb per lin ft to two $3\frac{1}{2}$ by $2\frac{1}{2}$ by $\frac{5}{16}$-in. angles. The verticals range from two 10-in. car channels, weighing 9.59 lb per lin ft, to two $3\frac{1}{2}$ by $2\frac{1}{2}$ by $\frac{5}{16}$-in. angles. In three cases, the verticals are built-up sections of four 4 by 3 by $\frac{1}{2}$-in. angles, with spreader plates, $6\frac{1}{2}$ by $\frac{3}{4}$ by 8 in. long; four 3 by 3 by $\frac{3}{8}$-in. angles, with spreader plates, $9\frac{1}{2}$ by $\frac{3}{4}$ by 10 in. long; and four 3 by 3 by $\frac{3}{8}$-in. angles, with spreader plates $6\frac{1}{2}$ by $\frac{3}{4}$ by 7 in. long. Drain holes are provided in the webs of both top and bottom chords so that they will drain as the units are lifted clear of the water. The bent hip-plate between the inclined end post and the top chord is of structural steel. This substitution of steel for the aluminum was made in order to avoid bending the latter. A camber of 4 in. which is approximately one-half the total calculated deflection, was provided in each truss. The remaining deflection is cared for by allowing the ends of the truss to rotate freely about trunnion pins on the ends of the nest castings containing the bearing rollers. The trunnion pins are received by bronze-bushed, cast, nickel-steel bearings bolted to the end gusset-plates of the truss with turned steel bolts.

The roller-nest casting is of special steel having an ultimate tensile strength of 100 kips per sq in., a minimum yield point of 60 kips per sq in., and an elongation of 20% in 2 in. After the castings were made they were thoroughly annealed to remove any strains incident to casting. Due to the limited space available for this nest, it was necessary to use relatively high-strength material and, therefore, cast steel was substituted for aluminum. The trunnion pins about which the trusses rotate were cast integral with the roller nest and chromium plated as a precaution against corrosion and to minimize friction.

The bearing rollers $18\frac{1}{4}$ in. in diameter are of cast nickel steel and are bushed in manganese bronze for the nickel-steel pins about which they rotate. Nickel steel was used in lieu of aluminum not only because a stronger material was necessary, but also due to the fact that the relatively small diameter of the rollers and the heavy bearing load made the use of aluminum unsuitable in this instance. The guide-rollers are of cold rolled steel. Their weight is so small relative to the total weight of the unit that it was felt that in this case the more expensive aluminum would not be justified.

Nickel-steel plates are used at the pick-up points due to the higher bearing value of this material. The pick-up pins are also of nickel steel and are adjusted in the units by means of nickel-steel adjusting screws. The seals are of white oak. Wood was chosen for this use due to its easy replacement, shock protection, and capacity to swell under water and so assist in making the seal.

All rivets are of steel and are, in general, $\frac{7}{8}$ in. in diameter. Steel rivets were used because it was felt that aluminum rivets would be impracticable, due to the special heating equipment and close temperature control necessary for their successful use. Where possible all rivets were cold-driven. From examination of both hot and cold-driven steel rivets in aluminum, it appears that less local deformation of the riveted material accrues with the use of the latter method. It is necessary, however, that some provision be made to avoid the use of excessive pressures while cold squeezing. All rivet holes were subpunched $\frac{1}{16}$ in. smaller and reamed $\frac{1}{16}$ in. larger than the nominal size of the rivet.

After the units were fabricated, the aluminum was thoroughly cleaned with a chemical cleaner and rinsed off with clean water. A red iron-oxide primer was then applied. After the primer had dried thoroughly, two coats of aluminum paint were applied. The steel was painted with red lead and two coats of aluminum.

The approximate weights, in kips, of the various materials in one bulkhead unit are as follows:

Structural Aluminum Alloy No. 27 S-T	37.9
Structural steel, including rivets	7.3
Structural nickel steel	0.5
Cast nickel steel	3.8
Cast steel (special)	1.9
Miscellaneous bolts, pins, bushings, etc	2.1
Timber	2.5
Total	56.0

The make-up of the sections of the top and bottom chords and of the diagonals is considerably different from the forms that would have been adopted had steel been used. Large aluminum alloy shapes are not available, ordinarily, due to the lack of rolling equipment. They can be obtained by using steel passes but only at a sacrifice in strength of about 10 per cent. The largest shape that can be extruded is one that can be contained in a circle 12 in. in diameter, due to the limitations of the size of the ingot. Shapes made by the extrusion process or by rolls made specially for rolling aluminum suffer no reductions in strength. Therefore, only shapes that could be contained in a circle 12 in. or less in diameter were used. The relatively high base cost of this material made it economical to allow considerably more fabrication per pound than is ordinarily the case for steel. For this reason, even small sections were built up instead of using a single shape of somewhat greater weight. If fabricated from structural steel, the chords would probably be made up of two channels, a fill-plate, and a cover-plate. The design adopted, however, while increasing fabrication utilized the minimum possible weight of material.

The deflection of the unit is calculated to be approximately 8 in., which is about three times the deflection which would be expected for steel. However, by cambering the trusses 4 in. and by using a swiveled roller nest in

the housings at the supports, it was possible to accept the apparently high deflection. As might be expected, secondary stresses of considerable magnitude occur in the trusses when they are under load, and consideration was given them in the design.

O. J. HORGER,[146] Esq. (by letter).—Those responsible for the non-failure of materials in their application to structural and machine parts find greater need to-day for an intelligent use of stress theories. For this reason Mr. Karpov's paper, reviewing the knowledge available, is of considerable interest.

It is not clear from observation of Fig. 3(*a*) for the un-notched tension specimen why the stress is not uniformly distributed for values within the yield point[147]. The same question applies to Fig. 9 for the case of a rectangular bar subjected to bending where the bending stress within the yield point should be linear.

The fatigue diagrams presented in Fig. 10 are apparently based on plain specimens; that is, without stress concentration. It would be interesting to see comparable diagrams on the basis of notched specimens. Such diagrams would be the ones actually required in most design problems since failure usually occurs in members due to local stress concentration, such as fillets, holes, etc.

Fig. 10(*b*) indicates that the lighter metal has a strength about equal to nickel steel on a weight-strength basis. When the lighter alloy is used the section dimensions must be increased over the steel so that a size effect is also involved in the calculation of comparable fatigue strength. This factor of size effect may be small, considering plain specimens, but with stress concentration it is important and must be considered. The writer is familiar with size-effect factors using steels as given in published literature, and would like to ask whether the author can give similar data on the light alloys?

Considering the effect of the aforementioned factors of stress concentration and size effect does the author believe that these considerations would alter the relative comparison shown in the diagrams of Fig. 10(*a*) and Fig. 10(*b*)?

A. W. DEMMLER,[148] Esq. (by letter).—Attention has been called by Mr. Beard to U. S. Navy Specification No. 48 S 5e covering manganese-vanadium steel in connection with steels suitable for fusion welding. The 0.18% carbon, 1.45% manganese, and 0.25% silicon, listed in this specification, are maximum values. The presence of vanadium in this combination results in distinct grain refinement with uniformity and also serves to insure toughness and freedom from sensitive hardenability.

Mr. Bain has also mentioned these features and, in discussing orally the cumulative effect of various alloy additions, made the true and interesting

---

[146] Research Engr., The Timken Roller Bearing Co., Canton, Ohio.

[147] "Photo-Elasticity", by Coker and Filon, 1931, Cambridge Univ. Press, England; also, "Theory of Elasticity", by S. Timoshenko, 1934, McGraw-Hill Book Co., New York, N. Y.

[148] Metallurgical Engr., Vanadium Corp. of America, Bridgeville, Pa.

point that simple arithmetic does not give the full picture in that "two plus two plus two may equal seven" in the behavior of the final product. In the absence of vanadium, 1.45% manganese would be frowned upon for fusion welding; yet with 0.10% to 0.12% vanadium a piece of 0.5-in. plate water-quenched from 2 400° F, and machined free of any decarburization, will have a Brinell hardness number of only 400, while air-hardening from this temperature will give a Brinell hardness number of about 250. Therefore, any danger of encountering a glass-hard condition from a welding operation is out of the question.

THEODORE BELZNER,[149] AFFILIATE, AM. SOC. C. E. (by letter).—So carefully has Mr. Templin covered the methods of operation, and the precautions, required in the manipulation of the various types of strain-gages for precise work on engineering structures and their models, that little can be added. Possibly a few references could be made to the measurements required after the preliminary work.

The skill required to obtain reliable results in strain-gage measurements is not in the possession of all; and the writer agrees with Mr. Templin, that,

"In the testing of structures, the errors arising from the personal equations involved in the manipulation of the instruments used, must be considered, in addition to those already mentioned. The magnitude of these errors becomes less, at a diminishing rate, as the experience of the observer increases."

During 1913 and 1914, a comprehensive series of extensometer investigations was made in connection with the strengthening of the end spans of the Williamsburg Bridge, by the Department of Bridges (later the Department of Plant and Structures), City of New York, in co-operation with the National Bureau of Standards, under the auspices of the late James E. Howard, Engineer Physicist, on the important truss members at the main towers and legs of the Brooklyn intermediate towers.

During these investigations, extending over a long period of measurements, a Howard extensometer of 20-in capacity was used throughout the entire test; and the precision attained with the strain-gage proved to be an invaluable aid, and its merits were illustrated in certain vital operations, especially with the various stages of wedging, and in the transferring of stress from the old to the new diagonal members of the end trusses.

The results obtained firmly convinced the writer that the most important objective to be considered in taking stress-strain measurements (other factors being equal) is to obtain consistent results; and in order to secure such results (which are absolutely essential), persistent patience and painstaking thoroughness, combined with good judgment on the part of the observer, are required, until he experiences little or no difficulty, and it is upon the observer that the value of such measurements will depend.

[149] Insp. of Steel, and Bridge Insp.-in-Charge, Brooklyn Bridge, Dept. of Plant and Structures, City of New York, Brooklyn, N. Y.

J. P. GROWDON,[150] M. AM. SOC. C. E. (by letter).—The engineer who is concerned with the design of structures, such as bridges, rather than the design of structural parts of machines, such as dragline booms, will be interested in the use of strong aluminum alloys when these alloys will: (1) Permit him to design and build a structure that would not otherwise be possible; and (2), when it will permit him to design and build a more efficient structure than can be obtained by the exclusive use of other material.

The first situation occurs in certain fields, such as that of aircraft design, but will be rare in the structural field because all the structures which are now required can be successfully constructed of other materials. The second situation will be more frequently encountered by the structural engineer, who can, in most cases, measure the efficiency of his design in dollars, either in the form of reduced maintenance cost or of less capital investment.

Reduced maintenance cost can often be achieved by utilizing the high resistance to corrosion possessed by aluminum alloys of the structural group as compared to alloys of other materials. Less capital investment can be achieved in many specific cases by utilizing the bulk-weight ratio as well as the high strength-weight ratio of these alloys.

The extent to which aluminum alloys can be used economically in any given structure will depend upon their cost, relative to the cost of other materials which can be used for the same purpose, the type and size of the structure, the physical characteristics of the alloy, the skill with which the designer makes use of it, and the price at which it can be purchased.

To-day, the cost of aluminum per pound used to replace low alloy steels will be five or six times the cost of such alloy steels. This cost differential effectively limits the use of structural aluminum to those places where 1 lb of the newer material will save several pounds of steel.

This use of structural aluminum has been well illustrated in bridges, both new and reconstructed. Referring to new bridges, of the suspension, cantilever, or truss type, this limitation will mean that aluminum can be used only in those parts of the structure where the saving in dead weight will be most effective in reducing the weight and cost of other parts. In new short-span bridges such a saving is small, whereas in new long-span bridges the possible saving in dead weight (and, hence, in cost) becomes very large; so that one may say that in short-span bridges no aluminum can be used economically for structural parts, but as the length of span increases, the possibility of saving money by its use will also increase. Furthermore, the longer the span, the greater will be the number of places in which it can be used to advantage.

Various types of bridges will require aluminum in different parts of the structure in order to secure the most economical result. In a suspension bridge, it will be used first in the deck and with longer spans in the stringers, floor-beams, and stiffening trusses. In a cantilever bridge aluminum would find its most profitable use in the suspended span, where a saving in weight

[150] Asst. Chf. Hydr. Engr., Aluminum Co. of America, Pittsburgh, Pa.

would reduce progressively the weight of the cantilever arms, the anchor arms, the towers, and the size of the foundations. Thus far, aluminum has found little utility in truss bridges except for railing and decorative parts.

In a bascule bridge a pound of weight in the outer end of the leaf requires several pounds of material in other parts of the structure to support it. A lift span, constructed entirely, or in part, of aluminum, would require a lighter counter-weight, lighter towers, smaller motors, and less power to operate it. In all bridges of the bascule or lift type aluminum deserves careful consideration from the standpoint of economy and efficiency.

In the rehabilitation and reconstruction of old bridges the high strength weight-ratio of aluminum has found a most effective use. Many old bridges, inadequate for modern traffic, can thus be reconstructed so as to reduce the dead load, increase the traffic capacity, or improve the character of the roadway. In some cases all three results may be accomplished.

From the many aluminum alloys available Mr. Hartmann has selected a single alloy of the duralumin type, (17S-T), and has largely limited his discussion to that single alloy. In thus selecting Alloy 17S-T as the typical alloy he has been wise since this alloy was the first of its type to be developed and has long been established in the structural field. As pointed out by Mr. Hartmann, there are many other alloys available to the structural engineer, and it is believed that certain of the newer alloys now available have physical characteristics which particularly adapt them for use in such structures as bridges. Among these characteristics may be mentioned: Alloys 53S-T and 27S-T, included in the paper by Messrs. Jeffries, Nagel, and Wood (see Table 7, Items Nos. 10 and 13). They differ from Alloy 17S-T, because of the lower tensile and yield strengths of the latter, (which are, respectively, 33 and 20 kips per sq in.), but more especially because of its extraordinary resistance to corrosion.

Item No. 10, Table 7, differs from Item No. 6 in that it has a greater yield strength (50 kips per sq in.) and a somewhat smaller percentage of elongation (9 to 13). These characteristics make Item No. 13 particularly suitable for applications where maximum resistance to corrosion is desirable, but where maximum strength is not required. Bridge railing is an example of such an application. The characteristics of Item No. 10 make it particularly suitable for those applications in which the maximum strength-weight ratio is desirable.

To secure satisfactory results, it is not sufficient merely to substitute an aluminum member for a similar steel member. The designer must take advantage of the particular properties of the material so as to utilize these properties to the best advantage and to minimize the effect of disadvantages which are inherent in certain of them. In addition to the ultimate strength and the yield strength, the designer must keep constantly in mind the modulus of elasticity, the temperature coefficient, the weight, and the cost. The relatively high price of aluminum makes it necessary for the designer to have

accurate knowledge of the properties of the material, the loads to which the structure will be subjected, and the stress which these loads will produce in every part of the structure. He must exercise his skill, ingenuity, and best judgment, in addition to his knowledge, not only to see that every part of the structure is adequate for the work which it must do, but that no material is wasted.

A properly designed structure utilizing aluminum in a greater or less degree will be different from a steel structure serving the same purpose, because the properties of the material are different. As an illustration of how the properties affect the design, it is interesting to note the effect of modulus of elasticity, which, of course, in an aluminum structure having a modulus of elasticity of 10 000 000 lb per sq in. will produce deflections much greater than in an identical steel structure having a modulus of elasticity of 29 000 000 lb per sq in. In many cases, this excessive deflection can be reduced within satisfactory limits by utilizing continuity wherever possible in the design. Other factors in which the design of an aluminum structure will differ from that of a steel structure will occur to the engineer who thinks seriously on the subject.

The Smithfield Street Bridge, across the Monongahela River, at Pittsburgh, Pa., was reconstructed in 1933 by replacing the entire wood and steel floor system with an aluminum floor system of Alloy 27S-T.[151] It has functioned satisfactorily since reconstruction and is an excellent example of the successful application of one of the newer light alloys in the bridge field.

Karl Arnstein,[152] Esq. (by letter).—An interesting presentation of the most important phases of models and model testing is contained in the paper by Mr. Templin. The modern trend toward light-weight designs of larger structures, requires that more consideration be given to the subject of general buckling. Mr. Templin refers to this problem in a general way only. It should be emphasized that, in order to obtain reliable general information on buckling in scaled down or scaled up models, very rigid specifications are required in designing the model and model members. Not only can general buckling be sensitive to the axial, bending, torsional, and shear characteristics of its individual members, but it is essential that the unit linear deformation (and, hence, also the relative angular deformation), under any system of forces or moments, be the same as the corresponding unit linear, and relative angular, deformation in the corresponding prototype member, under the properly scaled corresponding forces and moments.

For most types of engineering structures, the shear stiffness of its individual members is sufficiently large to have only a small effect on the general stability (unless a built-up section is represented by a single member in the model) and can be neglected. To meet the remaining requirements, it is necessary, for reasons mentioned by Mr. Templin, that the model member

[151] *Civil Engineering*, March, 1934.

[152] Chf. Engr., Aeronautical Dept., The Goodyear Tire & Rubber Co., Akron, Ohio.

be designed so that the axial, bending, and torsional stiffness can be varied independently. Such a model girder has been developed and used by the writer's company and has been explained, together with other interesting comments on this subject, by Mr. L. H. Donnell[153]. The application of this type of model representation may remove some of the objections raised by Mr. Templin in his valuable paper.

A. Christianson,[154] Esq. (by letter).—The weight savings accomplished through the use of structural aluminum in the framing of car bodies have proved to be a substantial addition to the weight saved through the other major application of aluminum in this field, namely, inside finish and fittings. The extra cost of providing these weight savings is offset by the savings in power and improvements in performance. The trend away from the conventional steam locomotive, of course, has accelerated the demand for light-weight construction.

Aluminum alloys are well adapted to light-weight car construction because they are available in forms that fit the needs of the car builder. Large-sized sheets with a high degree of flatness are readily obtained, and the shapes, particularly the special extrusions, meet all the requirements of form, thickness, and length.

The low unit weight of the aluminum alloys permits light-weight construction without drastic reductions of thickness of sheet and shapes. This has been found to simplify both design and construction. The car designer, having available a greater volume of metal, is able to distribute it effectively in the members and still not depart radically from conventional sizes which have been established through years of experience in car-building practice. The use of the greater volume of light-weight metal and the resulting thicker sections greatly reduces the tendency for buckling failures and other complications due to instability. The pleasing and substantial external appearance which always accompanies freedom from wrinkles is readily obtained in aluminum construction with no extra effort in the shop.

Mr. Hartmann makes some interesting comments on workmanship, indicating that aluminum construction should receive careful attention in the shop in order to help approach the degree of perfection for which the designer is striving. The importance of this cannot be too highly emphasized. It has long been the writer's contention that no construction can function as the designer intended, unless the shop work is perfect. Excellence in fabrication is of importance to aluminum construction for the same reasons that it is important to all other construction, and is accomplished in exactly the same manner. Aluminum alloy construction presents almost no new problems to the shop experienced in producing a high quality of workmanship in other metals.

[153] "Model Measurements and Airship Stress Analysis", pub. in "Report on Airships Forum", July 25-26, 1935.

[154] Chf. Engr., Eng. Dept., Pullman-Standard Car Mfg. Co., Chicago, Ill.

ROBERT E. GLOVER,[155] ESQ. (by letter).—In his discourse on "The Extent of Present Theoretical Knowledge" Mr. Karpov comments on the lack of information regarding the electric and magnetic forces of the electrons, and expresses the belief that the fundamental avenue of approach to the problems of stress is now closed because of a lack of essential basic information. He then refers to the "theory of stress" and concludes that, because no general solution of the differential equations is known, the designer is forced to fall back upon a number of more or less reliable assumptions among which the most important are that the material follows Hooke's law and that the stress follows a straight line distribution. The writer can not agree that the designer need be reduced to such straits. It is well known among students of the subject that the general solution of a partial differential equation may be of little use in cases where a particular problem must be solved. Since the differential equations of elasticity are of this type the lack of such a solution need not be cause for great concern. The question of the validity of Hooke's law does not admit of a general answer applying to all materials, but with regard to a given material, may be answered at the nearest testing machine.

To the writer's knowledge, there are at least four good, sound, carefully written texts on the theory of elasticity which contain a large number of solutions of the elastic equations, many of them illustrated with solved examples for particular cases. With these at hand, supplemented, perhaps, by some other excellent available texts on special subjects, such as photo-elasticity, plasticity, slab theory, elastic stability, and the contributions which are constantly appearing in technical literature, the designer should not find his problem of stress determination hopeless.

The uniqueness theorem[156] has a bearing on some of the statements made by Mr. Karpov. This theorem was published in 1859 by the distinguished investigator, G. Kirchhoff, whose name is so well known in the electrical world. He proved that under certain stipulated conditions (which, indeed, apply to the great majority of engineering structures), the differential equations of elasticity can have no more than one solution. If the existence theorem were also available, the case would be complete, and it could be inferred that the elastic equations, as they exist to-day, solved in conjunction with the supplementary conditions imposed by any particular problem are completely adequate under the postulated conditions. There seems to be small reason to doubt that this is actually the case, but if the required solution is known or can be found the existence theorem may be dispensed with, since the possession of a solution is ample proof of existence, and the designer can proceed with the assurance that, in his case, the problem is properly set. Furthermore, since no other solution can exist, he also has the assurance that the results he arrives at can not be altered by whatever information some later investigator may succeed in prying out of the electrons.

[155] Engr., U. S. Bureau of Reclamation, Denver, Colo.

[156] "Mathematical Theory of Elasticity", by A. E. H. Love, Fourth Edition, Paragraph 118.

It is true that the theory of elasticity is mathematically difficult, but it is also true that so many of these difficilties have been overcome by able investigators that the charge of practical uselessness can no longer be sustained. The writer has had occasion to apply the methods of the theory of elasticity to a number of problems and has obtained very satisfactory results. The Kirchhoff theorem has been of great assistance in connection with the trial-load method for the design of arch dams, by making it possible to determine what constitutes an adequate analysis.[157] These methods were also applied, under the writer's direction, to the problem of developing formulas for designing the supporting rings for the penstocks at the Boulder Dam, which is located about 30 miles southeast of Las Vegas, Nev. These formulas were obtained and used with entire satisfaction, and the results have been confirmed by extensive tests both in the laboratory and on the penstocks themselves in the field. These and similar formulas have been used more recently in the design of the Malheur siphon on the Owyhee project in Eastern Oregon. This pipe is 80 in, in diameter and is constructed with 60-ft spans, without intermediate stiffener rings.

ARTHUR C. RUGE,[158] ASSOC. M. AM. SOC. C. E. (by letter).—A remarkably complete and lucid discussion of the types and purposes of tests of engineering structures and their models has been presented by Mr. Templin. Although he does not specifically make a critical comparison of the testing of full-sized structures with that of their models, one feels that he is doubtless aware that defects in the model method are sometimes over-emphasized in relation to those defects which are inherent in the testing of many full-sized structures. The principal difference in this respect lies in the relative ease with which the model test conditions can be controlled and varied.

As a case in point, one might consider the dynamic tests of structures, which are becoming important as a means of interpreting the effects of earthquake motions. Consider a tall masonry chimney in which it is desired to study the vibration periods for the purpose of checking theoretical calculations. If the model method is selected, difficulties arise only in securing the proper material to represent the masonry and the foundation material. These difficulties may be very serious; but they are not insuperable.

If, on the other hand, one chose to test the actual chimney in the field, one might be misled at first by the apparent simplicity of the problem, but sooner or later one would discover defects more serious than in the model technique. The first great difficulty would be in generating the modes of vibration, and, assuming that has been done, one cannot know if the periods measured will be maintained for the large amplitudes which are really the most important, but which the investigator dares not, or cannot, produce in the test. For example, a chimney laid up with completely bare bricks would exhibit a set of natural periods not greatly different from those of the same

[157] "Fundamentals of the Trial Load Method for the Design of Arch Dams", by R. E. Glover, presented as a thesis to the Univ. of Nebraska in partial fulfillment of the requirements for the degree of Civil Engineer.

[158] Research Associate in Seismology, Dept., Civ. and San. Eng., Mass. Inst. Tech., Cambridge, Mass.

chimney laid up in good mortar; but the dynamic behavior under large amplitudes would be vastly different.

Next, it is impossible from field test data to separate the effect of the foundation from that of the masonry in producing the observed periods, unless broad assumptions are adopted as to the correctness of the very theory to be checked. In such a problem the model method is not nearly at such a disadvantage as it might at first seem. In the model, the conditions of amplitude, stress, and foundations can be controlled and varied in such a manner as to give a positive check on the theory involved. To a less extent the same arguments will be found to hold for certain purely statical tests of structures.

It is not to be ignored, of course, that a tremendous amount of work remains to be done in the development of model materials and artifices for overcoming difficulties in similarity; but it needs to be emphasized that there may be (and often are) pitfalls in the testing of actual structures which are likely to be overlooked entirely. In this connection, Mr. Templin very rightly points out the importance, at times, of considering the model itself as a structure, without assuming a simple relation to its prototype.

The statement (under the heading, "Test Methods: Models Made of the Same Material as the Prototype") that a "photographic" model of a gusseted truss would not be truly similar, needs to be clarified somewhat. Although it is quite true as stated that a geometrically scaled model will not result in the same scale ratio for areas as for moments of inertia, this fact alone cannot preclude the realization of perfect similarity conditions. In fact, unless these ratios are different, true similarity cannot exist in the usual sense of the word.

If, for simplicity, the assumption is made that the connections are welded, or that the riveted connections do not slip, it is difficult to understand why Mr. Templin makes the statement that "the degree of end restraint will not be the same as in the prototype, and the behavior of the various members of the model, under combined axial loads and bending, will be different from that of the corresponding members of the prototype." The elastic action of a gusset-plate cannot be said to be of a different nature from that of a beam or strut, although the stress distribution may not be equally simple; and, fortunately, models do not have the means to avoid complex stress distributions as is commonly done in analytical work.

Mr. Templin's point is very good in regard to the limitations of models; but he has chosen an unfortunate example for illustration. To present a better picture of the difficulties of scale effects in similarity problems, one needs only to consider structures in which more than one type of physical forces act simultaneously. In the gusseted truss only elastic forces are involved. In the case of a structure like an elevated water tank (considered dynamically) both gravity and elastic forces are found interacting in such a way that a "photographic" model actually fails to represent the prototype to a marked degree.

The classical dimensional analysis in the water-tank problem promptly leads to the result, $\lambda = 1$; or, the model must be made full size to give true similarity. By proper distortion of scale, however, one easily preserves

the similarity in spite of the first result, it being only necessary to find the means of keeping the same force scale for both gravity and elastic forces. To be sure, in practical work of this kind, one may have to be content with securing true similarity only in those features of the behavior he desires to study, but there can scarcely be objection to that.

ALEXANDER KLEMIN,[159] ESQ. (by letter).—In the construction of aircraft one encounters both complicated structures and complicated distributions of loads. The loads applied are air pressures and not only is the distribution peculiar but it varies with each condition of flight. The complete structure is very frequently tested to destruction.

Models are used infrequently. In the structural testing of aircraft, the technique is not too well defined and methods of determining stresses and strains are likely to be improvised for a particular construction. Those engaged in aircraft engineering have learned much from the Civil Engineering Profession and Mr. Templin's paper will add to such lessons. Every aeronautical engineer who makes structural tests should follow the principles enunciated.

PAUL E. GISIGER,[160] ASSOC. M. AM. SOC. C. E. (by letter).—In connection with the very informative paper on stainless high alloy structural steels by Mr. Morris, it may be of interest to cite a recent application of non-corrosive steel in the field of hydraulic engineering.

In the hydro-electric power plant of the Pennsylvania Water and Power Company at Holtwood, Pa., the trash screens which protect the turbine intakes against floating logs, trash, etc., and which were installed between 1910 and 1913, are now (1937) approaching the end of their useful life. Screening equipment consists of cast-iron guides bolted to the piers between individual intake openings (of which there are four for each of the ten main turbines and one for each of the two exciter turbines) and of individual screen units (five per opening or twenty per turbine), which slide in the guides and can be removed, changed, or replaced easily with overhead cranes.

The original screen units are made of structural steel channel frames, 11 ft high and 9 ft 6 in. wide. The screen bars are $4\frac{1}{2}$ by $\frac{3}{8}$-in. flat bars spaced $4\frac{5}{16}$ in. and held to the frames with bent and slotted attachment plates and bolts. Each such unit weighs about 4 500 lb so that the total of 210 units represents a considerable tonnage.

The established maintenance practice is to sand-blast and repaint the screens once every four years. During recent years it became increasingly necessary, however, to add miscellaneous repairs to this maintenance schedule and, by 1935, it was evident that replacement of at least a part of the screens could no longer be postponed.

[159] Prof., Daniel Guggenheim School of Aeronautics, Coll. of Eng., New York Univ., New York, N. Y.

[160] Structural Engr., Pennsylvania Water & Power Co., and Safe Harbor Water Power Corporation, Baltimore, Md.

An investigation was then made into the use of materials which would require less maintenance and possibly would last longer than the structural steel. In addition to several kinds of corrosion-resisting alloy steels this investigation included bronze, copper,[7] and aluminum. In order to be economically justified a material other than low carbon structural steel had to give reasonable assurance that the increased first cost would be offset by less maintenance and a longer life.

Comparative estimates in which such factors are of large influence are naturally somewhat uncertain and will have to be checked by experience. They were conclusive enough in this instance to decide in favor of new screens with a frame of structural steel as before, but with screen bars made of high-strength chromium alloy of approximately similar composition as Item No. 2, Table 4. Wearing strips of the same material were also provided along the contact line between screens and guides. This resulted in somewhat more than one-half the entire surface area of the screens being non-corrosive and the parts which still have to be painted are those which suffer the least wear are easiest to paint.

Each of the new screens which have the same outside dimensions as the old ones includes 1 050 lb of corrosion-resistant alloy steel and 2 350 lb of standard structural steel. The total weight of the new screens, therefore, is only 75% of the old ones which fact in itself is very desirable because it makes for easier handling. The saving results mostly from the higher strength of the alloy material, but also from the all-welded construction.

Another advantage resulting from the use of high-strength material as well as from welding is the very considerable reduction in the area that obstructs the water passage. This is quite evident when pictures of the old and new screens are compared, and the improved hydraulic effect is expected to be further emphasized by decreased friction between water and screen bars which do not become roughened by corrosion.

The welding of the high-strength chromium steel and especially its connection by welding to a different material were made the subject of close investigation. A number of types of welding rod were tried and welds examined and tested. The results indicated that generally a somewhat better penetration is obtained if the welding rod is of a composition similar to the base metal and that, therefore, the joints between ordinary steel and alloy steel for which a coated alloy steel electrode was used, had to be welded with more than the usual care. During all these investigations and tests the manufacturers of non-corrosive steel were most helpful in co-operating to arrive at the most suitable materials and methods. Of the old screens in the Holtwood Plant, 25% have now (1937) been replaced and it is intended to replace the remainder progressively during the next few years.

There is no doubt that hydro-electric structures offer a wide field for the application of non-corrosive high strength steels and that their use for such structures will increase rapidly as knowledge concerning these metals advances and as production on a larger scale will make it possible to lower their cost.

RUSSELL C. BRINKER,[181] JUN. AM. SOC. C. E. (by letter).—Engineers are given a clear-cut analysis of the possibilities and limitations of light-weight alloys in the papers of this Symposium. Several statements from the various papers might conveniently be linked for the purpose of greater emphasis.

In their "Summary," Messrs. Bain and Llewellyn state that, "* * * corrosive attack does not reduce the effective metal section in proportion to the thickness, but irrespective of section." Simple arithmetic thus shows that with the thinner sections of material with higher unit strength, the relative effect of corrosion is greater since a $\frac{1}{16}$-in. reduction in thickness due to rusting of a $\frac{3}{8}$-in. plate means a loss of 16.7 per cent. The same loss from a similar $\frac{1}{2}$-in. ordinary steel plate is equal to a section loss of only 12.5 per cent. With total strengths in direct proportion to the thicknesses, the high-strength steel would thus suffer more. If, however, the thickness was governed by other factors, such as column action, stiffness, etc., the effect might be more, or, in exceptional cases, less serious than indicated by these values.

Mr. Aston illustrates substantially the same condition (see heading, "Low-Alloy Structural Steel") and suggests a design solution in his analysis by means of a "unit corrosion-merit" value, his statement being, "in effect, therefore, in the selection of structural materials, the benefit to be derived, as far as it relates to corrosion, will be only to the extent that the corrosion-merit ratio exceeds the strength ratio for the metals under consideration."

Incidentally, Mr. Karpov's statement (see "Application to Actual Designs: Safety Factors and Working Stress") that, "in all engineering structures the factor of safety decreases as time goes on", will apply to the case of structures weakened by corrosion. Part of the spread between the design stress and the elastic limit is assumed to take care of this feature along with secondary stress, increased loading, etc. Hence, in choosing a design stress, the corrosive resistance of a new alloy steel should be known. In the past only too often paint maintenance has been assumed by the designer, but failed to come up to expectations. Rusted stringer flanges and connection angles, corroded to a point that makes support of only the dead load appear miraculous, are not uncommon sights. A classic example is that of a steel plate girder bridge that carried traffic practically to the time of its replacement when the deteriorated web could be punched through by a single blow of an ordinary sledge hammer. Truly, corrosive resistance will have to be specified along with ultimate strengths as alloys of greater and greater strength are put on the market.

The esthetic possibilities suggested by the alloy steels are not to be overlooked. Many American structures appear less graceful than similar European designs, at least in past constructions. The attitude in the United States has inclined toward the liberal use of materials and the limited use of the designers' time, whereas European economy has dictated the need of ample design time to analyze and produce a light and materials-saving structure. Perhaps with the double incentives of lighter but costlier material, the clumsy appearance of many "railroad-type" bridges will gradually disappear

[181] Exchange Teacher in Civ. Eng., Worcester Polytechnic Inst., Worcester, Mass.

from future highways. A deterring factor, however, is that, in general, the longer structures which have received the necessary close design scrutiny have attained greater esthetic beauty than the intermediate or short spans; but it is in the former and not in the latter classes that the high-strength steels will find their greatest usefulness. There has been no excuse for bulky structures in the long-span field where an extra pound of dead load weight at the bridge center would require as much as 5 lb of added metal to carry it. Certainly, if the use of alloy steels should extend to the shorter spans, many of the wasteful "standard designs" would be eliminated by the more costly material.

ARSHAG G. SOLAKIAN,[162] ESQ. (by letter).—Dealing with several phases of photo-elasticity (such as history, application, limitations, methods, apparatus, model materials, etc) the valuable paper of Mr. Brahtz is most timely. It reflects the wide interest shown in the last decade, in America as well as abroad, in this interesting optical method of measuring stress intensities in transparent models. The writer's discussion is intended simply to supplement certain parts of Mr. Brahtz's paper, and he has preserved the order of representation used by the author.

It is true that Sir David Brewster has been universally recognized as the founder of photo-elasticity, because of his discovery in 1816 of the stress-optical phenomenon known as double refraction of polarized light in transparent isotropic materials under stress. It was Erasmus Bartholinus, however, who, in 1669, first observed the phenomenon of polarization by the double refraction of ordinary light in its passage through a uni-axial crystal, such as Iceland spar, a material used extensively for polarizing prisms in polariscopes. It is evident that without polarized light, Brewster would have not found it possible to observe the double-refraction effect in a stressed plate.

In America, the pioneers in the art of photo-elasticity have been Carus A. C. Willson[163] and the late Charles Lee Crandall, M. Am. Soc. C. E., and Anson Marston,[164] Past-President, Am. Soc. C. E., but it has been due to the numerous valuable researches and publications of Mesnager, in France, and Filon and Coker, in England, that photo-elasticity has become a practical and useful method for the analysis of stress distributions in machines and structures of a two-dimensional nature.

Mr. Brahtz refers to a paper[165] by the late A. H. Beyer, M. Am. Soc. C. E., and the writer, in connection with the possibility of stress analysis in reinforced concrete through composite models, made of bakelite and cast with metal rods of circular cross-section embedded. As a necessary improvement on this type of test, the circular-section reinforcement may be replaced advantageously by flat strips, having a width equal to the thickness of the

[162] Lecturer in Civ. Eng., Columbia Univ., New York, N. Y.

[163] "The Influence of Surface Loading on the Flexure of Beams", *Philosophical Magazine*, December, 1891.

[164] "Friction Rollers", *Transactions*. Am. Soc. C. E., Vol. XXXII (1894), p. 99.

[165] "Photo-Elastic Analysis of Stresses in Composite Materials", *Transactions*. Am. Soc. C. E., Vol. 99 (1934), p. 1196.

model. This modification will distribute the metal uniformly across the entire thickness and also will eliminate any three-dimensional stress effect on particles in the immediate vicinity of such rods as were formerly proposed. It may be of interest to add, in this connection, that a photo-elastic material of preferably liquid form (such as marblette,[166] for example) that can be handled easily under laboratory conditions as a matrix for the models, and also affords good adhesion with the metal inserts and develops the least amount of initial strain effects after being cast, will be of great help to investigators in work of this nature.

Mr. Brahtz emphasizes the necessity for developing a cement that can be used to combine models of the same or different elastic properties, thus opening a wide field of research in a great many problems of practical importance to engineers, such as shrinkage stresses in dams, welded connections, built-up structural sections, space frames with rigid joints, etc. It should be noted that such a cement, made of liquid marblette and hydrochloric acid and setting under room-temperature conditions, has been used by the writer in the qualitative analysis of shrinkage stresses in dams, as reported in a discussion[167] of a paper by Howard G. Smits, Jun. Am. Soc. C. E.

A special type of polariscope (with aluminum-coated mirror reflectors instead of lenses) has been advocated for instruments producing a large

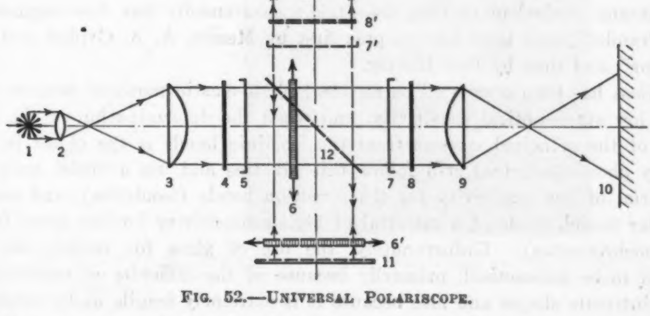

FIG. 52.—UNIVERSAL POLARISCOPE.

field of parallel rays, with the minimum space and lowest cost as governing factors. The writer doubts that such instruments with mirror reflectors will command much popularity, especially in view of the recent development of

[166] "A New Photo-Elastic Material," by A. G. Solakian, *Mechanical Engineering*, December, 1935.

[167] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 937.

large-sized and moderately priced artificial polarizing media in the United States. A polariscope having a field of 10-in. parallel rays, for example, has been designed recently by the writer, using polarizing glass plates both for the polarizer and analyzer, with a total length (not including the screen) of about 6 ft. By the addition of a glass plate (at 45° with the axis of the instrument) and a reflection mirror, with the second half of the instrument turned 90° (as shown by the dotted-line arrangement in Fig. 52), this "transmission" type of polariscope is easily transformed into the "reflection" type, which latter is of extreme importance in a great many specific cases that could not be handled by the transmission type of polariscope.

Referring to Fig. 52, when the apparatus is set up as a transmission type of polariscope, the light source is at Point 1; Point 2 indicates the condenser lens; Points 3 and 9 the lenses for parallel light; Point 4 is the polarizer; Points 5 and 7 are quarter-wave plates; Point 6 is the model; Point 8 is the analyzer; and Point 10, the screen. In the converted set-up (the reflection type), Points 1 to 5, inclusive, are the same as before; Point 12 is a glass plate; Point 6′ is the model; Point 11, the mirror, and Points 7′ to 10,′ inclusive, are the same as in the transmission type, except that they are turned through 90 degrees.

The idea of evaluating the sum of the principal stresses at a point, by measuring the lateral strain of the stressed model at that point was first suggested by A. Mesnager[168] who designed and used a lateral strain-gage similar to that used by Vose. Coker's lateral extensometer is a more practical type of Mesnager's instrument. The optical flat-model combination for obtaining Newton's interference fringes, to serve the same purpose, was also first suggested by Mesnager, and, later, was adopted by V. Tesar[169] and then by Frocht, to be abandoned finally on account of the mechanical difficulties of securing accurate results encountered in its application. The membrane method of making the same measurements was first suggested by L. Prandtl[170], and later was adopted first by Messrs. A. A. Griffith and G. I. Taylor[171] and then by Den Hartog.

Glass has been suggested as an ideal photo-elastic material because of its very low stress-optical sensitivity, and when the determination of the direction of the principal stresses from the isoclinic bands is the object in view. Many photo-elasticians still follow this practice and use a model made of a material of low sensitivity for the direction bands (isoclinics), and another, similar model, made of a material of higher sensitivity for the stress fringes (monochromatics). Unfortunately, the use of glass for models has been found to be impractical, primarily because of the difficulty of machining it into intricate shapes and also because it is extremely fragile under stresses of moderate intensity. The writer has recently found that a commercial synthetic plastic, having a stress-optical sensitivity only 1.25 times greater than

[168] "Sur une Methode pour déterminer a l'avance les tensions qui se produisent dans une Construction", *Comptes Rendus* November, 1912.

that of glass, with a transparency rivaling that of glass, and possessing none of the disadvantages of the latter, can very advantageously replace the use of glass in models.

Considering the problem of determining stresses in models of machines and structures of the three-dimensional type, it has been suggested the previously silvered surface of a strip of photo-elastic material be cemented against the metallic surface of the prototype considered. By using polarized light reflected through and back from this cemented strip, the surface stresses (which, in general, are the largest of all across a given cross-section) can be determined from the isoclinics and monochromatics, in the usual manner. This idea was first suggested by Mesnager.[172] In 1936 the writer cited[167] the adaptability of liquid marblette as a coating on polished metallic surfaces. Successful results along this line have been thus far obtained only with very thin coatings, not of sufficient thickness to produce a fringe pattern under stresses of low intensity. Although such stresses can be measured by one of the compensation methods known to photo-elasticians (such as color matching, quartz-wedge compensators, Coker's tension bar, etc), these methods do not possess the ease and simplicity of the fringe-pattern method now universally in use. By additional coatings on the original one, the thickness of the skin layer can be increased to any desired amount, but the non-uniformity of the layer thus deposited may be objectionable. With the marblette liquid cement the writer has been able to produce a satisfactory

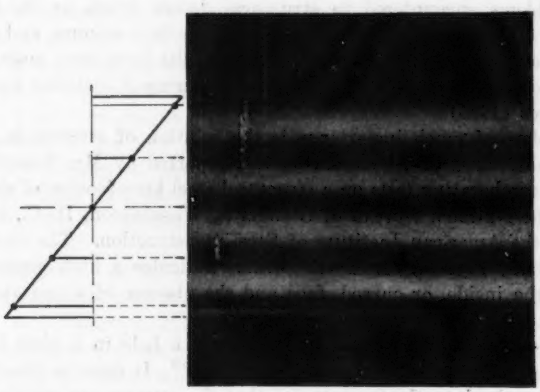

FIG. 53.—SURFACE STRESSES IN METALLIC STRUCTURES AND MACHINES FROM A STRIP OF PHOTO-ELASTIC MATERIAL CEMENTED TO THE PROTOTYPE.

bond between the surface of a metallic strip and a silvered surface of a piece of $\frac{1}{8}$-in. marblette. As this cement sets under room temperature conditions, initial strain effects in the cemented photo-elastic material are eliminated. Fig. 53 is a fringe pattern of stress in a model thus prepared, under a uniform bending moment applied to the metallic strip.

Finally, it is interesting to note that the interferometer (or rather the interferometer-polariscope) as designed and built by the engineers of the U. S. Bureau of Reclamation is similar in principle as well as in construction to that first designed by H. Favre,[173] in Switzerland. A brief translation in English of Favre's paper concerning the theory and use of this instrument was made by the writer[174] in 1932. An interferometer-polariscope of the Favre type was developed by the writer for the Photo-Elastic Laboratory of Columbia University. Similar instruments are reported to have been constructed for McGill University and the University of Buenos Aires.

H. D. Hussey,[175] M. Am. Soc. C. E. (by letter).—Structural engineering, as it involves the modern alloy steels, has developed to a highly technical state. The papers in this Symposium emphasize this fact. The use of these steels requires a better understanding of the phenomena of fatigue, stress concentrations at holes and fillets, buckling of plates, etc., as well as a better knowledge of the materials themselves. The writer wishes to emphasize the statements by the various authors concerning some of these factors.

Mr. Karpov gives a general outline of certain stress phenomena that are receiving much study, including an exposition of the theory of fatigue. He states that stability problems are less understood than problems of stress and that the tendency is to use higher factors of safety with respect to stability as compared to stress. It should be emphasized, however, that many stability problems encountered in structural design (such as the buckling of web-plates in a girder, plates under compression in a column, and outstanding flanges) have been solved,[176] and that the results have been embodied in the Specifications of the American Railway Engineering Association for Steel Railway Bridges (1935).

A problem of much importance is the solution of stresses in rigid-frame knee-sections. The over-sized model test reported by Mr. Templin is interesting as corroborating tests on a structural steel knee-section of similar shape made at the National Bureau of Standards, Washington, D. C., in collaboration with the American Institute of Steel Construction. The stress diagram on Line *A-A'*, Fig. 14, across the corner, indicates a high concentration of stress on the inside, or curved, face and the absence of stress at the outside corner.

The problem of stress concentration about a hole in a plate has received much study, both theoretical and experimental.[177] It must be observed that in such studies the investigator assumes that the stresses are within the elastic range at all times. The phenomenon of stress concentration about a hole in a plate, when the theoretical stress exceeds the yield point, has not been

[176] "Elastic Stability of Plates," by Otis E. Hovey, M. Am. Soc. C. E., *Proceedings*, 36th Annual Convention, Am. Ry. Eng. Assoc., Vol. 36, 1935, p. 715.

[177] "Theory of Elasticity", by S. Timoshenko, 1935, p. 75, and "Stress Concentration Produced by Holes and Notches", by A. M. Wahl and R. Beeuwkes, Jr., *Transactions*, Am. Soc. Mech. Engrs., Vol. 56, 1934, Paper APM-56-11.

explored so widely. Theory indicates that the stress at the edge of a hole in a wide plate may be three times the average stress on the net section. If the average stress is one-half the yield point the stress condition adjacent to the hole is shown in Fig. 54. (By "theoretical stress" is meant the stress

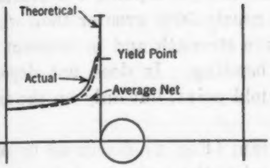

FIG. 54.—STRESS CONDITIONS ADJACENT TO A HOLE IN A PLATE.

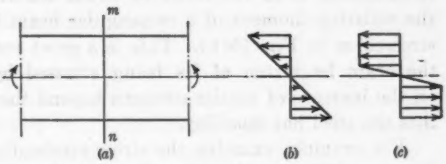

FIG. 55.

that would result if proportionality of stress and strain continued to any limit.) Since the maximum stress cannot be much greater than the yield point there is some re-adjustment of stress due to yielding of the material adjacent to the hole. Due to this yielding there results a small permanent set on release of the load. Repetition of this stress condition produces no further yielding, but a sufficiently large number of repetitions will lead to failure by fatigue.

The problem of riveted joints and stress concentration at rivet holes has received the consideration of several of the authors. A better understanding of this problem depends, among other factors, upon a more thorough knowledge of the theory of plasticity.

A problem of much importance is the question of proper, or permissible, ratio of yield point to tensile strength. Mr. Moisseiff calls attention to the fact that several of the new alloy steels have a high ratio. In the field of bridges and buildings, it has been considered that this ratio should not exceed 70 per cent. It seems appropriate to inquire whether this, or any, limitation should be applied to ductile materials such as those under discussion.

The reason for a low ratio of yield point to tensile strength is to provide a reserve of strength against high concentrations of stress at joints, holes, fillets, etc. It is apparent at once that this reserve strength cannot provide against an increase of direct stress, either tension or compression, beyond the yield point, because, being the point of transition from an elastic to a plastic state, this is the useful limit of any member under those stresses. This reserve strength, therefore, can operate only under conditions of bending stresses beyond the yield point.

A study of stresses beyond the yield point shows that the bending resistance of a beam continues to increase after the stress in the outer fiber has reached the yield point, depending upon the make-up of the beam. For a rectangular section this increase may be as high as 50 per cent.[178] Fig. 55(*b*) shows the stress diagram on Section *m-n* of the beam in Fig. 55(*a*) when

[178] "Strength of Materials", by S. Timoshenko, Pt. I 1930, p. 237.

stressed to the yield point. The stress diagram of a beam stressed beyond the yield point can be represented with sufficient accuracy by Fig. 55(*c*). The deformation increases with the increase in bending moment on the beam, but the stress does not increase much beyond the yield point. When the total deformation is in the order of about ten times the yield-point deformation the resisting moment of a rectangular beam is nearly 50% greater than when stressed as in Fig. 55(*b*). This is a great reserve strength and is inherent in the beam by virtue of its being stressed by bending. It does not depend on the increase of tensile strength beyond the yield point, but only on the fact that the steel has ductility.

For example, examine the stress-strain diagram (Fig. 2) discussed by Mr. Karpov. When strains beyond the yield point exist, the amount of the strain is influenced very little by the shape of the stress-strain curve. It is apparent that the relief of stress concentrations is caused by the yielding of the material at the over-stressed parts and not by the numerical value of the tensile strength. Indeed, were it not for plastic elongation of the material there would be no relief. In such cases the important characteristic of the stress-strain curve is the amount of elongation rather than the increase in stress beyond the yield point. This leads to the conclusion that the physical properties of greatest importance are yield point and ductility (as measured by elongation and reduction of area), and that the tensile strength is secondary to these. Thus, if it is possible to produce a satisfactory ductility, the ratio of yield point to tensile strength is of minor importance.

The writer welcomes the papers by metallurgists in Section II of the Symposium. The paper by Messrs. Bain and Llewellyn is of interest to the structural engineer because of the explanation of the metallurgy of alloying elements. Their discussion of "Interpretation of Specimen Tensile Tests" is worthy of note. Such discussion, coming from those with a different point of view, should be of value to the engineer in appraising, correctly, the materials he uses.

RALPH FREEMAN,[179] M. AM. SOC. C. E. (by letter).—The evolution of high strength steels in structural engineering in Great Britain has led to the adoption of qualities of steel differing materially from those used in the United States, as recorded in the paper by Mr. Moisseiff. Nickel steel has not been used to any significant extent for bridges or for other structures designed in Great Britain, no doubt because no bridge has been constructed having a span long enough to require the use of a superior quality of steel, obtainable only at a material increase of cost.

As stated by Mr. Moisseiff (see heading, "History of Silicon Steel"), "silicon" steel was first produced in 1907 for the construction of part of the upper structure of the *Mauretania* and data regarding this steel and the silicon steel in the *Lusitania* have been reported by Sir Robert Hadfield.[180]

The plates rolled were of large dimensions (to 38 ft in length, 8 ft in width, and 1¼ in. in thickness), requiring ingots as heavy as 16 tons.

[179] Managing Partner (Sir Douglas Fox & Partners) Westminster, London, S. W. 1, England.

[180] "Metallurgy and Its Influence on Modern Progress", by Sir Robert Hadfield.

The plates were also subjected to the most severe tests in order to prove their resistance to sudden shock and violent stress beyond the yield point. In one series of these tests plates, 6 ft by 3 ft by 1 in. thick, were placed on supports 4 ft apart and tested by dropping a 3-ton steel ball on them from heights increased successively to 31 ft. Presumably, this was the maximum practicable value since the plates did not crack although they buckled.

In spite of the apparent successful application of this steel for shipbuilding, it does not appear to have been used again for this purpose and was not adopted for bridge building until the construction of the Sydney Harbor Bridge during the period, 1923–1928.

When preparing the designs for the Sydney Harbor Bridge, the writer considered the advisability of using various alternative qualities of steel, from mild steel (with a yield stress of about 15 tons per sq in.) to alloys having a yield point of 50 tons per sq in. The conclusion was reached that no high-class alloy steel effected a saving in weight which justified the extra expense but that "silicon" steel, having a yield stress of 20 tons per sq in., or one-third higher than that of mild steel, would effect a substantial reduction of cost. This steel complied with the following analysis:

	Percentage
Carbon	0.32 to 0.42
Manganese	0.60 to 1.00
Silicon	0.15 to 0.25

The rolled material included plates as wide as 8.25 ft and 2.25 in. thick, weighing 10 tons, and angles of 12 in. by 12 in. by 1.25 in. The permitted working stresses were 30% higher in tension and 25% higher in compression. The cost of the raw material was about 25% in excess of that of mild steel. No special difficulties of fabrication were experienced and the cost of fabrication was little more than that of mild steel. Nearly 40 000 tons of this steel were used for the Sydney Harbor Bridge, but as far as the writer is aware, "silicon" steel has not been used by British engineers for any other structural work.

This circumstance, no doubt, arose from the fact that at the time of the construction of Sydney Harbor Bridge, attention was being given in Great Britain to the production of high tensile steel superior to "silicon" steel, especially for shipbuilding, and led to the production of various alloys containing small percentages of manganese and chromium which could be produced at a cost very little more than that of silicon steel and would have distinctly superior physical properties.

These high-strength tensile steels are now extensively used for shipbuilding, bridge construction, and other structural steelwork. Steel used for the latter purpose is defined by a British Standard Specification which declares the physical properties of the steel, but does not state the chemical analysis. The yield point must be higher than 23 tons per sq in. for sections

or plates not exceeding 1.25 in. in thickness, reduced to 22 tons for thicknesses up to 1.75 in. Actual manufactured plates and sections of the kind in most general use (that is, of thicknesses as great as 1 in.), have a yield stress of 24 tons per sq in. The breaking strength is specified to be between 37 and 43 tons per sq in. The quantity of steel of this character produced in recent years in Great Britain exceeds 300 000 tons.

The steel of this quality which has been produced most extensively is a chromium-copper-manganese alloy complying with the following composition:

	Percentage
Carbon (maximum)	0.30
Chromium	0.70 to 1.1
Copper	0.25 to 0.50
Manganese	0.70 to 1.0
Silicon	0.20

Another alloy contains 1.0% to 1.5% of manganese, as much as 0.5% of copper, and no chromium. Other types contain smaller proportions of chromium and copper.

High tensile steel plates have a tensile strength transverse to the direction of rolling equal to that in the direction of rolling and sustain the usual cold bend tests (bending through 180° over a diameter equal to three times the thickness of the test piece without cracking).

The yield stress of high tensile steel of the foregoing type is approximately 50% higher than that of British mild steel. The permissible stresses allowed for this quality of steel are usually taken as 50% in excess of those allowed for mild steel.

The raw material cost of British "high tensile" steel can be taken roughly as 25% in excess of that for mild steel, and fabrication costs are not significantly higher, except as the consequence of the reduced tonnage resulting from the use of a stronger material.

Rivet steel commonly used for structural steelwork has a tensile stress of 26 to 30 tons per sq in., and it has been felt that with rivets of this class full advantage could not be taken of the superior strength of high tensile steel. Rivet steels of improved quality are produced, having tensile strengths (before driving) as high as 30 tons per sq in., and a strength in shear in high tensile plates exceeding that of mild steel rivets in mild steel plates by about 50 per cent. These rivets have not yet been used extensively.

Modern "evolution" of high strength steels when all is said appears to be anything but evolution when one achievement is recalled which occurred in an age now apparently forgotten in its own country. The steel used for the arch ribs of the Eads Bridge over the Mississippi River, at St. Louis, Mo. (completed in 1874), is not only one of the most astonishing features of this wonderful bridge, but an example of quality in a structural material that has probably never been surpassed.

In 1881, Mr. C. N. Woodward recorded[181] the fact that the steel staves that formed the ribs of the arches, were of chromium alloy which rolled very well. This was in 1872. The steel actually used is said to have had a tensile strength of 120 000 lb per sq in. Tests made in 1869 for the late James B. Eads, M. Am. Soc. C. E., apparently of the steel proposed for the bridge, indicated a superior quality. One series of these tests, made at Messrs. Kirkaldy's Testing House, in London, in 1869, of chrome steel bars, showed that the limit of elasticity in tension had an average value of 82 000 lb per sq in., the corresponding average ultimate strength being 155 000 lb per sq in.!

The writer subscribes entirely to Mr. Moisseiff's views regarding the advantages and limitations of high strength steel. He has found that high tensile steel is a source of great economy for long spans and has the effect of greatly increasing the economic span. It is also economical for small spans where freight costs are high. For a light road bridge recently built in Rhodesia, crossing a river, 1 000 ft wide, with difficult foundation conditions, it was found to be advantageous to use a single arch span of high tensile steel with no river piers. The use of such steel made this type of bridge practicable. Had mild steel been used the bridge would have been of a different type (girder spans on piers) and would have been far more costly.

Another bridge carrying a precisely similar roadway and having the same span is now (1937) about to be built, but in a locality where the freight cost will be about £19 per ton. In this case, the suspension type of bridge with high-tensile steel stiffening trusses is the least costly the economy arising to a large extent in consequence of its smaller total weight and the reduction of freight costs.

The saving of freight costs to distant parts of the British Empire, from Great Britain, by using high tensile steel, is also in many cases the means of affecting considerable savings. For sites where the total freight may be as much as £19 per ton, this will be readily appreciated.

In using high tensile steel for bridge structures the writer has paid particular attention to reducing to a minimum the number of different sections to be used, and finds that when this aspect of design is carefully studied the small number of sections which is really essential is somewhat surprising. With a class of steel which is not in general use this is important; otherwise, costs may be greatly increased.

The possible combination of normal and high tensile steels is frequently advantageous and is made readily practicable by the fortunate, but somewhat remarkable, fact that for all steels used for structural purposes the modulus of elasticity is the same. As far as the writer has been able to ascertain, there is no more variation between values for the modulus of elasticity for different kinds of steel than there is for different specimens of the same kind. This uniformity of the modulus permits the interconnection of

181 "A History of the St. Louis Bridge", by C. N. Woodward, pub. by G. I. Jones & Co., 1881.

various classes of steel without risk of indeterminate stresses which would be caused by different moduli of elasticity.

A. V. KARPOV,[182] M. AM. SOC. C. E. (by letter).—The purpose of the Symposium is exceptionally well defined in the seven terse questions given in the "Foreword" by Mr. Jones. The papers and the discussions give at least partial answers to each of these questions, although they show also that, at the present stage of engineering development, and in all probability for many years to come, no final answer can be given on many of these problems. Engineering development forges ahead, and it seems that no better goal can be accepted by the Structural Division of the Society than to keep up to date the valuable data collected in this Symposium.

The most fundamental conclusion that can be drawn from the Symposium is the impossibility of limiting the field of advanced structural engineering to stationary structures of fundamental character. The broader viewpoint is necessary, expanding into border fields of structural design which are commonly assigned to mechanical engineering.

The determination of actual stresses in structural elements is leading into fields which are different from conventional design practice. New methods of attack are developing both in the theoretical and experimental handling of structural problems. Fatigue, impact, and creep test are supplementing the work of the ordinary metal testing laboratories; small and large scale models are being used extensively; indirect methods of strain and stress measurements have been added to the direct strain measuring methods that were used in the past; and the vibrator test is being used in the laboratory as well as in the field.

This very extensive theoretical and experimental work, which at present is being conducted in a large number of laboratories in the United States, seems to suffer from lack of co-ordination and insufficient exchange of information concerning the work proposed or being done. The different testing programs in the field of structural research that were mentioned in the Symposium, suggest the necessity for steps to be taken to remedy these conditions. The Society, which by its very nature is interested in promotion of engineering knowledge without paying undue attention to the commercial aspects, is the most logical organization which could undertake successfully such a co-ordination and co-operation and could bring closer together the different educational and industrial organizations working in the field of structural research. Such a co-operation would result in a properly planned and co-ordinated research program, eliminating unnecessary overlapping and wasteful repetition of work.

Part II of the Symposium brought out forcefully the fact that structural engineering is no longer a single-metal field. As in all fields of engineering, materials must be chosen, depending upon the suitability for each particular design. The requirements are becoming so exact that it does not seem

[182] Chairman, Committee of the Structural Division, on Fundamentals Controlling Structural Design; Designing Engr., Hydr. Dept., Aluminum Co. of America, Pittsburgh, Pa.

probable that in the near future a universal alloy will be introduced that can take the place that open-hearth mild steel took in the past.

In line with the papers and discussions of the Symposium there seem to be at present three outstanding problems that should be solved:

First.—A more suitable definition of terms that have a clear meaning in their application to ordinary structural steel, but which lose this clearness if applied to high-grade steel alloys or to light-weight alloys. More appropriate definitions of ultimate strength, yield point strength, and related physical properties of materials should be developed. The particular and most pressing objective would be the proper definition of yield point strength and its relation to other fundamental properties.

Second.—The problem, made clear in the Symposium, concerns the necessity of introducing additional characteristics of structural materials. The time-honored coefficients such as ultimate strength, yield point, and elongation are still the basic coefficients that are necessary to form engineering judgment as to the suitability of a material; but they are obviously insufficient: Fatigue, creep, impact, corrosion, and welding properties must also be considered. To give a practical definition of these properties and to outline the extent to which they should be used in structural designs is an important field that should be properly covered.

Third.—Welding is rapidly growing in importance in structural designs. The problem of weldability of alloys is encountered more in the field of metallurgy; but the manner in which welds are made is becoming a problem in structural engineering. The researches that were and are being made have disclosed the importance of fatigue considerations in welded joints. The remarkable increase in fatigue strength that may be obtained by changes in the design of welded joints, the comparison with riveted joints, and the determination of conditions under which different kinds of joints should be considered, are fields which undoubtedly will occupy the attention of the structural designer.

Part III must be considered in light of the theoretical, Part I, and the metallurgical, Part II. "The picture" that can be gained from Part III, gradually emerging from a single material stage and developing into multiple material designs, can be taken as a guide to an understanding of the development trend in structural engineering. The self-sufficiency of the structural designer of the past is gone, probably forever. The best handbooks available cannot keep a structural designer abreast of the latest practice. A correct design may result only from the correlated work of the theoretical designer, structural laboratory engineer, and metallurgist. If the structural designer wishes to maintain a leading part in this work, which naturally is his, he must possess the insight and ability to understand the problems of all the professions involved, as was evidenced to such marked degree by the author of one of the papers in Part III.

Part IV is the logical conclusion of the entire Symposium. Light-weight designs are encountered in the most recent and most modern field. The importance of this field is not often realized. Many such designs cannot be rationalized due to lack of engineering knowledge. The stability

problems, which were more or less neglected in the past, are becoming of the same importance as the stress problems. Corrosion, expected life span of a structure, fatigue and creep properties, and stress concentrations, are all problems whose importance is considerably accentuated in these designs. It is interesting to note that these problems are of particular importance in two structural fields which are as far apart as can be imagined—in aircraft and in long span bridges. The modifications of standard design formulas that were proposed during this session of the Symposium may be accepted as a clear indication of the necessity to consider the difference in properties of new alloys, as compared with structural steel. Different treatment is necessary to obtain the entire advantage of the light-weight design.

A useful field of endeavor would be to watch the trend of light-weight designs and to bring to the attention of the structural designer the most important and practical developments.

LEON S. MOISSEIFF,[183] M. AM. SOC. C. E. (by letter).—The valuable papers presented in the Symposium and the many discussions it has brought forth testify to the timeliness of the undertaking. The Society, through its Structural Division, has succeeded, at an opportune time in gathering and presenting to the Engineering Profession the knowledge, the information, and the experience of engineers active in the making of structural metals and in fabricating them, in the planning of structures, and in their design, erection, and utilization. The Society, moreover, has been fortunate in securing a group of papers which has proved interesting enough to provoke a many-sided and illuminating discussion by men of information and reflection.

The authors of the Symposium wisely did not attempt to offer complicated mathematical analyses and subtle discussions of the various phases of structures built of metal. Instead, they have presented to the profession the thoughts which have matured in their minds during many years of experience, in making and forming of metal and in designing and building structures. The Symposium has been successful in producing a representative cross-section of current American engineering thought. A comprehensive study of the papers reveals the present trend of structural development.

The Symposium has brought forth a symphony of many instruments. The low tones of the heavy metals and the high ones of the light metals unite in one sustained theme. They announce that to create structures for the wants and comforts of the many, such structures must be efficient and economical. They must be built of materials which possess suitable qualities to fulfill the special requirements and functions, and they must be workable, dependable, uniform, and enduring in order to justify the trust placed in them. It is the constant business of producers and fabricators to search and test the products of the mills and shops, and to establish the capacities and limitations of these products to sustain and endure the attacking forces and agents in space and time.

[183] Cons. Engr., New York, N. Y.

These capacities must be utilized further by the planners and designers to the best advantage so as to produce efficient and economical structures. It is the task of engineers, therefore, to strive to approach the fullest utilization of their materials in strength and endurance, in economy and comfort. Only then when the fullest knowledge of materials and structures will be gained will this aim have been attained. To acquire this knowledge it devolves upon engineers to study the true behavior of structures under the action of forces by analysis and strain measurements on models, by tests in laboratories, and by observations in the field.

The Symposium shows that engineers are realizing that the elementary approach in analyzing structures was well enough for the smaller dimensions where cheaper materials could be used and some of it could be wasted, but that for large structures the most suitable material is demanded and almost all of it should be utilized. Engineers realize that a deeper insight into the behavior of structures is required and that much of it can be attained by modern methods of analysis and search, and they feel that the application of such knowledge is imperative in the design of important structures. It must not be forgotten that the admission of higher unit stresses and larger strains demand more care in analysis and proportioning and that all advance in this direction is based on the mental probity of the engineers.

A. V. KARPOV,[184] M. AM. SOC. C. E. (by letter).—The purpose of the paper was to bring to the attention of the structural designer the fact that the theories on which structural designs are based by no means can be considered as perfect. These theories are based not only on approximations but in many instances on assumptions that are contrary to present knowledge. The result is that instead of developing theoretically correct methods, structural research is leaning toward a larger use of empirical and not correlated coefficients. The developments of fatigue data and stress concentration factors are probably good illustrations of this thought.

Professor Mirabelli's discussion gives an interesting method of a more satisfactory correlation of the experimentally determined stress-strain relation and the actual behavior of structural elements. Such investigations should be conducted extensively. Mr. Horger raises a number of most important questions in his short discussion. The boundary conditions and their influence on stress distributions is a problem that requires considerable additional study. If the influence of boundary conditions is accepted then there should be a different stress distribution within the thickness of the material and at the boundary. Figs. 3(*a*) and 9 are indicative of the most probable change of stress distribution at the boundaries for specimens subjected to tension-compression and bending, respectively. The additional data with reference to fatigue strength, size effect, and stress concentrations are not yet available and, therefore, the last question asked by Mr. Horger can not be answered at present.

The writer does not agree with Mr. Glover's conclusions that the investigators of the past gave all the necessary information that can be further

[184] Designing Engr., Hydr. Dept., Aluminum Co. of America, Pittsburgh, Pa.

developed. Theories based on incorrect assumptions cannot be satisfactorily developed beyond very narrow limits. His work on trial load arch dams and supporting rings for penstocks, mentioned in his discussion, would seem to be of very considerable interest.

R. L. TEMPLIN,[185] M. AM. SOC. C. E. (by letter).—Not only has Professor Timby amplified many points raised in the paper but he has also indicated some additional uses of models. In commenting on the merits that he has emphasized, which obtain when using stainless steel models fabricated by "shot" or spot welding, the writer wishes to state that he has used numerous spot-welded aluminum alloy models of structural units with very satisfactory results. Although it is scarcely probable that any one individual would be familiar with all the recent developments in model testing and analysis, it is apparent that Professor Timby has assembled information on a group of model studies which covers the apparent range of application quite thoroughly. The examples cited both in the paper and in the discussion, represent considerable evidence to show the increasing extent of the use of models in various engineering fields.

Many improvements have been made on strain-gages since the time the Howard gage (mentioned by Mr. Belzner) was introduced. Nevertheless, as was stated in the paper, there is still considerable of the personal equation involved in the manipulation of the modern strain-gage and this presents a factor which must be considered in obtaining and interpreting strain-gage results.

The model girder referred to by Dr. Arnstein would seem to offer some interesting advantages in certain model studies.

A problem very similar to that mentioned by Professor Ruge was encountered in the model of the Santeetlah Pipe Line.[14] The load was applied by gravity and although the model could be scaled down photographically, the result was that the stresses were also reduced photographically. Consequently, it was not sufficient simply to rely upon the model test directly, but to use it to substantiate the theoretical development for this type of loading. The example suggested by Professor Ruge appears to be likewise of this type and, therefore, an excellent one to illustrate the point raised. The gusset-plate problem that he has mentioned will not give exact similitude because the modulus of elasticity for the model would not be reduced from that of the prototype in the same proportion as the scale ratio.

Professor Klemin's reference to full-sized structural tests of aircraft is an excellent example of a case in which the load conditions on the actual structure are so indefinite as to make model testing relatively unreliable, except in the study of component parts of the structures.

J. H. A. BRAHTZ,[186] ESQ. (by letter).—In closing this paper, the writer wishes to express his appreciation for the many interesting discussions that have appeared. These discussions have brought out many points of interest

[185] Chf. Engr. of Tests, Aluminum Co. of America, New Kensington, Pa.

[186] Director, Photo-Elastic Laboratory, U. S. Bureau of Reclamation, Denver, Colo.

and valuable details which were not included, or were insufficiently elaborated, in the paper. In reviewing the discussions briefly, these will be taken up in the order in which they appeared.

In his excellent discussion, Mr. Vose emphasizes the difficulties in producing a truly two-dimensional state of stress. It is a fact that it never really occurs. In order to have a plane state of stress the plane plate $(x\,y)$ should be infinitely thin, and in the case of plane strain the plate should be infinitely thick in order to comply completely with the definitions of those states, in which the stresses σ_x, σ_y, and τ_{xy}, are independent of the elastic constant of the material. In photo-elastic experimentation, of course, a small finite model thickness is necessary. Consequently, the average stresses over the thickness of the model are measured. It is true that these stresses will be effected to some extent by the lateral stresses near discontinuities on the boundaries. On the other hand, the same effect occurs in the prototype so that the deviations between experimental and actual stresses in this respect are practically only caused by the ratios of the elastic properties in the two materials. This is one of the many reasons why the maximum errors of experimentation in such regions cannot be expected to be less than 10% and often may be even greater.

Mr. Vose calls attention to the convenient portable reflecting polariscope designed at the Massachusetts Institute of Technology, which should be of great help in the type of observations mentioned in his discussion.

In a very lucid discussion Professor Rathbun describes a number of experiments with riveted connections. The very ingenious technique of multi-materials of varying optical sensitivity no doubt will prove extremely useful in the future. The aforementioned three-dimensional difficulties now become acute. It was this problem that the writer had in mind when stating in the paper that the elastic properties of the model materials should be such as to imitate as closely as possible the conditions in the prototype. Due to plastic flow, the writer has had difficulties in calibrating the highly sensitive materials, accurately. Professor Rathbun's discussion brings out clearly the truth of the statement that "photo-elasticity has proved its value, is here to stay, and new apparatus, model materials, and technique are being developed continuously."

In his very valuable discussion Professor Timby explains clearly the three contributing reasons for an adequate safety factor. The writer is in full agreement with these viewpoints. The live loads, including wind and temperature effects, are seldom accurately known and can only be assumed for many types of structures, as for example, bridges, buildings, ships, etc. In such structures as dams these effects are defined more clearly, but many other uncertainties enter, among which may be mentioned earthquake effects and uncertainties in the quasi-elastic properties of the materials in the dam proper relative to those of the foundation. The photo-elastic laboratory of the U. S. Bureau of Reclamation has proved extremely useful in connection with designs of hyperstatic structures (for example, large drum-gates) in obtaining the most economical sections.

The interesting discussion by Mr. Solakian deals to a large extent with the history of the fundamental physical phenomena, which enables present-day photo-elastic experimentation. He argues that the polariscope designed and constructed by the writer at the California Institute of Technology and having the large field lenses replaced by aluminum-coated parabolic or spherical mirrors, will be less popular since the introduction of new "polarizing media." These polarizing glass plates will successfully replace the far more expensive Nicol prisms. The writer fails to see the point since it is the high cost of high-grade lenses *versus* the comparatively low cost of high-grade reflectors that matters.

In conclusion, the writer can state that the new interferometer of the Favre type which was recently designed and constructed by the engineers of the U. S. Bureau of Reclamation, has proved highly satisfactory in its application. The polariscope is now being used only in: (1) Such experiments, in which merely the boundary stresses are needed; (2) for preliminary design studies in order to obtain an optimum section, which is then analyzed in detail by the interferometer; and (3) for checking the principal stress differences obtained in the interferometer.

The interferometer differs from the instrument described by Favre in several respects. For example, it gives both principal stresses and their direction in one operation, whereas Favre obtains the direction and magnitude of the principal stresses in separate instruments.

M. J. R. Morris,[187] Esq. (by letter).—Referring to Mr. Herzog's discussion, the writer agrees that he has not gone into detail as far as possible, as it was the primary intention to cover as large a field in general as possible; his comments, therefore, are very well taken. There is no doubt that the addition of alloying elements, such as molybdenum and columbium, will open up new fields to the stainless alloys, and will help greatly in the actual fabrication of some of these alloys by making them more easily handled and possibly more nearly "fool-proof." As time goes on and improvements follow experimental work, these alloys will come into more and more prominence and broader use with the civil engineer just as they have already been a boon to chemical and industrial engineers in general.

Mr. Gisiger cites the application of stainless bars in connection with trash screws protecting the turbine intakes against floating logs, trash, etc., of the Holtwood Plant, of the Pennsylvania Water and Power Company, at Holtwood, Pa. This is an excellent example of the reduction in weight made possible through the use of corrosion-resistant stainless steel over structural carbon steel; also, the increased efficiency provided by decreasing the area covered by the bars, themselves, which obstruct the passage of the water.

In connection with welding these stainless alloy bars to structural carbon steel, the writer has found that, in general, a heavy, flux-coated alloy electrode will give the most satisfactory weld.

[187] Chf. Metallurgical Engr., Central Alloy Dist., Republic Steel Corporation, Massillon, Ohio.

If mild steel electrodes are used, the weld metal (which will have a smaller cross-section than the structural steel) will be subject to any localized corrosion that may be set up as a result of the stainless alloy being in contact with mild steel. If the weld, itself, is stainless, then the corrosion will be transferred to the heavy, structural shape, which will be much more capable of distributing and minimizing its effect so as to be of very little consequence.

In laying a stainless weld on mild steel, it is best to deposit at least two beads on top of each other to eliminate the effect of pollution from the steel. The lower bead fused to the steel will be less corrosion resistant than the record on subsequent beads. Such applications well illustrate previous statements as to the broad use of stainless alloys in the hydraulic field.

ZAY JEFFRIES,[188] ESQ., C. F. NAGEL, JR.,[189] ESQ., AND R. T. WOOD,[190] ESQ. (by letter).—In commenting on the writers' paper, Mr. Hobrock has given emphasis to the desirability of consulting the manufacturers of materials before making final selection of a particular alloy. Quite correctly, he points out that this is not a feature peculiar to aluminum, or to any one metal, but applies to all. However, it probably applies less to those older metals for which many years of use in a particular service have built up a present satisfactory practice by the process of "cut and try," the soundness of which has been reasonably well proved or at least accepted. In passing, it might not be out of order to suggest that following "tradition" carries with it certain dangers—namely, what was quite adequate yesterday may be inadequate tomorrow—if not to-day. Engineers should not necessarily select alloys or materials to-day because they were satisfactory a few years ago.

Materials suppliers are constantly making progress, both in the greater uniformity of the properties of materials, and in the development of improved products possessing superior qualities, range of sizes and forms, and closer tolerances. Furthermore, the manufacturer is constantly enlarging his knowledge regarding the properties of those materials.

It is the latter point that Mr. Hobrock has emphasized. Some danger, from a commercial angle, may lurk in the possibility that a purchasing agent, becoming aware of the existence of characteristics other than those commonly mentioned in purchase specifications, may unnecessarily include specifications covering non-pertinent properties. Nevertheless, as Mr. Hobrock properly states, the satisfactory performance of a structure may not depend upon the more commonly published properties, but possibly upon other characteristics such as, for example, the strength at certain elevated temperatures. Although these other fields of properties have not been fully charted, a substantial beginning has been made, and the knowledge available should be put to use. This should not result in every writer of materials specifications attempting to state and define the limits of every

[188] With Incandescent Lamp Dept., General Electric Co., Nela Park, Cleveland, Ohio.
[189] Chf. Metallurgist, Fabricating Div., Aluminum Co. of America, Pittsburgh, Pa.
[190] Chf. Metallurgist, American Magnesium Corporation, Cleveland, Ohio.

conceivable characteristic (that would be utterly unwarranted and abusive of human intelligence), but it does mean that the engineer should ferret out to just what actions his particular structure will be subjected, and then ascertain from the manufacturer what information is available as to the properties of his product with respect to those conditions. One should not expect that the desired "road map" will be forthcoming in all details, but in many cases numerous useful "land marks" can be shown.

Mr. Hobrock's contribution to this subject of "consulting the supplier" deals mainly with the uncommonly published properties of alloys. This is important. The writers' main reason for presenting this thought was somewhat different, although not at all contradictory. Progress is continually being made in the perfection of range of dimensions, both as to maximum sizes and tolerances and, more important, in knowing just what can and cannot be accomplished from an economical viewpoint. This feature is of special importance in the field of castings, although it is not confined to that field.

Slight changes in the detail design of a casting, for example, or a more complete understanding on the part of the foundryman as to how the product is to be used, may permit of a more favorable method of gating, which, in turn, may lower the cost of the product, or may permit the production of a casting in which the metal at critical locations will possess more favorable characteristics.

An alloy is defined by its composition alone. The properties of Alloy *A*, for example, may well be different when in the form of a thin sheet, as compared with a rolled shape. The processes by which the original ingot is converted into various wrought shapes may differ widely and, hence, the final characteristics may differ. Furthermore, the characteristics of the ingot (caused by the method of manufacture and the dimensions) may vary depending upon the particular wrought product for which it is intended. The structures of those different ingots are not all alike, and the effect of this original ingot difference may affect the final characteristics and, hence, one should not casually refer to "properties of the alloy" when considering the design of a structure but, rather, should think in terms of the properties of the particular type of material concerned. Many published tables fail to reveal whether the properties stated apply to sheet alone, to forgings alone, or to rolled shapes, etc. When using any table for design purposes, therefore, one should know to what particular type of product those properties apply.

James Aston,[191] Esq. (by letter).—The logic of Mr. Clapp's suggestions will be admitted by all who are actively interested in the corrosion problem. Engineers are concerned primarily with the serviceability of materials, and a systematic study which would evaluate their utility in particular types of service, or would enable one to apportion properly the effects of service factors, would be invaluable in enabling a more correct appraisal and use of metals to be made. Service data have been gathered in con-

[191] Metallurgist, Pittsburgh, Pa.

siderable amounts, largely by individual efforts of competing manufacturers, with release prompted largely by the biased discretion of the compiling interest.

Actually, the task is of great complexity and magnitude. One must have the several metals in indisputably parallel conditions of service; they must remain undisturbed throughout their service life; and, particularly, interest and records must be kept alive through the long life span of many metals in many services. In corrosion testing, the temptation is to accelerate the test, or to attempt to control conditions in a laboratory set-up. With such procedure, unbalancing of the several factors involved will probably seriously distort the results as compared with what might appear to be similar conditions in actual service. Furthermore, results from a controlled or specific type of service are applicable only to that condition, and cannot be interpreted more broadly. Finally, failure of material is the only true end point of a test, with the criterion of failure dependent upon the commodity involved and the service requirements.

By way of illustration, one may cite the sheet metal tests conducted by the Corrosion Committee of the American Society for Testing Materials. In this field, one finds a co-operating personnel of outstanding qualifications. The tests were carefully planned, were carried out on a comprehensive scale, and were painstakingly observed and recorded. The contribution to knowledge has been of great value; yet 1937 sees the passing of the twentieth anniversary of the tests, with a clearing up, at best, of only a few points related to atmospheric exposure of bare sheet steel. There is still almost as much controversy as in the beginning due to disputed points in the conduct of the tests; or a doubt regarding the practical value of tests of bare sheets when actual utilization requires paint or metallic protection; and particularly because in a twenty-year period many real or fancied advances have been made in the production of steel, with all the uncertainties and arguments formerly prevailing with respect to their relative merits.

E. C. Hartmann,[192] Assoc. M. Am. Soc. C. E. (by letter).—Many of those who have discussed the writer's paper have commented on various phases of shop practice. In his excellent description of the design and construction of the emergency bulkheads for the Gallipolis Dam, Mr. deLuccia emphasizes the need for great care in workmanship. He raises a doubt as to whether the average shop practice for structural steel is suited for aluminum alloys. Mr. Christianson also emphasizes the need for careful shop work, but states that aluminum alloys present no new problems to the shop experienced in producing a high quality of workmanship in other metals. Mr. Lehman states that with proper instructions one can rely on the shop to handle the material properly so that no parts are damaged. All these viewpoints may be summarized in the term,

[192] Research Engr., Aluminum Co. of America, New Kensington, Pa.

"good shop practice". In the writer's experience with fabrication methods in various types of construction, he has yet to find the shop which, when properly instructed, cannot produce a first-class aluminum alloy structure.

The question of riveting aluminum has received some attention by the discussers. Mr. Lehman describes the use of hot-driven steel rivets in aluminum structures and Mr. deLuccia describes cold-driven steel rivets, which is a newer development. To complete this picture a number of examples of the use of aluminum alloy rivets could be mentioned as, for instance the truss-type, traveling cranes of 76-ft spans built in 1930 and fabricated throughout with hot-driven 0.75-in. aluminum alloy rivets.

Professor Hunsaker has questioned the advisability of using steel rivets in aluminum structures because of the possibility of corrosion at the junction of the two metals in cases where the paint protection is not adequate. The possibility of such corrosion cannot be denied, and because of this possibility steel-riveted aluminum-alloy structures must receive adequate paint protection. On the other hand, tests have shown that unpainted full-sized structural joints, involving hot-driven steel rivets, subjected to sea-coast conditions for two years retain their original strength. It should be remembered in this connection that visible surface corrosion can occur without appreciable reduction of strength, particularly in structural shapes and plates which have the advantage of greater bulk compared to the thinner materials used in aircraft.

Both Mr. deLuccia and Mr. Growdon have commented on the necessity for thinking in terms of aluminum when designing structures of aluminum, especially with reference to the question of deflection. The writer was particularly pleased with this phase of Mr. deLuccia's description of the bulkheads of the Gallipolis Dam. It is quite evident that in these structures arbitrary limitations based on conventional practice were not permitted to interfere with the logical development of the design of a light-weight structure to serve a specific purpose. Aluminum structures, of course, can be designed without this approach to the problem, but maximum economy and minimum weight are rarely attained without it.

Mr. Sturm's discussion presents a refreshing and thought-provoking concept of the relation of bulk of metal to stability. Stability problems are almost certain to be encountered more frequently in light-weight construction than in conventional construction, whether the weight savings are accomplished by the use of light-weight, low-modulus materials, or by the use of thin sections of the heavier materials. The question of bulk of metal is important in both instances. In the structures made up of thin sections of the heavier metals the reduction in bulk compared to conventional construction is largely responsible for the stability problems encountered; and in light-weight materials the relatively greater bulk is advantageous in overcoming the effect of lower modulus.

Professor Plummer has suggested a more complete treatment of the economic factors which influence the selection of materials for light-weight construction. In this connection this writer was pleased to note the com-

ments of Mr. Lehman, Mr. Growdon, and Mr. Christianson, indicating that in three fields as widely separated as construction equipment, bridges, and railway cars, problems in economics arising in connection with specific applications of aluminum alloys have been solved satisfactorily. Mr. Lehman's interesting statement that, "the selling of such a benefit is often more difficult than the proof of economy," no doubt will be echoed with feeling by all who have been associated with the commercial development of the newer materials.

Two of the discussers have described aluminum alloys not specifically mentioned in the paper. As pointed out in the paper, there are several such alloys available, and the selection of the best one for a specific purpose involves a consideration of many factors. The day has passed when each engineer could expect to be familiar enough with all available materials to make his selections entirely on the basis of his own experience. Any logical modern approach to the problem of selection of material should certainly include consultation with the producers of the materials.

MEMOIRS OF DECEASED MEMBERS

ONWARD BATES, Hon. M. and Past-President, Am. Soc. C. E.[1]

DIED APRIL 4, 1936

Onward Bates was born February 24, 1850, in St. Charles County, Missouri, the eldest son of Judge Barton and Caroline Matilda (Hatcher) Bates. The family home was known as Cheneaux Farm and here his early youth was spent. He attended the local schools, but considerable of his early education was directed by his parents, and also by his distinguished grandfather, the Hon. Edward Bates.

On March 1, 1865, Onward, at the age of 15, entered the Fulton Iron Works, at St. Louis, Mo., as an Apprentice to learn the machinist trade. Edward Bates recorded in his diary this event as follows:

"Feby. 28 tuesday morning — Comes my grand-son, Onward Bates who arrived in town last night, with his aunt Sarah — Julian's wife. He comes, by previous arrangement of his father (Barton Bates), to enter himself Apprentice to Gerard B. Allen (Allen & Filley) to learn the trade of a Machinist. He is a very ingenuous youth, of good, solid parts: Not brilliant, but uncommonly heedful and apt to learn, and retentive of all he learns He is well advanced, for a boy of 15 — Has read more than most lads (perhaps without much method) — Is, as I hear, pretty well versed in Geography, Grammar, Arithmetic and Algebra — Knows a little Latin, and perhaps a smattering of German. In temper, he is docile and tractable, and in manners, respectful, orderly and moral — Yet of a firm and independent character of mind.

"I have high hopes that he will avail himself of all his opportunities, and make himself a man of whom his near kindred may be proud

"He will live with us — that is, spend his nights and spare time at our house. And so, we hope to be able to exercise a fair degree of care over his habits and associations."

Before the completion of the apprenticeship, the late Charles Shaler Smith, M. Am. Soc. C. E., who was building a bridge over the Missouri River, at St. Charles, Mo., engaged Mr. Bates as Draftsman and Inspector. This was the beginning of his engineering work. After about a year he accepted the position of General Assistant to Captain William S. Nelson, who had a contract for the caissons for the piers of the St. Louis Bridge.

In 1871, Mr. Bates entered Rensselaer Polytechnic Institute, at Troy, N. Y., as a Special Student. He attended the Institute for two years, until 1873, when he was again employed by Colonel Smith as Assistant Engineer and Inspector on the East Approach of the St. Louis Bridge and other work.

[1] Memoir prepared by a Committee consisting of T. L. Condron, Edgar S. Nethercut, and W. A. Rogers, Members, Am. Soc. C. E.

The late Don Juan Whittemore, Past-President and Hon. M. Am. Soc. C. E., has commented[1] on this employment as follows:

"Col. Smith was at that time President of the Baltimore Bridge Co., which has the contract for this east approach. While inspecting this work at the shops of the Detroit Bridge & Iron Works, he was appointed by Capt. Eads, the Chief Engineer of the St. Louis Bridge, as shop inspector for the bridge company. He thus served on the same work in the double capacity of inspector for the contractor and for his client as well. While this work was being manufactured, Mr. Willard S. Pope, President of the Detroit Bridge & Iron Works, thought there should be an adjustment of the schedule of prices paid his company by the Baltimore Bridge Co. for the metal work, and upon taking this question up with Col. Smith the latter instructed Mr. Bates to arrange with Mr. Pope a new schedule of prices which would be fair to both parties. The circumstances of the manufacture of this metal work are worth recording as showing, at that period, the confidence and respect existing between engineers, when one inspector could serve both parties and when the contract prices could be disregarded and readjusted to secure equity."

Upon the completion of this work later in 1874, Mr. Bates entered the employ of the Cincinnati Southern Railway Company as Draftsman under the late Louis Gustave Frederic Bouscaren, M. Am. Soc. C. E., Principal Assistant to the late Thomas Davis Lovett, M. Am. Soc. C. E., Chief Engineer. The late Charles Louis Strobel, Hon. M. Am. Soc. C. E., was Mr. Bates' immediate superior in the office and in charge of the design of the bridge over the Ohio River. Later, Mr. Bates was promoted by Mr. Bouscaren to be Inspector of Iron Bridges and Trestles, and he continued in this capacity until June, 1877.

He then became Inspector of Iron Bridges for the Chicago, Milwaukee and St. Paul Railway Company, under Mr. Whittemore, Chief Engineer, with headquarters at Milwaukee, Wis.

In March, 1878, Mr. Bates was sent to Australia by Colonel Smith and Mr. William Sellers, President of the Edge Moor Iron Company, of Wilmington, Del., as their representative. He remained in Australia for more than three years, returning to the United States in August, 1881. In Australia, he designed and built several iron bridges and viaducts.

In the United States, Mr. Bates was again employed with Colonel Smith and, later, became President of the Pittsburgh Bridge Company. From March, 1884, until April, 1886, he was again associated with Colonel Smith as Assistant in his practice of Consulting Engineer. For one year, from April, 1886, to April, 1887, he was engaged in mining in Mexico, following which he was with the Edge Moor Iron Works, at Wilmington, Del., until February, 1888.

Mr. Bates, at this time, returned to the Chicago, Milwaukee and St. Paul Railway Company as Engineer and Superintendent of Bridges and Buildings. For thirteen years, he remained with this Company, until March, 1901, when he organized the Bates and Rogers Construction Company. He withdrew from this Company in 1907, selling his interest to his associates, and sought to retire from active engineering. On important occasions he was chosen as

[1] *Engineering News*, February 11, 1909.

Arbitrator on engineering and contracting matters for which service his training, judgment, and fairness conspicuously qualified him.

Although he did not complete his college work, he was on many occasions honored by degrees. In 1897, the University of Wisconsin, at Madison, Wis., conferred on him the Honorary Degree of Civil Engineer. In 1918, he received the Honorary Degree of Doctor of Engineering from Rensselaer Polytechnic Institute, and, in 1924, the degree of Doctor of Laws from the University of Missouri, at Columbia, Mo.

He represented the Society on the John Fritz Medal Board of Award for four years—from 1910 to 1913—and, in 1911, he was the President of that Board. In 1918, Mr. Bates was appointed Chairman of the Committee on Development of the American Society of Civil Engineers which Committee was discharged in 1919. In this position, he showed remarkable ability and fairness. He was a Member and Honorary Member of the Western Society of Engineers and served as its President in 1899.

Mr. Bates was a member of the Institution of Civil Engineers of Great Britain; the Franklin Institute; the Royal Society of Arts (England); the University Club of Chicago, Ill.; the Chicago Engineers Club; the Theta Xi Fraternity; and for many years, was a Trustee of the Chicago Bureau of Public Efficiency.

He contributed many papers and discussions to the publications of the Society and to those of the Western Society of Engineers. Among the latter should be mentioned a paper on "Fundamentals",[3] presented in 1911, for which he received the Octave Chanute Medal, and also a paper on "Arbitration"[4] presented in 1912. He wrote and presented addresses before many engineering colleges, including Purdue University, and the Universities of Illinois and Wisconsin. His subjects for these addresses were related to citizenship and character. While with the Chicago, Milwaukee and St. Paul Railway Company, he called frequent conferences of his Staff and his addresses on these occasions were intimate and inspiring.

During his retirement he wrote delightfully regarding his family, for private circulation, and these booklets included "Bates, *et al* of Virginia and Missouri", "A Good Name", and "Onward and Onward: A Romance of Four Continents." There was a charm in his writing which was most evident in his personal correspondence which he continued until a short time before his death.

While the engineering accomplishments of Onward Bates were conspicuous and important, he will be remembered because of his outstanding character. By his devotion to the principles of his religion, he became the friend and counselor of all who came in contact with him. He sought to do well by every one and gave of his ripe judgment to establish right and justice in his dealings, as well as in his engineering practice.

In 1892, Mr. Bates was married to Virginia Castleman Breckinridge, of St. Louis, Mo. Mrs. Bates survives him. He had no children to bear his name, but it is with pride that those, who either worked under his direction

[3] *Journal*, Western Soc. of Engrs., Vol. XVI, November, 1911, p. 769.
[4] *Loc. cit.*, Vol. XVII, June, 1912, p. 481.

or were associated with him in his societies, claim to have received from him inspiration for better engineering and life. Mr. Bates always evidenced a great desire to be helpful, by counsel and inspiration, to the young men with whom he came into contact.

He was a member of the Presbyterian Church which he joined in 1866, and which he served as an Elder for many years. His high ideals were inspired by his Christian experiences and his love of the good name which he inherited and which he maintained honorably through his entire life. He has left behind him a memory of inspiration, counsel, example, and love. The profession has profited by his life.

Mr. Bates was elected a Member of the American Society of Civil Engineers on January 4, 1882, and an Honorary Member on October 15, 1923. He served as Vice-President of the Society in 1906 and 1907 and as President in 1909.

MILO SMITH KETCHUM, Hon. M. Am. Soc. C. E.[1]

Died December 19, 1934

Milo Smith Ketchum was born on January 26, 1872, on a farm three miles north of Elmwood, Ill., the son of Smith Ketchum and Ann (Clement) Ketchum. He was the ninth in direct descent from Edward Ketchum who came from England to Ipswich, Mass., in 1634. The history of the Ketchum family is typical of many families which go to make up the history of America. The children and the children's children of Edward spread to Connecticut, Long Island, New York, and 1800 found them near Cayuga, N. Y. While many of them remained in the United States after the Revolution, some of them were loyalists and moved to Canada, settling in the Provinces of Ontario and New Brunswick.

The branch of the family to which Milo Smith Ketchum belonged went to Crawford County, Ohio, in 1822, and settled near Bucyrus, on the northern edge of Sandusky plains in Whetstone Township. Other New England families to whom the possession of land was a great ambition were settled in this vicinity. His father, Smith Ketchum, was born near Bucyrus, Ohio, in 1840, and went to Illinois in 1852. He was one of a family of six tall men, all of whom were more than 6 ft in height. The lack of educational opportunities was no measure of his education. He attended an academy near his home where he studied the common branches of knowledge, ancient history, and algebra, and thus gained the foundation for two striking abilities he had later in life, that of an excellent public speaker and conversationalist. For more than forty years Smith Ketchum was a Minister in the Primitive Baptist Church, preaching without compensation and ministering to the people of his community who made up that brotherhood. He was a powerful

[1] Memoir prepared by W. C. Huntington, M. Am. Soc. C. E.

and formative influence in the life of his son, as well as on the lives of those about him. He had a fine and discriminating feeling for the dignity of personality. Self-determination and States' rights were a part of his family tradition which went back to a great-grandmother who was a descendant of Roger Williams. This feeling led to his interest and sympathy for the Confederacy during the Civil War.

Milo Smith Ketchum grew up in the companionship of his father and in the tradition of freedom. From him during the long days on the farm, he learned to know intimately the wild life of the plains. This love of the open and the soil was never lost, for during the whole of his mature life Dean Ketchum owned and directed several large farms in Colorado and Kansas.

The country schools of Illinois provided the elementary education of Milo Smith Ketchum. These schools were ungraded, so that it was possible to advance in any subject as fast as the student was able to progress. His interest from the beginning was in mathematics and history. He finished the regular nine-term course in the Elmwood, Ill., High School, in five terms, and took a teacher's examination in Peoria, Ill. The following years were occupied in the task of teaching country schools. During this time he took the examination for the United States Military Academy, at West Point, N. Y., but the appointment went elsewhere and this was an end to his interest in military affairs.

His great interest in mathematics led him to enter the University of Illinois, in 1891, where he chose Civil Engineering because that course contained more of his favorite study than any of the other divisions. His college days were filled with concentrated study in the field of his choice.

During the summer of 1893, Mr. Ketchum taught surveying at the Michigan School of Mines, at Houghton, Mich., and it was here that he was first initiated into the problems of mine structures. From these, and from later experiences in the Coeur d'Alene, in Idaho, he drew the material for his book on "Mine Structures" (1912).

In June, 1895, he received the degree of Bachelor of Science in Civil Engineering, with the distinction of being the Valedictorian of his Class. The two following years were spent as Assistant in Civil Engineering and Mathematics at the University of Illinois. Since there was little or no opportunity for graduate work in Civil Engineering at that time, he turned his activities to the career of a practicing engineer. In 1900, he was awarded the professional degree of Civil Engineer by his Alma Mater.

During the period of nine years immediately following his graduation from the University of Illinois, he served as Instructor and Assistant Professor of that institution; as Structural Engineer with the Gillette-Herzog Manufacturing Company, in Montana and Idaho, during the period of labor troubles shortly after the Bunker Hill-Sullivan catastrophe; and as Contracting Manager at Kansas City, Mo., for the American Bridge Company. His period of service with the American Bridge Company, although short, meant much to him. In this organization he became acquainted with many men whose friendship he valued very highly throughout his life. He was glad to be known as an "American Bridge Company man".

In 1904, Professor Ketchum was appointed Head of the Department of Civil Engineering at the University of Colorado, at Boulder, Colo., and a year later was also made Dean of the College of Engineering. The next fifteen years were among the happiest of his life. Throwing himself into the numerous and varied duties of building an outstanding institution from a very small beginning, he made many life-long friends among his students and colleagues. In this position, he had a marked influence on the lives of many of the men who came in contact with him in their early manhood and who prized his friendship highly in later years. The success of many of his former students can be attributed quite largely to their association with him, and not a few of them chose careers in college teaching because of the inspiration received from him.

In 1919, Dean Ketchum resigned his position at the University of Colorado to become Director of Civil Engineering at the University of Pennsylvania, at Philadelphia, Pa., and, in 1922, he joined the Staff of the University of Illinois, at Urbana, Ill., as Dean of the College of Engineering and Director of the Engineering Experiment Station. Here he enjoyed his associations with many of his friends of earlier days and with other members of the Staff who worked with him in advancing the already high standards of these organizations. "'Alertness and a spirit of co-operation throughout the staff were outstanding accomplishments of Dean Ketchum's leadership". Because of ill-health he resigned as Dean and Director at the College of Engineering at the University of Illinois in 1933, and was appointed Research Professor of Civil Engineering. In this capacity he again took up the investigation of pressures in deep bins, the subject on which he had written his Bachelor's thesis and which had continued to interest him. In September, 1934, he retired from the active Staff, but he remained in Urbana, and his affiliation with the University as Dean Emeritus continued until his career was ended.

Dean Ketchum's first book, "The Surveying Manual," which appeared in 1900, was written jointly with W. D. Pence, M. Am. Soc. C. E., then a member of the Staff at the University of Illinois, and was the outgrowth of his early teaching experience in surveying. His next book, "Steel Mill Buildings," was developed at the request of the publishers from a paper presented by him in 1902 before the Illinois Society of Engineers and Surveyors, later known as the Illinois Society of Engineers. Dean Ketchum wrote the remaining four books of this remarkable series while he was at the University of Colorado, serving as Dean and teaching a full-time schedule in the Civil Engineering Department. "Walls, Bins, and Grain Elevators" appeared in 1907; "Highway Bridges" in 1908; "Mine Structures" in 1912; and the "Structural Engineers Handbook" in 1914. From that date much of his time was required in keeping his many books abreast of the times. The total sales of Dean Ketchum's books have been considerably more than 100 000 volumes. His books should continue to exert a strong influence on structural practice under the direction of his competent and well-trained son, Milo Smith Ketchum, Jr., Jun. Am. Soc. C. E.

Although primarily a teacher, college administrator, and author, Dean Ketchum devoted quite a portion of his time to his consulting practice. Much of this work was done along with other duties, but on two occasions he was on leave of absence from the University of Colorado. During the years, 1909 and 1910, he joined H. S. Crocker, Past-President, Am. Soc. C. E., to carry on an extensive engineering practice under the firm name of Crocker and Ketchum, with headquarters in Denver, Colo. During the World War, Dean Ketchum was assigned the almost impossible task of representing the War Department in the construction of the \$70 000 000 smokeless powder plant at Nitro, W. Va. This was a rush job necessarily started with incomplete plans, with many organizations at work, with conflicting interests, and with no clear definition of authority and responsibility at the beginning. Twenty thousand men were at work placing nearly three hundred car loads of materials per day. He performed this task with the greatest credit to himself and to those whom he represented.

Dean Ketchum was always active in the affairs of technical societies and inspired younger men to become interested in such organizations. During his earlier years at the University of Colorado, nearly one-fourth of his income was devoted to attending engineering society meetings. Then, and particularly later, he felt fully repaid for this sacrifice. He was a member of the American Society for Testing Materials, the American Railway Engineering Association, the American Concrete Institute, the Western Society of Engineers, the Illinois Society of Engineers, the Society for the Promotion of Engineering Education, Sigma Xi, and Tau Beta Pi. He was a national honorary member of Chi Epsilon Civil Engineering Fraternity.

Honors came to Dean Ketchum from many sources. He was elected Secretary and President of the Society for the Promotion of Engineering Education; Director (1918–1920) and Vice-President (1925–1926), of the American Society of Civil Engineers, and shortly before his death he was elected an Honorary Member of that Society, an honor which comes to few. He was awarded the honorary degree of Doctor of Science in 1926 by the Colorado School of Mines, and, in 1927, by the University of Colorado.

From the humble beginning of a country school-master, Dean Ketchum rose to be one of the nation's foremost educators. To train men for life by means of engineering rather than to teach them engineering was his philosophy.

As an author he won distinction through his many outstanding books. Having combined teaching and practice in his own experience and showing rare judgment in the selection and preparation of material and skill in its presentation, he produced books which were pioneers in their respective fields and which were of service alike to student and practicing engineer.

As an engineer, his services were often sought as a consultant in structural design, as an arbitrator in controversies arising out of construction operations, and as an expert on patent litigation.

He was frank and definite in stating his position on matters that were referred to him. He valued highly the friends which he had in all parts of the United States and in all walks of life. In his last address given to

a group of civil engineering students just four days before his death, he spoke feelingly of the meaning of friendship.

He was an intensely human man, large in stature and intellect, with strong and upright character, dynamic personality, and rare judgment who seemed destined to lead. He had the capacity for making quick decisions which would stand the test of deliberate analysis, and he never wavered in the face of difficulty or opposition but was inspired by them.

Dean Ketchum's life was rich in accomplishment and his influence will continue through his many books, through the organizations in the development of which he played an important part, and through the many men who are stronger because of their association with him.

He was married on September 17, 1903, to Mary Esther Beatty, of Newton, Iowa, and is survived by his widow and three children, Martha Esther (Mrs. N. C. Debevoise), Elizabeth Jane, and Milo Smith Ketchum, Jr.

Dean Ketchum was elected an Associate Member of the American Society of Civil Engineers on September 4, 1901; a Member on March 3, 1908; and an Honorary Member on October 2, 1934.

CHARLES LOUIS STROBEL, Hon. M. Am. Soc. C. E.

Died April 4, 1936

Charles Louis Strobel was born in Cincinnati, Ohio, on October 6, 1852, the son of Karl and Ida L. (Merker) Strobel. His early education was received in the public schools of Cincinnati, which he left in 1869 to enter the Royal Institute of Technology, in Stuttgart, Germany, from which he was graduated in 1873 with the degree of Civil Engineer.

It seems significant that there is no record of any scientific analysis of stresses in framed structures prior to the Sixteenth Century, nor any similar record from that time until about 1840. Construction was carried on by the "fit-and-try" method and successful attempts were recorded and duplicated while others were improved or discarded. Essentially all the fundamental development in the use of iron and steel in framed structures occurred during the 50-yr period succeeding 1840.

Following the early discovery of the scientific mathematical principles of design, and during this development period, there lived a group of engineers who, by their initiative, developed not only the scientific principles of construction, but also the means of carrying on the work. Charles Louis Strobel was one of this group.

From 1874 to 1878, he was Assistant to the late L. G. F. Bouscaren, M. Am. Soc. C. E., Chief Engineer, Cincinnati Southern Railway Company (now a part of the Southern Railway Company). Mr. Strobel, being in

[1] Memoir prepared by the following Committee: Albert F. Reichmann, *Chairman*, Edward Haupt, and George T. Horton, Members, Am. Soc. C. E., for publication jointly by the American Society of Civil Engineers and the Western Society of Engineers.

charge of the design of bridges and viaducts, found it necessary to analyze competitive designs submitted by competing bridge companies. Two of the notable structures designed and built under his supervision were the Ohio River Bridge, in Cincinnati, with one span of 519 ft, and the Kentucky River High Bridge built on the cantilever principle. The construction on this railroad was in advance of the times, and Mr. Strobel introduced, probably for the first time in the United States, the method of calculating stresses from definite locomotive-wheel concentration followed by uniform train loads. This method has since become common practice. He further contributed to the development of the scientific design of structures by computing the bearing and shear values of rivets and the bending, as well as shear and bearing values, of pins.

Mr. Strobel was Engineer and Assistant to the President of the Keystone Bridge Company, in Pittsburgh, Pa., from 1878 to 1885, and, from 1885 to 1893, its Consulting Engineer and Agent in Chicago, Ill., as well as Consulting Engineer for Carnegie, Phipps and Company, Limited, the Chicago, Milwaukee and St. Paul Railway Company, Burnham and Root, Architects, and others. While acting as Consulting Engineer for Carnegie, Phipps and Company, Limited, Mr. Strobel standardized rolling-mill practice by designing standard sections for I-beams and channels.

He originated Z-bar columns which were used as towers by the Chicago, Milwaukee and St. Paul Railway Company for a viaduct in connection with the Randolph Bluffs Bridge, over the Missouri River, and many other structures.

The steel work for the Chicago Auditorium, Adler and Sullivan, Architects, was designed under his supervision, the late Edgar Marburg, M. Am. Soc. C. E., assisting in the design. Mr. Strobel supplied the steel to Mr. H. A. Streeter for the Tacoma Building, and also for the Woman's Temple, Home Insurance Building Annex, in Chicago, and many other buildings since replaced in many instances by more modern and larger structures.

Mr. Strobel's connection with the development of steel skeleton construction and numerous railroad and highway bridges over the Missouri, Mississippi, Ohio, and other rivers, is a matter of record.

One of his most notable achievements was the design and construction, in 1890, of the 525-ft span for the Ohio Connecting Railway, over the Ohio River below Pittsburgh. This structure was erected on falsework, 143 ft high, on coal barges and floated into place. The structure weighed 900 tons and the falsework an additional equal amount, making a total of 1 800 tons.

Probably the most important contribution of Mr. Strobel to Engineering Science was the development and publication of a handbook of information on the use of iron and steel in construction. This book was first edited by him in 1881 and was entitled "A Pocket Companion of Useful Information and Tables Appertaining to the Use of Wrought Iron for Engineers, Architects and Builders." Later editions giving the properties of steel sections were prepared and edited by Mr. Strobel in 1884, 1887, 1890, and

1892, and published by Carnegie, Phipps and Company. These early publications were the bases of later editions generally known as the "Carnegie Handbook." Supplemented by similar books of other manufacturers, these handbooks did much to promote the use of steel in construction by supplying a reliable source of information not otherwise available to prospective users of steel.

In 1894, Mr. Strobel entered into a contract with the City of Chicago for the construction of the first Rolling Lift Bascule Bridge, which was designed by the late William Scherzer, M. Am. Soc. C. E. This connection led to his activities in this type of construction and, under his direction and supervision, a number of bascule bridges of various types were designed or constructed. In collaboration with Mr. Theodore Rall, the "Rall" type was successfully developed.

In 1895, Mr. Strobel designed for Mr. James B. York, wide, flanged, I-beam sections, 8, 9, 10, 12, and 15 in. deep, as well as 18, 24, and 30-in. I-beams, all to be rolled in universal mills. The smaller sections were the forerunners of the present column sections and the 30-in. section of the present girder beams. Mr. York failed to interest American manufacturers in his process which later was developed abroad.

Mr. Strobel organized the Strobel Steel Construction Company in 1905 to take over his personal business, and he was active in its management until his retirement in 1926

In 1890, he was married to Henrietta Baxter, of Chicago, who died in 1905. There were two children by this marriage, Charles L. Strobel, Jr., and Marion (Strobel) Mitchell. The latter has attained prominence in the literary world as a poetess and authoress as well as a book reviewer. In 1910, he married Mary Wilkins who, with his two children, survives him.

Mr. Strobel was very much interested in literature, the theater, music, and world affairs and subscribed to many publications. Being possessed of a retentive memory he could discuss intelligently foreign as well as domestic affairs. He was independent in politics, but always interested in electing the best men to office.

He attended services at St. James Protestant Episcopal Church and also those of the Chicago Ethical Society conducted by Dr. Horace J. Bridges.

Mr. Strobel was a man of high integrity and was moderate in all things. His modesty and diffidence at times created the impression of aloofness which did not exist, and on close acquaintance he was most friendly and affable.

Those fortunate enough to be present recall with much pleasure the celebration of his eightieth birthday at the Chicago Engineers Club, when he and his lifelong friend, the late Onward Bates, Past-President and Hon. M. Am. Soc. C. E., were presented with Honorary Membership in the Club.

In the summer of 1934, while on vacation in Santa Barbara, Calif., he suffered an illness which rendered him temporarily blind and although he recovered in a small measure, he severely felt the handicap of not being able to read as before. When able, he continued his attendance at the

Chicago Orchestra Concerts and Sunday Church services. His inability to get around freely and maintain his former friendly contacts caused him much regret.

His passing on April 4, 1936, removed another of that group of truly great pioneer engineers who, by establishing the fundamentals of scientific design and construction, have built the bridges over which the present and future generations may pass.

He was a member of the Western Society of Engineers (Trustee from 1892 to 1895), and a member of the Institution of Civil Engineers of Great Britain, the New York Engineers' Club, the Chicago Club, as well as the Onwentsia, University, Commercial, Casino, and Arts Clubs, of Chicago.

Mr. Strobel was elected a Member of the American Society of Civil Engineers on December 3, 1879, and an Honorary Member on October 3, 1932. He served as a Director of the Society for the term ending 1886, and again in 1894, to fill a vacancy. He was Vice-President in 1911-1912, but later declined the nomination for President as he felt that the office should be filled only by an engineer engaged in purely professional work.

WILLIAM ANDERSON AYCRIGG, M. Am. Soc. C. E.[1]

DIED MAY 30, 1936

Born in Passaic, N. J., on April 26, 1859, William Anderson Aycrigg, the son of Benjamin Bogert Aycrigg and Catherine Elizabeth (Anderson) Aycrigg, received his preliminary education at the D. S. Evertson School, in New York, N. Y. He entered Rensselaer Polytechnic Institute, at Troy, N. Y., in 1880, from which he was graduated in June, 1884, with the degree of Civil Engineer.

During the first months after his graduation, Mr. Aycrigg was employed in the Engineering Department of the City of Omaha, Nebr., and his special work was in connection with the surveying and laying out of new streets in that young but rapidly growing city. The following year found him with the Union Pacific Railroad Company as Assistant Engineer, with headquarters at Omaha, which position he held for three years.

In 1888, Mr. Aycrigg was with the Birmingham (Ala.) Bridge and Bolt Company, from which he went to the Edge Moor Bridge Works, at Wilmington, Del., with which Company he was Assistant Engineer from 1889 to 1891. He then went to New York City where he opened an office as Consulting Engineer and where he remained until the end of 1898. At that time he accepted the position of Supervising Bridge Engineer with the Union Pacific

[1] Memoir prepared by Edward W. Aycrigg, Esq., Stamford, Conn.

Railroad Company at Omaha. He was in charge of the replacement of all the wooden trestles with steel bridges from Omaha as far west as the State of Utah. Mr. Aycrigg remained with the Union Pacific Railroad Company until the fall of 1905. He then went to San Francisco, Calif., where he was engaged as Bridge Engineer for the Western Pacific Railroad Company which was building a new railroad line to the coast. Most of his work was the construction of bridges in the Feather River Canyon, through which the road-bed was being laid. He remained with the Western Pacific Railroad Company until the spring of 1908, when he returned to Omaha and opened an office for private practice as a Consulting Engineer.

Two years later he moved to Stamford, Conn., where he continued his practice as a Consulting Engineer for a number of years before finally retiring from business.

Mr. Aycrigg was a Thirty-second Degree Mason, a member of the Chi Phi Fraternity, the Stamford Yacht Club, and the Woodway Country Club. He was a communicant of the Protestant Episcopal Church and, at the time of his death, was a Vestryman at St. John's Episcopal Church, in Stamford. He was also very much interested in the Boy Scouts of America. He had been connected with that organization since 1912, and had received the Silver Beaver as a token of his work. In regard to Mr. Aycrigg's "service to boyhood", the following editorial appeared in the *Stamford Advocate*, on January 15, 1932:

"Our fellow townsman, William A. Aycrigg, has every reason to be proud of the distinguished service medal awarded to him last Wednesday by the Executive Committee of the Boy Scouts of America, and Stamford shares in the honor due to one of her citizens. The service rendered by him to the boys of Stamford has been, not only distinguished, but has been long.

"Mr. Aycrigg early saw the possibilities in the Boy Scout movement and started in as the first Scout leader of Stamford as long ago as 1912. His interest was not a flash in the pan. Through all these years he has been an active supporter of the movement.

"The job of being a Scoutmaster is not an easy one. The master has to have tact and patience. Unless he is regular in his own attendance, he can not expect regularity in the attendance of the boys. It is not enough to have the motive of loyalty to the community. The leader in such an enterprise must have real liking for the boys and must have retained, in large measure, his own boy spirit.

"Mr. Aycrigg's distinction is that he has been a guide and counsellor of the individual boys and has also been a guide and counsellor of the Boy Scout activities in Stamford. He has been zealous in promoting the formation of other troops and in encouraging the expansion of the work. The distinguished service medal is a symbol of the high value that lies in disinterested work in behalf of the rising youth of any community."

On October 20, 1887, he was married to Jessie Kelsey Wilcox. Mrs. Aycrigg, a daughter, Mrs. Lee Roy Robbins, a son, Edward W. Aycrigg, and seven grandchildren survive him. A son, William Arthur Aycrigg, died in 1910.

Mr. Aycrigg was elected an Associate Member of the American Society of Civil Engineers on May 4, 1892, and a Member on May 4, 1898.

JOHN CAPRON BALCOMB, M. Am. Soc. C. E.[1]

Died November 25, 1936

John Capron Balcomb was born in San Diego, Calif., on March 2, 1878. He was the son of Robert G. and Frances M. (Spencer) Balcomb. Both parents originally came from the East, his father from Salem, Mass., and his mother from Ithaca, N. Y. Soon after John's birth the family moved to Denver, Colo., where he received his education in the public schools and in the Denver High School.

Mr. Balcomb started his career in the engineering field at the age of 20. Between 1898 and 1901 he was engaged in work for the State of New Mexico as Draftsman and Instrumentman on river gaging and canal surveys. In September, 1901, he joined the Engineering Staff of the Santa Fé Central Railway Company (later, the New Mexico Central Railway Company), first as Engineer in charge of thirty miles of grading, and, later, as Chief Draftsman in charge of mapping and designing; he located and surveyed a 75-mile pipe line between Deming, N. Mex., and El Paso, Tex., and did all the mapping and drafting for this work.

Between October, 1904, and March, 1906, Mr. Balcomb had field charge of main-line reconstruction and bridge work for the Denver and Rio Grande Railroad Company; from April to December, 1906, he was Resident Engineer for the St. Louis, Rocky Mountain and Pacific Railroad Company, at Raton, N. Mex., in charge of grading, bridge work, and track-laying on two residencies.

Mr. Balcomb was with the Chicago, Milwaukee, and St. Paul Railway Company, in Montana, from January, 1907, to May, 1911, as Resident Engineer on heavy main-line construction, and on the location and mapping of town sites, including the field work and mapping of a 12 000-acre irrigation project. From June to August, 1911, he was with the Idaho-Northern Railway Company, in Idaho, as Resident Engineer in charge of heavy mountain construction.

In September, 1911, he left for Brazil where he was employed by the Rio de Janeiro Tramway, Light and Power Company, Limited, in charge of all engineering, including surveys and design and the construction of the $5\frac{1}{4}$-mile Pirahy Tunnel; he became Chief Engineer of the Company and, for two years, was principally occupied in investigating, and in making reports on, hydro-electric projects.

Mr. Balcomb returned to the United States in July, 1916, and was engaged in contracting work as a member of the firm of George V. Slack and Company, until the end of 1917. In January, 1918, he went as Division Engineer for the Chile Exploration Company, to Chuquicamata, Chile, in charge of work involving heavy excavation, reinforced concrete and structural steel erection for smelters, machine shops, foundries, mill buildings, etc. From August,

[1] Memoir prepared by Eugene E. Halmos, M. Am. Soc. C. E.

1919, to February, 1922, he was in business for himself as a Contractor on sewer construction in New York City. In March, 1922, he returned to Brazil as Engineer in charge on reclamation and dam work at Ceara, for Dwight P. Robinson and Company.

In March, 1924, Mr. Balcomb joined the Staff of Stevens and Wood, Engineers and Constructors, and remained with that organization for eight years. In this period he constructed three large steam power stations, one at Toronto, Ohio, another at Deep Water, N. J., and the third at Sioux City, Iowa. Between September, 1929, and March, 1931, he was in charge of the construction of the extension of the Spier Falls Hydro-Electric Station on the Hudson River, in New York State. It was during the execution of this difficult undertaking that the writer first had an opportunity to become intimately acquainted with Mr. Balcomb. Between September, 1932, and November, 1933, he was Superintendent in charge of highway construction and the erection of the beautiful three-hinged arch bridge over the Ausable Chasm, in Essex County, New York.

In the early part of 1934, Mr. Balcomb was appointed Surveyor for the Forest Service of the Department of Agriculture, with headquarters at Charleston, S. C. In September, 1934, he joined Parsons, Klapp, Brinckerhoff and Douglas, Consulting Engineers, as Supervising Construction Engineer of the Sutherland Project, on the writer's staff at North Platte, Nebr., and continued in this position until July, 1936, when he was transferred to the Engineering Department of the New York World's Fair of 1939. He became ill at his desk about six weeks prior to his death.

Mr. Balcomb always regretted that, due to lack of money, he was not able to acquire a college education. He spent much of his spare time in studying and educating himself in the theory of engineering and always kept himself well informed of the advances in the profession as recorded in textbooks and periodicals He had a splendid physique, was an indefatigable worker, and was most interested in the execution of large and difficult undertakings, which he was eminently fitted to study from both a practical and a theoretical point of view. He had a remarkable knowledge of construction machinery and particularly of all types of earth-moving equipment; his judgment of the choice of proper construction methods and machinery was infallible. He was very methodical and accurate in keeping costs of construction work and the data thus collected enabled him to make reliable estimates on projected work. He was a kind-hearted but exacting executive, and was respected and liked by both his superiors and by those under him.

In private life he was a splendid family man, a good companion, and a brilliant conversationalist. He was very fond of classical music and never missed an opportunity to hear a worth-while operatic performance or a concert.

Mr. Balcomb was a Mason, a member of Montezuma Lodge, of Santa Fé, N. Mex., a Knight Templar, and a member of the Mystic Shrine; he was also an active Rotarian and lectured at many Rotary Club meetings on technical subjects.

He was married, in 1916, to Helen Pope Robertson, of Charleston, S. C. She and one son, John Duncan Balcomb and two brothers, Kenneth C. and Spencer Balcomb, survive him.

Mr. Balcomb was elected a Member of the American Society of Civil Engineers on January 19, 1920.

ANGUS FRANCIS BARCLAY, M. Am. Soc. C. E.[1]

Died January 31, 1937

Angus Francis Barclay, the son of William and Elizabeth (Anderson) Barclay, was born in New Orleans, La., on January 20, 1879. He was educated in the public schools of New Orleans and the Soule Business College, at that time a semi-technical as well as a business school.

In 1897 and 1898 Mr. Barclay was employed as Rodman on the location and construction of the New Orleans and Northeastern Railroad (later, a part of the Southern Railway System).

He held a position in the fabricating shops of the Berlin Iron Bridge Company, at East Berlin, Conn., in 1899 and 1900. Leaving this position in 1900, he returned to railroad engineering and was employed, successively, by the Illinois Central Railroad Company on line and grade revision work in Tennessee; by the St. Louis and San Francisco Railroad Company on the construction of the Chalmette Terminal, in New Orleans; and by the New Orleans and Northeastern Railroad Company as Locating Engineer.

In 1906, Mr. Barclay accepted a position as Rodman with the New Orleans Public Belt Railroad and was promoted, successively, to Field Engineer, Chief Engineer, and General Manager, which positions he held during the entire time from 1906 until his death, with the exception of a period between 1912 and 1916, during which time he served as Construction Engineer for the Trans-Mississippi Terminal Company (later, a part of the Texas Pacific-Missouri Pacific System) on the construction of its freight and passenger terminals in New Orleans. Fully 90% of the New Orleans Public Belt Railroad was constructed under Mr. Barclay's direct supervision.

In 1926 and 1927, he served as a member of the Advisory Board of Engineers with Ralph Modjeski, the late Daniel E. Moran, and Howard C. Baird, Members, Am. Soc. C. E., which Board was charged with the design of the foundations and superstructure of the Mississippi River Bridge, at New Orleans, and although the construction of the bridge was under the direct supervision of Modjeski, Masters, and Case, Mr. Barclay kept closely in touch with all the details of the construction.

[1] Memoir prepared by a Committee of the Louisiana Section, consisting of V. J. Bedell, J. A. McNiven, and A. F. Theard, Members, Am. Soc. C. E.

Always interested in the welfare of the Engineering Profession, he was an active member of the Louisiana Engineering Society.

Mr. Barclay enjoyed the respect and admiration of his fellow members of the Society and his associates and the leading citizens of New Orleans, and his outstanding character and integrity reflected high honor upon his profession.

On July 3, 1907, he was married to Kentucky Oliver, of Brookhaven, Miss., who died in 1929. He is survived by three children: Mrs. Allen B. Rogers, William O. Barclay, and Dorothy Barclay.

Mr. Barclay was elected a Member of the American Society of Civil Engineers on January 16, 1928.

ALBIN HERMANN BEYER, M. Am. Soc. C. E. [1]

Died April 19, 1936

Albin Hermann Beyer, the son of Hermann Albin and Theckla (Schmidt) Beyer, was born near Freiburg, in Saxony, Germany, on September 19, 1880.

Although the area near Freiburg had been a great mining center in earlier days, the first mining school in the world having been founded there in 1702, the principal industry in the small village where the Beyer family was settled was the manufacture of wooden toys. Hermann Albin Beyer apparently realized that machine methods would displace the older hand methods, even in this field, and was interested in developing this necessary machine equipment. In connection with the manufacture and distribution of these machines, he came to the United States in 1893, bringing his son, Albin, with him. Young Beyer, then thirteen years old, was placed in public school and, later, entered the Boys' High School, in Brooklyn, N. Y., from which he was graduated in 1899, entering the Civil Engineering Course at Columbia University in New York, N. Y., in the fall of the same year.

As a student at Columbia University, Mr. Beyer won high honors and was elected to Tau Beta Pi and Sigma Xi, honorary fraternities. Although he was of a studious type of mind and did not enter organized athletics, he was of strong physical build, took part in many class battles, and was an expert swimmer. He enjoyed in particular the outdoor life and experience at the Summer Surveying Camp, Camp Columbia, near Litchfield, Conn., which has been an important element in the Civil Engineering Course at Columbia for more than fifty years. In fact, upon graduation with the degree of Civil Engineer in June, 1903, he accepted an appointment for the summer as Assistant at the Camp, and also found it possible to return in the summers of 1904 and 1905.

Upon the close of the Camp in 1903, Mr. Beyer was appointed Instructor in Mechanics at Cornell University, at Ithaca, N. Y., holding this position

[1] Memoir prepared by J. K. Finch, M. Am. Soc. C. E.

until September, 1905, when he entered active practice in connection with a railroad location survey in Indiana.

His experience at Cornell under that outstanding teacher of mechanics, Professor Church, was always recalled by Mr. Beyer, not only with great pleasure, but as a most valuable element in his engineering training. The work at Cornell also included one season with the Cornell Summer Surveying Group.

When, upon completion of the railroad location survey in the fall of 1906, the project did not go forward to construction, Mr. Beyer returned to New York City to become Time-Keeper and, later, Superintendent of Construction on the Pelham Bay Bridge. This work, consisting of six concrete arch spans and a Scherzer lift, was built by the Godwin Construction Company. This job having been completed, Mr. Beyer, in October, 1907, became Assistant Superintendent of the power-house and yards of the Church E. Gates Lumber Company, in Brooklyn, and, later, he superintended a building operation in The Bronx. It was in October, 1908, however, that he entered upon an engagement as Designing Engineer and Principal Assistant to Alexander Potter, M. Am. Soc. C. E., a Consulting Engineer, in New York City, engaged on the designs of various water supply and municipal works. This position Mr. Beyer held for nine years.

It will be recalled that the technique of analysis and design in reinforced concrete was being rapidly developed during this period. Mr. Beyer, possessing to an unusual degree a keen analytical mind in mechanics, and also having an intensely practical viewpoint, originated for Mr. Potter a number of designs in this then comparatively new material, which established his reputation as a versatile and practical designing and construction engineer. These designs were part of plans for water supply, sewerage, and drainage systems for a number of cities in the United States, Canada, and Cuba, such as Coatesville, Pa., Muskogee, Okla., Corpus Christi and San Antonio, Tex., etc., but his work also involved as well appraisals and the design of miscellaneous other structures.

In October, 1917, Mr. Beyer received an appointment as Associate in the Department of Civil Engineering at Columbia University, and the remainder of his career was devoted to teaching. In 1920, he was appointed Associate Professor, and, in 1928, became Professor of Civil Engineering.

At the time Professor Beyer joined the Faculty at Columbia, it was anticipated that, although American engineers had been slow and conservative in following European trends in this field, continuous structures would become of increasing importance in American engineering practice. Professor Beyer's first problem, therefore, was to broaden the instruction in Strength of Materials and Structural Analysis and Design to meet these anticipated developments. The structural tradition in the Department had been established by the late William Hubert Burr, M. Am. Soc. C. E., and Professor Beyer, responsible for this broadened Structural Engineering program, carried on this tradition of a progressive and forward-looking viewpoint in a most effective and constructive manner. In spite of the fact that he was intensely individualistic in his manner and methods, Professor Beyer was a

born teacher. In addition, he brought to his teaching that rare combination of practical experience and a highly developed ability in the field of mathematical and mechanical analysis which is possessed by so few men. He treated his students as he did his own sons, and the high regard in which they held him both as a friend and as a teacher is attested by the fact that they dedicated to him the Yearbook of the Engineering School which was published just about the time of his death.

His duties at Columbia also involved the direction of the work of the Civil Engineering Research Laboratories. The personnel of these Laboratories have not only conducted many of the approval tests for the Building Departments of the several Boroughs of New York City, and a large number of special tests and researches for various public organizations and engineering industries, but they have also undertaken a considerable amount of fundamental scientific and engineering research. Professor Beyer's direction of all this work, in addition to his teaching duties, even with the aid of a loyal and enthusiastic staff, was a very considerable burden. His duties also involved the maintenance and operation of the Columbia Fire-Testing Station at Greenpoint, Brooklyn, N. Y., and the development of a photo-elastic laboratory which has done pioneer work in this new and interesting field. Professor Beyer's enthusiasm and willingness to talk over with and assist his associates in the solution of their problems remain as a permanent inspiration and influence in this field. He always gave the same attention and care to his University duties that he devoted to his own personal affairs.

Professor Beyer maintained an extensive consulting practice during his almost twenty years of University service. He served on many committees having to do with building, construction, and machinery problems, such as the Committee on the Revision of the New York Building Code, the Committee of the American Society of Mechanical Engineers on Shafts and Bearings, and several committees of the American Society for Testing Materials. He was particularly interested in the development of fire-resistant construction in buildings.

He was a member of the American Society for Testing Materials, the American Concrete Institute, and the American Fire Protective Association.

In 1909, he was married to Emma Eiermann, who died in 1934. Two of his sons, Theodore and Harold, survive him.

Professor Beyer was elected a Member of the American Society of Civil Engineers on July 11, 1921.

JOHN BIDDLE, M. Am. Soc. C. E.[1]

DIED JANUARY 18, 1936

John Biddle was born in Detroit, Mich., on February 2, 1859, the son of William Shepherd and Susan Dayton (Ogden) Biddle. His forebears

[1] Memoir prepared by General Biddle's niece, Miss Susan Dayton Copland, Detroit, Mich.

had been identified with the military service of their country since the middle of the Eighteenth Century. During the War of 1812, his grandfather, John Biddle, was sent on duty from Philadelphia, Pa., to Detroit. After the war, he was given a grant of land near the latter city and, instead of returning to Philadelphia which had been his home, he settled on his new property.

John Biddle—his grandson—had his early schooling in and near Detroit and in Philadelphia. In his "Memoirs" which he wrote informally in 1931, he described at length his childhood days in the country near Detroit, where he and his brothers enjoyed their outdoor life, hitching a young steer to their toboggan, riding horseback, fishing, and nutting. Schooling here was in the typical little school house of the MacGuffey Reader days, and he and a brother were paid $1.50 per week for keeping the school clean and the stove fires going. When he was thirteen years old, he went to school in Geneva, Switzerland, for three years, and then to Heidelberg, Germany, for six months. At seventeen years of age, Mr. Biddle entered the University of Michigan, at Ann Arbor, Mich., where he took the "Latin Scientific" Course for a year. He found it possible, in addition to his required work, to read extensively in the University Library, making himself "especially well acquainted with the early English dramatists." (At that time, 1876–1877, there were no organized athletics and no gymnasium. A nondescript football game was played in which each side consisted of as many boys "as happened to turn up".) During the year at Ann Arbor, he became a member of the Delta Kappa Epsilon Fraternity.

His entrance to the United States Military Academy, at West Point, N. Y., hung on a thread of chance. One day early in August, 1877, his father saw a newspaper notice of a competitive examination to be held in Detroit for the cadetship at West Point. His son took the examination and received the appointment from Michigan. He was graduated from the Academy in 1881, second in his Class.

Following West Point, he was a student at the Engineer School of Application, at Willet's Point, N. Y., from September 30, 1881, to June 15, 1884; Engineer Officer, Department of Dakota, U. S. Army, in charge of all surveys and reconnaissances for military purposes in that Department to December 15, 1887; and Assistant Instructor of Practical Military Engineering, at West Point, N. Y., to April 1, 1891. During this tour of duty, he was sent on detached service to Johnstown, Pa., after the disastrous flood of 1889, and rendered valuable service in the relief work there. He was then stationed, until June, 1898, at Nashville, Tenn., as Assistant and in charge of river and harbor work. Until June, 1893, he was Assistant in the Engineer District, in local and responsible charge of a survey of part of the Tennessee River, and of open channel work on the Upper Tennessee and Cumberland Rivers, and their tributaries, including, snagging, excavation, dam-building, a dike at the mouth of the Cumberland River, and extensive shore protection at the mouth of the Tennessee. From June, 1893, to June, 1898, he was in charge of the improvement of the following rivers: The Tennessee, above Chattanooga, Tenn.,

and below Bee Tree Shoals; the Cumberland above and below Nashville, in Kentucky, and Tennessee; and the Hiawassee, Caney Fork, French Broad, Little Pigeon, Clinch, and Obion Rivers, in Tennessee. He was also in charge of the supervision and construction of various bridges across these rivers.

In February, 1898, he was designated a Delegate to the Eighth International Congress of Navigation which was held in Brussels, Belgium, in July of that year.

At the beginning of the Spanish-American War, he was commissioned Lieutenant-Colonel and Chief Engineer in the 6th Corps, 1st Division, U. S. Volunteers, the first troops to enter Puerto Rico. From August to December, 1898, he was stationed at New York City, Lexington, Ky., and Macon, Ga. Following this, he was Chief Engineer of various Departments in Cuba, until September 19, 1899. On January 1, 1899, the City and Fortress of Matanzas, Cuba, was delivered to Lieut-Col. Biddle, who was commanding the American forces there, and the American flag was raised on the Fortress and all public buildings.

Lieut.-Col. Biddle was discharged from Volunteer Service in May, 1899. In August, of that year, Gen. James H. Wilson, U. S. Army, then of the Headquarters Department of Matanzas and Santa Clara, Cuba, wrote to Brig.-Gen. John M. Wilson, Chief of Engineers, as follows:

"Now that they are raising additional volunteer regiments and are going to prosecute the War in the Philippines with vigor, I am very anxious that John Biddle shall have an opportunity to participate in the campaign * * *. He is one of the very best and most active officers in your corps. He is particularly energetic and enterprising in reconnoitering and surveying country, and I am sure he would gain distinction for himself and shed lustre upon the engineers if he had a chance in the Philippines. I have therefore to ask if you can not arrange to send him there * * *. If you would do this you would confer not only a favor upon me and him, but I am sure you would contribute largely to the success of the war in that far away region."

From September, 1899, to March 29, 1900, Captain Biddle was en route to and in Manila, Philippine Islands, as Engineer Officer of the Department of the Pacific. He was then Chief Engineer Officer of the Philippines Division until April 28, 1901, on which date he was commissioned a Major in the Regular Army. He was en route to and in the United States, serving on a Military Board until August 1, 1901.

Following this, Major Biddle was assigned for six years as Engineering Commissioner for the District of Columbia, a longer period of service than any of his predecessors. The tributes paid him at a farewell reception given in May, 1907, by fellow commissioners, department heads, and employees, suggest his work and the quality of service which he gave during this period. Commissioner MacFarland addressed the assembly as follows:

"In all the general work of the Board of Commissioners determining policies, deciding disputed questions, advocating the District's interest before Congress and administering the District's affairs, you have done

your full part. The recommendations you have made to the Commissioners as to the affairs especially assigned to you as Engineer Commissioner have always been well considered, judicious, and progressive. They gave the Board just the basis it needed for intelligent action and showed your thorough grasp of the duties of the Engineer Department. At the public hearings of citizens, so necessary and illuminating under our form of government, at meetings of citizens' associations, and in private conferences, you have shown that spirit of co-operation which is essential to the relations between the Commissioners and the citizens and have helped to maintain the good understanding which makes so strongly for effectiveness in the common effort for the advancement of the national capital. We wish you could have remained for the opening of the District Government building, the union station, the sewage disposal system, and the Connecticut Avenue bridge, all representing so much of what especially turned on your recommendations."

Speaking for the employees the Collector of Taxes, E. G. Davis, added, in reference to the public improvements with which Major Biddle had been associated:

"These things do not successfully progress by chance, they need not only technical ability but careful and continued attention. But what has most endeared you to the employees in this building is your uniform kindness and courtesy to your subordinates, which is, after all the test of a true gentleman * * *. We believe that you have appreciated our fidelity to you and to the public service and we want you to know that your kindness to us without ostentation has made it a privilege to serve under you. For my own part I desire to say that I have felt a keener intellectual edge after every interview with you."

While Major Biddle was serving in this capacity, he was detailed, in 1902, to Gen. James H. Wilson as Senior Aide-de-Camp to attend the coronation of King Edward the Seventh.

Commissioned a Lieutenant Colonel in 1907, Colonel Biddle was assigned as Chief Engineer Officer of the Department of California and Division Engineer of the Pacific Division. His service in this capacity lasted until 1911, and included river and harbor work at various points in California and at Honolulu, Hawaiian Islands, with headquarters at San Francisco. Commissioned Colonel in 1911, he was detailed, until 1914, as a member of the General Staff in charge of the War College Division. That he performed his duties with distinction is evident from a letter of June 30, 1914, written to him by Maj. Gen. W. W. Witherspoon, U. S. Army, then Chief of Staff, which expresses "deep regret at your separation from the General Staff during my term of office as chief of that body. The earnestness of purpose and the industry and acumen that you brought to bear upon all the work you had as head of the War College Division of the General Staff, in my opinion, places you at the head of the eligibles for most important classes of duty."

This opinion of his work was confirmed by Maj.-Gen. Leonard Wood, U. S. Army, the same month when he wrote to Colonel Biddle:

"I have just learned of your relief from duty on the General Staff, and, although no longer Chief of Staff, it may not be improper, inasmuch as most of your service on the General Staff came under my direct obser-

vation, to express to you my very high appreciation of the manner in which you conducted the affairs of the War College Section of the General Staff. The work done by you was particularly satisfactory and the results attained reflect great credit upon you, not only because of their value and merit, but because they were secured under conditions of considerable difficulty incident to the injection into the General Staff of a very large amount of new personnel. I regret exceedingly, that the General Staff is no longer to have the benefit of your experience, information, and sound judgment."

Colonel Biddle's next service was in Savannah, Ga., where he was in charge of rivers and harbors from July to September, 1914. The World War had broken out in Europe in August, 1914, and he was assigned as Military Observer with the Austro-Hungarian Army in Western Galicia and Poland from November, 1914, to June, 1915. He returned to the United States to be in charge of rivers and harbors in Baltimore, Md., and Wilmington, Del., for a few months. He also served as a member of the Board of Engineers on Rivers and Harbors.

On July 1, 1916, he was appointed Superintendent of the United States Military Academy, at West Point, by President Wilson. He served as such until May, 1917, when he was assigned to organize and command the 6th United States Engineers, a special regiment which was among the first of the troops sent abroad by this country in the World War. He had been given the rank of Brigadier-General, U. S. Army, on May 15, 1917, and was promoted to Major-General, National Army, on August 15, 1917. He commanded the United States Railway Regiments with the British Army in France from July through October, 1917, laying railroads for the use of the American and Allied troops.

He then was ordered to Washington, D. C., to become Assistant Chief of Staff "acting as Chief much of the time through General Bliss' absence in Europe on the Supreme War Council." In March, 1918, he was sent to England to command Base Section No. 3, including all American troops and activities in the United Kingdom. He served in this capacity until July, 1919.

In a letter to General Biddle dated June 13, 1919, the Hon. Newton D. Baker, Secretary of War, wrote,

"Now that we are nearing the end of our work abroad, I am glad to have an oportunity to tell you how valuable it seems to me your work in England has been. From the beginning of your command there, I have never had a complaint or an unfavorable comment. Indeed, all returning soldiers and travelers speak with uniform gratitude and approval of you and your staff. This has given me deep satisfaction, and I am sure it will be pleasant to you to know that your labors have been thus successful."

Later, Mr. Baker again wrote in commendation of his service there, as follows:

"General Biddle performed his task in England with the greatest possible success; the dispatch of many hundred thousand soldiers through England was accomplished under his direction smoothly; the relations

between American soldiers and English soldiers were maintained in a cordial way, and the military business of the War Department with the War Office in London was dispatched promptly and intelligently."

Appreciation of his work during this period was expressed by General Pershing, also, in a letter written June 29, 1919:

"It would be difficult to say all the things I could say of the way your big task has been handled. Your consummate tact and your understanding of the British have continued to leave us a record that we are all proud of.

"You are leaving with the good will of the people among whom you have lived and served, and with the appreciation of all your own countrymen who know of your fine record.'"

The British, likewise, were generous in their praise of General Biddle's services. In July, 1919, J. A. Corcoran, of the War Office in London, wrote the General, "The (Army) Council for their part would take this opportunity of recording the high sense which they entertain of the spirit of co-operation and comradeship with which their endeavors have at all times been met in the task which lay before the two Governments and Armies."

In recognition of his work abroad, General Biddle was made an Honorary Member of the Military Division, Knight Commander, Order of the Bath in Great Britain, and was given the award of the Royal Victorian Order, and the Distinguished Service Medal, "for exceptionally meritorious and distinguished services. In command of American troops in England, by his tact and diplomacy in handling intricate problems, he made possible the transshipment of thousands of men to France. To his executive ability the efficient handling, control and dispatch of casual troops through England is largely due." He was also elected Honorary Knight Vice-President of the Ancient Club of the Knyttes of Ye Round Table.

While in London, General Biddle, with several American officers, took as their residence the house of Sir John and Lady Harrington (the latter the daughter of the late Senator James McMillan of Michigan). Through their establishment they were able to fulfill the social obligations which fell to them as representatives of their country. The Prince of Wales attended their dances, and the association of these years probably accounted for General Biddle's traveling with him as a member of his staff on the Prince's subsequent visit to the United States. In this connection, it is interesting that during President Wilson's stay in England, General Biddle accompanied him on his visit to King George V.

On returning to the United States from England in August, 1919, General Biddle was in command at Camp Travis, Texas, and, later, of Camp Custer, Michigan, until he was retired as Brigadier-General at his own request on December 1, 1920, after forty-three years of service.

In 1924, General Biddle was notified of the following citation: "John Biddle, Brigadier General, United States Army, retired, then Lieutenant Colonel, Chief Engineer, 6th Army Corps, United States Volunteers.

For gallantry in action against Spanish forces at Coamo, Porto Rico, August 9, 1899." This entitled him to wear the Silver Star for gallantry in action.

On June 21, 1930, he was promoted to Major-General, U. S. Army, (Retired). He maintained no residence after his retirement, but traveled extensively in Europe and America, finding friends wherever he went. His health gradually failed and, after two years of invalidism, he died at Fort Sam Houston, Texas, on January 18, 1936, at the age of seventy-six.

General Biddle will be remembered because of his brilliant military career; but, more than this, because he was a genius in the art of human relationships. His friends were legion, and of all ages and stations in life. He will be remembered by them for his loyalty, his ability to project himself into their lives and see through their eyes, his light touch of humor, and his personal sacrifices for them. His devotion to the members of his large "family," whether or not they conformed to his code, was outstanding, and he opened opportunities for many of the younger generation at his own expense and personal inconvenience. Never marrying, he undertook to educate and launch a number of boys in whom he became interested from time to time.

The numerous quotations included herein suggest that his tact and ability to endear himself to others were invaluable assets in the performance of his military duties. Assignments to European duty of one type or another throughout his career point to a recognition of his eligibility for such service because of these qualities, his background, and his facility with languages.

As his life is reviewed, it is striking how General Biddle steadily advanced to the rich fulfillment of the promise of his youth. That he was destined for responsibility and achievement seemed evident from his boyhood. In 1874, when he was fourteen years old, his professor in Geneva, Switzerland, wrote of him:

"John is a serious young man, conscientious and very gifted. He has worked well, he has achieved success without the least appearance of struggle or fatigue. He is a pupil as I like them and how I wish that mine were all like him. We are already very fond of him, and his behavior at home is not only beyond reproach but extremely amiable.

"Although he is serious minded his maturity is not the artificial kind that comes from lack of vitality. Indeed he knows very well how to laugh and enjoy himself with his comrades. He has a certain shyness, very gracious at his age because it does not come from lack of decision or energy. I have great hopes for John and anticipate a great future for him."

That he lived up to this promise and his later opportunities is evident from these pages. His achievement is epitomized in the terse final paragraph of the announcement of his death issued by Maj-Gen. E. M. Markham, Chief of Engineers, U. S. Army, M. Am. Soc. C. E.:

"Admired by all who knew him, General Biddle's distinguished service in a long and varied career will always serve as an inspiration to the officers

of the Corps of Engineers. He excelled both as a Military leader and as an Engineer."

General Biddle was elected a Member of the American Society of Civil Engineers on July 4, 1894.

HARRY CHESTER BOYDEN, M. Am. Soc. C. E.[1]

Died October 25, 1936

Harry Chester Boyden, the son of Mason A. and Cornelia W. Boyden, was born in Readville, Mass., on April 23, 1873. Descended from a family prominent in New England life since 1700, his father and grandfather lived in Worcester, Mass., and it was here that young Harry received his Grammar and High School education. He then entered Worcester Polytechnic Institute, from which he was graduated in 1894 with the degree of Bachelor of Science in Civil Engineering. He returned to the Institute later to receive the degree of Civil Engineer in 1923.

The first year after his graduation from the Institute Mr. Boyden spent in Melrose and Waltham, Mass. This was followed by seven years in the Engineering Department of the Boston and Albany Railroad Company on construction, maintenance of way, and the design of grade separation structures.

In 1902, he started West, going to Corning, N. Y., where he was Assistant Resident Engineer on double-tracking of the New York Central and Hudson River Railroad. In December of the same year, he went with the Delaware, Lackawanna and Western Railroad Company as Assistant Engineer on Construction and built the Car Repair and Locomotive Shops, at Scranton, Pa. He was also engaged on the construction of third-track and a tunnel near Scranton.

Mr. Boyden then went to California with the Atchison, Topeka and Santa Fé Railway Company and was one of the first Resident Engineers of the Los Angeles County Highway Commission, under the late Frank Hall Joyner, M. Am. Soc. C. E., a former New Englander, who was its Chief Engineer. The California Highway Commission was being organized at this time, and its Chief Engineer, the late A. B. Fletcher, M. Am. Soc. C. E., sought Mr. Boyden who held several important residencies.

A few days after the United States entered the World War, Mr. Boyden was commissioned a Captain in the Engineer Corps. Although scheduled three times for overseas service he was kept on training work at Camp Humphreys, Virginia, being advanced to the ranks of Major and Lieutenant Colonel. Later, he was commissioned Colonel in the Engineer Reserve Corps.

[1] Memoir prepared by George D. Whittle, M. Am. Soc. C. E.

After the war, Colonel Boyden spent some years with the Portland Cement Association on promotional work, and then followed a period as Dean of the College of Engineering, Ohio Northern University, at Ada, Ohio, and five years with the Celite Company, lecturing at universities throughout the United States.

During this period, his health began to fail, as a result of a weak heart which followed an attack of influenza during the war, and pleurisy and diabetes forced him to retire from active work in 1929. Retirement, however, did not bring back health, and a lowered vital resistance sent him in 1935 to the Veterans' Hospital, at Livermore, Calif., where he died on October 25, 1936. Funeral services were held at the Chapel of the Chimes, in Oakland, Calif.

On December 22, 1896, he was married to Emilie Louise Schreiner, of Springfield, Mass. He is survived by his widow, a daughter, Marion Alice Skiolvig, a son, Robert Eldridge Boyden, and two grandchildren.

Colonel Boyden was a member of Painted Post Lodge, A. F. and A. M., of Corning, N. Y., and of Berkeley (Calif.), Post No. 7 of the American Legion.

During the years prior to his retirement, he wrote many articles on concrete and related subjects. His judgment in engineering matters was respected by his associates. He was a man of high ideals, of strong convictions, and a firm believer in the American home and for what it stands.

Colonel Boyden was elected a Member of the American Society of Civil Engineers on June 3, 1908.

EDWARD GATLING BRADBURY, M. Am. Soc. C. E.[1]

Died March 11, 1936

Edward Gatling Bradbury was born in Brooklyn, N. Y., on June 14, 1870, the son of Edward Emerson and Sarah Jane (Sykes) Bradbury, and was a lineal descendant of Thomas Bradbury, of Wicken Bonant, England, who came to America in 1630 as an agent of Sir Fernando Gorges, Governor of Maine, and who, settling in Agamenticus (York) Me., and, later, in Salisbury, Mass., became quite an important figure in early Colonial affairs—his wife, Mary, having been condemned to death as a witch during the Salem insanity, but not executed.

In 1881, Mr. Bradbury's parents, after residing some years in Dedham, and Somerville, Mass., moved to Providence, R. I., where he received a public school education and was graduated from the High School in 1888.

Immediately after his graduation, Mr. Bradbury obtained employment on the Staff of the City Engineer of Providence, the late Samuel Merrill Gray,

---

[1] Memoir prepared by G. Gale Dixon, Clyde T. Morris, and Frank A. Barbour, Members, Am. Soc. C. E.

M. Am. Soc. C. E., and served as "Assistant" under Mr. Gray and his successor, the late J. Herbert Shedd, M. Am. Soc. C. E., until 1890, when he resigned to take a position as Recorder and, later, as Inspector in the United States Army Engineer Office, at Newport, R. I., in charge of Major W. R. Livermore and, later, of the late General (then Captain) William Herbert Bixby, U. S. Army, M. Am. Soc. C. E., who subsequently became Chief of Engineers, U. S. Army. His work included wreck removal, dredging, and the building of breakwaters and jetties.

In the summer of 1892, Mr. Bradbury found employment under F. Herbert Snow, M. Am. Soc. C. E., then City Engineer of Brockton, Mass., as Chief of Party on surveys preliminary to the construction of the sewerage system of that city. He continued his service under Mr. Snow as Assistant Engineer on sewer design and grade crossing abolition until November, 1897, when he became the first employee of the newly formed engineering partnership of Snow and Barbour. In 1899, when this firm opened an office in Columbus, Ohio, he moved to that city as its Western Representative and continued as such until 1905. During this period he supervised the construction of sewers and sewage disposal systems in Mansfield and Lakewood, Ohio, and at numerous institutions, and made plans for sewerage systems at Springfield, Cuyahoga Falls, and Wadsworth, Ohio.

In 1905, Mr. Bradbury took over the Columbus Office and continued in private practice in his own name until 1922—except for a period of two years when Mr. George P. Shute was associated with him under the firm name of Bradbury and Shute. In this private practice, Mr. Bradbury designed and supervised the construction of twenty or more sewerage and water supply systems, including those at Galion, Sidney, Bremen, Medina, Columbiana, and Alliance, in Ohio, and Crystal Falls, Mich. In his private practice, he also investigated and reported on numerous water supply, sewerage and sewage disposal projects, including such municipal systems as those at Newark, Zenia, Norwalk, Niles, Delaware, Salem, and Van Wert, in Ohio, and Iron River, Mich.

From 1910 to 1917, Mr. Bradbury was associated with Frank A. Barbour, M. Am. Soc. C. E., of Boston, Mass., under the firm name of Barbour and Bradbury, in various professional undertakings, independently of the individual practice of the two members. Under this association, the improved water supply system of Akron, Ohio, was designed and constructed, Mr. Bradbury acting as Resident Engineer on the entire work. Other work done by the firm included investigations and reports on the water supply for the Goodyear Tire and Rubber Company, the Goodrich Rubber Company, Columbia Chemical Company, and on flood protection at Tiffin, Ohio.

In 1917, on a call from the Supervising Engineer at Camp Devens, Massachusetts, Mr. Bradbury promptly responded, and designed and supervised the construction of the sewerage system and, in its later stages, of the water supply system at that cantonment.

Returning to Ohio late in 1917, Mr. Bradbury was appointed County Sanitary Engineer of Franklin County—coincidentally with the creation of

the department and office—and continued to hold this position until his death. In 1922, the expansion of the County work compelled the practical abandonment of his private practice.

As County Engineer, he designed and supervised the construction of approximately 200 miles of water mains and sewers, involving the expenditure of more than $3 000 000. He served as Secretary for many years and also as President of the organization known as the Ohio Conference of County Sanitary Engineers, and he has been credited with having been responsible, more than any other person, for the County Sanitary Law now operative in Ohio. In the development of the method of assessing betterments now largely in use in this County work, he was particularly interested. He was the author of the paper entitled "County Sewer District Work and Assessment of Cost According to Benefits."[2]

Mr. Bradbury was a member of many technical organizations and a Past-President of the Ohio Engineering Society, the Engineers Club of Columbus, and of the Central Ohio Section of the Society. His ethical standard was of the highest and his personal integrity above reproach. "Brad", as he was known to his intimates, was a many-sided personality—a steadfast friend, considerate, alert, humorous, and a distinct social addition to any group. His capacity for rapid, quantitative thinking was notable and presumably inherited. An uncle had been the author of "Bradbury's Arithmetic" and other textbooks well known to past generations of school boys. An unusual flair for the impromptu production of humorous verse was also a notable characteristic.

In his family life, Mr. Bradbury was fortunate. He was married in 1894 to Cora Bell Gay, daughter of Alford and Frances I. (Swett) Gay, of Brockton, Mass., and three children were born to the union. His widow and two sons, Alford Gay and Irving Lewis, survive him.

At its meeting on March 11, 1936, the Central Ohio Section of the Society passed the following resolution:

"*Whereas,* Edward Gatling Bradbury was a Past-President and honored member of this Central Ohio Section of the American Society of Civil Engineers; and

"*Whereas,* Through his untiring service and staunch loyalty this Section was organized and has enjoyed continued success; and

"*Whereas,* His fellow members feel deeply the loss of Mr. Bradbury as a respected friend and valued associate because of his fine character, outstanding ability and congenial fellowship:

"*Be It Resolved* that we, the Central Ohio Section of the American Society of Civil Engineers, do and hereby does express to Mrs. Bradbury and all the other members of his family our heartfelt sympathy at their great loss.

"*Be It Further Resolved* that a copy of this resolution be sent to his family."

Mr. Bradbury was elected an Associate Member of the American Society of Civil Engineers on November 7, 1906, and a Member on August 31, 1909.

---

ERNEST WILLIAM BRANCH, M. Am. Soc. C. E.[1]

DIED MARCH 8, 1936

Ernest William Branch was born in Smithfield, Me., on March 26, 1863, the son of William David and Ann Eliza (Newcomb) Branch. He was graduated from Williston Seminary, at Easthampton, Mass., in 1883; received the degree of Bachelor of Arts from Boston University, at Boston, Mass., in 1888; the degree of Bachelor of Laws from Suffolk Law School, at Boston, in 1916; and was admitted to the Massachusetts Bar the same year.

Mr. Branch began his professional career with the firm of Whitman, Breck and Company, Civil Engineers, of Boston, while still in college, and upon graduation he remained in the employ of that Company. In 1896, he was a member of the firm of Whitman and Branch.

On August 1, 1896, the Board of Sewerage Commissioners of the City of Quincy, Mass., appointed Mr. Branch as Engineer for the Board on the construction of a sewerage system for the city. On February 20, 1905, the system was substantially completed. This work comprised the building of forty-five miles of sewers, a pumping station, and a force main about three miles long, connecting with the Boston Outfall Sewer in Squantum, Mass.

Upon the completion of this sewerage system, Mr. Branch returned to private practice, with an office in the Adams Building, in Quincy. For a number of years, he also maintained an office in Boston. His general practice covered most of the Northeastern States. He was a Registered Engineer and Surveyor in New York State.

During the World War he served as Project Engineer for the United States Housing Corporation on its three tracts in Quincy, and, in addition, gave instruction in Surveying to men in training for the United States Army.

Mr. Branch was a member of the Boston Society of Civil Engineers, and Beta Theta Pi, and President of The Boston University Alumni Association. He served as Councilor-at-Large in the City Council of Quincy during 1909 and 1910.

He was prominently identified with Bethany Congregational Church, of Quincy, and for many years was Superintendent of the Sunday School.

Mr. Branch was a man of cheerful disposition, a great lover of children, of which he had none, and was greatly respected in his community. As an Engineer, he was a hard and indefatigable worker, and always had the ethics of the profession at heart.

He died on March 8, 1936, at Daytona Beach, Fla., where he maintained a winter residence. He was buried at Camden, Me.

On March 18, 1890, he was married to Fairvilla A. Gould, of Camden, Me., who survives him.

Mr. Branch was elected a Member of the American Society of Civil Engineers on September 6, 1905.

[1] Memoir prepared by George H. Newcomb, Treas., Ernest W. Branch, Inc., Quincy, Mass.

JOHN BRUNNER, M. Am. Soc. C. E.[1]

DIED JUNE 15, 1936

John Brunner was born in Weddige, Sweden, on November 22, 1864, the son of John and Anna Brunner. He received his early education in the public schools of Sweden, and, later, attended special schools preparatory for college. He entered the Royal Institute of Technology, at Stockholm, Sweden, in September, 1883, and was graduated in May, 1887, with the degree of Civil Engineer.

Mr. Brunner served in the Engineering Corps of the Swedish Government during the summers of 1884, 1885, and 1886, and after his graduation, until December, 1887, he was Assistant Engineer on Construction, in connection with the survey and the construction of the Northern Trunk Line, Swedish State Railroad, to the iron ore deposits in Northern Sweden.

In March, 1888, he came to the United States and his first position in this country was as Draftsman with the Stonemetz Printing Machine Company, at Millbury, Mass., where he was employed from May to July, 1888, at which time he left to take the position of Assistant Engineer in the Bridge Department of the Boston and Maine Railroad Company. He held this position until June, 1890, when he was appointed Assistant Engineer with the Mount Vernon Bridge Company, at Mount Vernon, Ohio. In September of that year, Mr. Brunner was promoted to the position of Chief Engineer, which position he held until May, 1895. During this period the Mount Vernon Bridge Company built numerous bridges under his supervision for the Pennsylvania Railroad Lines, the Cleveland, Cincinnati, Chicago and St. Louis Railroad Company; the Cleveland, Akron, and Columbus Railroad Company; the Chicago, Peoria, and St. Louis Railroad Company; the West Side Metropolitan Elevated Company, in Chicago, and for the Cities of Chicago, Ill., and Cleveland, Ohio. The Bridge Company also fabricated the steel work for the Administration Building and the Art Galleries for the World's Columbian Exposition in Chicago.

In May, 1895, Mr. Brunner accepted the position of Assistant Engineer in the Engineering Department of the Carnegie Steel Company, and shortly thereafter was promoted to be Assistant Chief Engineer of the Structural Division. It was at this time that the Duquesne (Pa.) Works of the Carnegie Steel Company was rebuilt and new equipment and buildings were added to the Homestead (Pa.) Works and the Edgar Thomson Works. Mr. Brunner also had charge of the steel designs for the Call Building and the Ferry Building, in San Francisco, Calif., which buildings survived the earthquake without any damage as a result of the precautionary measures taken in the design of the steel work to withstand earthquake shocks.

[1] Memoir prepared by a Committee of the Illinois Section consisting of Albert F. Reichmann, M. Am. Soc. C. E., Walter G. Zimmermann, Assoc. M. Am. Soc. C. E., and B. F. Affleck, Esq., of Chicago, Ill.

In July, 1896, Mr. Brunner became Bridge Engineer, and, later, Chief Engineer, of the City of Pittsburgh, Pa. Under his direction several new bridges were built and old bridges remodeled; and the construction of Bigelow Boulevard was begun and completed. Extensive relief sewers, carried through tunnels, were also constructed to take care of the excessive rainfall which occasionally occurred in the East Liberty Section of the city. Mr. Brunner left this position in 1902 to accept that of Assistant General Superintendent of the North Works of the Illinois Steel Company, in which capacity he served until 1912. During this period new mills and new ore-handling equipment were constructed at the South Works of the Company. The designs of the structural work of buildings and ore-handling equipment and the fabrication and erection were handled by the North Works. The erection of buildings at the Gary (Ind.) Works and the designs for some of the structural work were also handled by the North Works.

In April, 1912, Mr. Brunner was transferred to the Chicago Office of the Illinois Steel Company, in charge of Metallurgy and Inspection, and from July, 1923, to January, 1936, he was Manager of the Department of Metallurgy and Inspection. In January, 1936, he was appointed Consulting Engineer of the Company.

During Mr. Brunner's service with the Illinois Steel Company, extensive experiments and investigations of rails were made, beginning in 1912 with investigations of the strength of rails at low temperatures, and other experiments on repeated stresses to determine the cause of so-called "transverse fissures."

The metallurgy and inspection of steels obtained from the Illinois Steel Company by foreign countries during the first years of the World War (1914–1918) were in Mr. Brunner's charge. Later, after the United States entered the war, he was placed in charge of the metallurgy and inspection for the munition and ordnance steels furnished by the Illinois Steel Company to munition and gun-makers for the United States Government. This work was done in consultation with the Ordnance Divisions of the Army and Navy, in Washington, D. C.

After the war, he again took up the investigation of rails with thermal treatment which resulted in the adoption of comparatively simple and practicable methods of operation by means of which rails of longer durability and greater safety under traffic are rolled. Other carbon and alloy steels were also investigated and improved through proper thermal treatment.

Mr. Brunner was married on November 16, 1892, to Cora Mitchell, of Mount Vernon, Ohio, who survives him.

In 1919 he was knighted by the King of Sweden in the Royal Order of the North Star (Kungliga Nordstjerne Orden) for his achievements in engineering research. In February, 1936, he was awarded the John Ericsson Medal by the American Society of Swedish Engineers for development work in improving steel rails by heat treatment.

Mr. Brunner was a member of the American Society for Testing Materials, Western Society of Engineers, American Iron and Steel Institute, American

Railway Engineering Association, Army Ordnance Association, Association of American Steel Manufacturers (President, two years), Art Institute of Chicago (life member), and a Fellow of the American Geographical Society. His club activities included the Chicago Engineers and Alpine of Canada. He was a member of the Masonic Fraternity.

Mr. Brunner was elected a Member of the American Society of Civil Engineers on March 2, 1898.

ROBERT DUNN BUDD, M. Am. Soc. C. E.[1]

Died July 30, 1935

Robert Dunn Budd was born at Petersburg, Va., on October 29, 1873, the son of Judge Joseph S. and Frances E. (Dunn) Budd. After receiving his preliminary education at the famous McCabe School, at Petersburg, he attended Hampden-Sidney College, at Hampden-Sidney, Va., for two years, and the Virginia Military Institute, at Lexington, Va., for three years.

From 1894 to 1898 Mr. Budd was associated with Captain R. T. Dunn, of Petersburg, in private engineering practice. He was then, for two years, with the Richmond, Petersburg and Carolina Railroad Company as Instrumentman and, for a time, as Resident Engineer.

After engaging in non-technical activities for about three years, Mr. Budd, in 1903, was employed on engineering work for the City of Petersburg, the Virginia Passenger and Power Company, and the W. Brill Lumber Company. From October, 1903, to August, 1904, he was with the Richmond, Fredericksburg and Potomac Railroad Company as Draftsman and Engineer.

In August, 1904, Mr. Budd was appointed as City Engineer of Petersburg, in which capacity he served until his retirement, because of ill health, in October, 1930. Upon retirement as City Engineer, he was appointed Consulting Engineer to the city, holding that position until the time of his death.

In his work as City Engineer, Mr. Budd exercised a profound influence upon the development and improvement of the community and made his greater reputation. He was recognized among his associates and professional acquaintances as an all-round well-versed engineering authority and was often consulted by them. Having an unusually retentive memory, his long tenure as City Engineer of Petersburg gave him an almost uncanny knowledge of the various engineering structures of that city, particularly of the underground structures.

Between the time he took office and his retirement, he played the major engineering part in enlarging inadequate and limited water and sewerage systems until only extremely isolated sections of the city were without adequate water and sanitation. The source of water supply was changed to

[1] Memoir prepared by William A. Smith, Esq., Petersburg and Richmond, Va.

provide adequate water for any demands, under almost any conditions. The reservoir, pumping plant, and filter plant were modernized and enlarged to provide both safe water for domestic use and an adequate supply for fire protection and for any industrial uses likely for years to come. He had charge of the transformation of the City's thoroughfares from a few streets, with antiquated pavements and sidewalks, to a city with most of its streets improved with modern sidewalks, curbs, gutters, and roadway pavements. He designed, installed, or improved storm drainage for a large part of the City's water-sheds. Former difficult approaches to the city over temporary bridge structures were replaced under his direction with permanent structures of adequate design.

For a number of years Mr. Budd was a member of the Virginia Board for the Examination and Certification of Professional Engineers, Architects, and Land Surveyors.

His devotion to his work and his unswerving loyalty to his community were equalled only by his unselfishness in being helpful to all those to whom he could be of service. He was especially distinguished for his interest in improving the knowledge and abilities of young men who, from time to time, worked under him. He was patient with the inexperienced and unstintingly gave them, both during and after working hours, the benefit of his broad experience in both the theory and practice of engineering. This unselfish interest developed better and most loyal subordinates, and equipped them to meet the engineering probems with which they were confronted when leaving his employ for larger fields of engineering endeavor under less benevolent superiors.

He is survived by his widow, who was Marie T. Steel, of Petersburg (to whom he was married on June 14, 1900), and by two children, Robert Dunn Budd, Jr., and Elizabeth D. Budd, and by a brother and two sisters.

Mr. Budd was elected a Member of the American Society of Civil Engineers on October 4, 1910.

MOSES BURPEE, M. Am. Soc. C. E.[1]

DIED AUGUST 18, 1936

Moses Burpee was born on February 25, 1847, at Sheffield, New Brunswick, Canada, the fourth of six children of George and Phebe Burpee. At the age of five, the boy began attending the local schools where he remained until he had completed all the courses offered, which included those required for college entrance. During this time, he helped his eldest brother with work on the farm and, for himself, developed a liking for mechanics and some facility in the use of tools. An aunt was able to give him lessons in free-hand drawing which helped him in his later work.

[1] Memoir prepared by H. W. Oxnard, M. Am. Soc. C. E.

In the fall of 1865, he left home for Philadelphia, Pa., where an uncle, Coburn Burpee, gave him work in his machine shop. Here, Mr. Burpee gained practical experience in mechanics and in the operation of the steam power plant, and also, for three winters, he attended Evening Classes in Mechanical Drawing at the Franklin Institute and at the Polytechnic Institute. Drawings which he then made are still preserved and show an unusual degree of perfection.

During these years the promotion of railroads in New Brunswick had reached the stage of construction and, in 1868, Mr. Burpee returned to work on one of the first of these lines, the Fredericton Railway. On its completion early in 1869, he was transferred to the main line, chartered as the European and North American Railroad Company, for work on a section between the eastern terminus at Fairville and Tracy, N. B. When operation of the line began in November, 1869, Mr. Burpee was made Station Agent at Fredericton Junction. In the fall of 1870, he was put in charge of the location and construction of a 3-mile extension of the road, from Fairville to a deep-water terminal at Carleton, later West St. John, N. B.

From 1871 to 1878, Mr. Burpee was employed as Assistant Engineer by the New Brunswick Railway Company in which position he gained valuable experience in the field work of location and construction, as well as the making of maps and profiles and the design of Howe trusses in the office. This road was begun in 1871 at a point on the east bank of the St. John River, opposite Fredericton, N. B., and during Mr. Burpee's term of service had reached Grand Falls, N. B., with a short branch to Woodstock, N. B., and a longer one to Caribou, Me. There were three crossings of the St. John River.

Construction of new lines having ceased for a time in New Brunswick, Mr. Burpee decided to look elsewhere. In March, 1879, he went to Chicago, Ill., and from there to Milwaukee, Wis., where the Chief Engineer of the Chicago, Milwaukee, and St. Paul Railroad Company offered him work on a new line about to be built in Dakota. For the remainder of that year Mr. Burpee served as Draftsman in the Construction Office, first, at Canton, (So.) Dakota, and, later, as the work progressed, at Parker, (So.) Dakota. In 1880, he was in charge of location surveys from Ortonville, Minn., to Lake Traverse, and from Aberdeen, (So.) Dakota, running first 40 miles south and then 40 miles north; then on construction west from Mitchell, (So.) Dakota. The year following, Mr. Burpee was Division Engineer on construction in Iowa, with headquarters first at Marion and, later, at Tama. During 1882, he continued in charge of the construction of 70 miles of road between Mitchell and Chamberlain, (So.) Dakota, and of a branch line in Iowa, from Spenser to Okoboji and Spirit Lakes.

In the spring of 1883, Mr. Burpee became a Division Engineer for the Canadian Pacific Railway Company in charge of construction of 100 miles from Maple Creek, Saskatchewan, to Calgary, Alberta. Grading on this line was relatively light and rapid progress was made, a speed of 10 miles per day being attained on track-laying. In the fall, Mr. Burpee made a survey for a branch line in Manitoba and before the end of the year returned to New Brunswick.

In the summer of 1884, he began a survey for the Central Railway of New Brunswick, but this project was not successful and had to be abandoned.

During the winter of 1884–85, Mr. Burpee made a preliminary survey for the International Railway Company, a predecessor of the Canadian Pacific Railway Company, in Maine, between Lincoln and Moosehead Lake, across which a long trestle bridge was planned. The survey was finally abandoned in favor of one running around the south shore of the lake, but Mr. Burpee had gained some knowledge and experience of much value to him in later work in this same forest country.

In the spring of 1885, he was made Chief Engineer of the New Brunswick Railway, which now included all the lines in New Brunswick on which he had previously worked as well as some additions made during his absence. He was at once confronted with the difficult job of restoring the road after it had suffered severely from freshets in the St. John River. Two of the river bridges had been washed out and had to be replaced while water was still at flood stage. In 1887, this road became a part of the Canadian Pacific Railway with which Mr. Burpee remained as Chief Engineer of the Atlantic Division. With the addition of 160 miles more of the road his circuit was extended to Megantic, Province of Quebec.

F. W. Cram, General Manager of the New Brunswick Railway, declined to remain with the road after it was taken over by the Canadian Pacific and instead began the promotion of a new line from Bangor to the northern part of Maine. Early in 1891, he had accomplished the organization of the Bangor and Aroostook Railroad Company, of which he offered Mr. Burpee the post of Chief Engineer. Mr. Burpee accepted this offer and commenced a service which continued with satisfaction to all concerned as long as he lived. For thirty-seven years he was active as Chief Engineer and then, from January 1, 1928, continued in an advisory capacity as Consulting Engineer.

The Bangor and Aroostook Railway Company acquired the Bangor and Piscataquis Railroad which comprised a main line from Old Town to Greenville, Me., and a branch from Milo, Me., to Katahdin Iron Works by way of Brownville, Me., at which point the new construction was to begin. Mr. Burpee soon had three surveying parties in the field which, within a year, had completed the location from Brownville to Caribou, with branches to Fort Fairfield, Me., and to Ashland, Me. A general contract for construction was let early in 1893, and work was rushed, permitting operation as far as Houlton, Me., to begin on January 1, 1894, to Caribou and Fort Fairfield, on January 1, 1895, and to Ashland on January 6, 1896. Later additions of considerable length were made in 1899, 1902, 1905, 1907, and 1910, in each of which years it was necessary to organize new location and construction forces. Because of these successive organizations a comparatively large number of young engineers came under Mr. Burpee's influence, none of whom was too inexperienced to attract his interest and attention, and few of whom failed to profit from his example of kindliness and devotion to duty.

Mr. Burpee was truly a railroad pioneer, beginning his career at a time when railroads in any territory were in their infancy and in that in which he began his work were still unknown. From this early stage to the present, he was not only a very interested observer, but a contributor as well to the development of the art.

He was a Life Member of the Engineering Institute of Canada and the American Railway Bridge and Building Association, and, for many years, a member of the American Railway Engineering Association.

Mr. Burpee was deeply interested in religion, being a member of the First Congregational Church, of Houlton, of which for many years he was a Deacon. He also served as a Trustee of the Bangor Theological Seminary for twenty years. His recreations were sketching, water-color painting, and photography, in all of which he had much talent.

On March 4, 1880, he was married to Caroline Alexander, of Fredericton Junction, N. B., who survives him, as do his two children, Mary G. Burpee, a teacher of voice culture at Houlton, and George W. Burpee, M. Am. Soc. C. E., a member of the firm of Coverdale and Colpitts, Consulting Engineers, in New York City.

In recent years Mr. Burpee enjoyed many interesting and extended motor trips, including the ever enjoyable ones from his home at Houlton to Fredericton and Sheffield. It was on one of these trips that he caught the cold which developed into pneumonia and resulted in his passing on August 18, 1936. Thus ended a life full of usefulness, of unusual kindliness and thoughtfulness for others, and one which had won the respect and affection of all who were privileged to know him.

Mr. Burpee was elected a Member of the American Society of Civil Engineers on September 3, 1884.

GEORGE J. CALDER, M. Am. Soc. C. E.[1]

Died March 18, 1936

George J. Calder was born at Sonora, Calif., on August 5, 1884. His early education was received in the public schools of his native State. In 1905, after graduation from the Stockton, Calif., High School, he entered the University of California, College of Civil Engineering, at Berkeley, from which he was graduated with the degree of Bachelor of Science, in 1909, with honorable mention.

Mr. Calder devoted his professional career to civil engineering construction, in which he showed proficiency, both as an Engineer of Design and as a Contractor. He combined successfully the viewpoints of the Engineer who plans and the Contractor who builds. He had the faculty to understand men, to work with them, and to earn their loyalty and support.

[1] Memoir prepared by Charles Derleth, Jr., M. Am. Soc. C. E.

His first engagements after leaving college in 1909 took him to San Francisco, Calif., and Stockton, mainly upon the design of reinforced concrete and steel framed buildings. He soon became a successful Superintendent of Construction for buildings, particularly in the region of Sacramento, Calif. Beginning in 1915, Mr. Calder served the City of Sacramento by preparing reports and designs for flood-control projects, such as the Sacramento By-Pass Weir; later, he was engaged as Superintendent of Construction on various municipal buildings, and sanitary and storm-sewer installations. He was prominent in private structural design of steel and concrete buildings, with Sacramento architects.

In January, 1920, Mr. Calder joined Charles Gilman Hyde, M. Am. Soc. C. E., in the planning, design, and construction of the Sacramento Filtration Plant, for which, later, he served as Resident Engineer. In October, 1923, the writer as Chief Engineer for the Carquinez Highway Bridge across Carquinez Strait, retained him as Resident Engineer for the American Toll Bridge Company. Throughout the design and construction of this notable bridge, Mr. Calder rendered valuable services not only as the responsible Engineer in the field, but also in his counsels with the Chief Engineer and with the officials of the Company. When the Carquinez Bridge neared completion in November, 1926, Mr. Calder was elected Vice-President of the American Toll Bridge Company. He deserves credit for developing the bridge approaches, building adequate toll houses, and devising successful methods for collecting tolls. When the Carquinez Bridge was opened to traffic in May, 1927, Mr. Calder was selected by the Bridge Company to succeed the writer as Chief Engineer, and, at the same time, he remained a member of the Board of Directors for the Bridge Company until 1935.

As Engineer and Contractor, Mr. Calder was an expert in heavy underwater construction. In January, 1933, he became President of the Duncanson-Harrelson Company, of San Francisco, Specialist Bridge, Dock, and Wharf Contractors. As the directing head of this Company, he built the Mare Island Causeway for the United States Navy Department, and much under-water work in and about San Francisco Bay. His firm did diamond drilling and exploration work for the San Francisco-Oakland Bay Bridge.

Throughout his life Mr. Calder was active in fraternal circles, notably in the Masonic Order. During his residence in Sacramento, he was a prominent Rotarian. He never forgot his Alma Mater, and was always ready to help students at the University of California. He remained a member of the Engineering Honor Societies. He endeared himself to succeeding classes of students at Berkeley, and when called was ever ready to attend their meetings. On the evening of March 17, 1936, he attended a meeting of the Honor Society, Tau Beta Pi, as its chief speaker. Just as he was finishing this speech of counsel and cheer to the boys, he was stricken with a cerebral hemorrhage to which he succumbed on the morning of March 18, 1936.

His friends will long remember Mr. Calder's loyalty to his Alma Mater and his great interest in and love of young men. It was in service to youth

that he was stricken at the zenith of a successful career. His future had great promise. He died a young man at fifty-one, leaving a reputation for a kindly and generous nature.

He is survived by his widow, Mrs. Geneva Calder, a daughter, Georgene, and a son, George B. Calder.

Mr. Calder was elected a Member of the American Society of Civil Engineers on April 23, 1928.

JOHN HIRST CATON, 3d, M. Am. Soc. C. E.[1]

Died May 2, 1936

John Hirst Caton, 3d, the son of John H. and Mary (Cranston) Caton, Jr., was born in Philadelphia, Pa., on July 27, 1883, where he lived until he was twelve years old. His family moved to Rhode Island, finally settling in Edgewood, where John attended the Cranston Grammar School. He was graduated from the Cranston High School in 1900 with honors and was an outstanding football enthusiast.

During the following two years Mr. Caton worked as an Apprentice Civil Engineer with J. A. Latham and Company, of Providence, R. I., on surveying. The next year he was engaged as Engineer Surveyor for Mr. J. A. Nickerson, of the Shady Hill Nursery Company, Boston, Mass., on landscape construction work. The following year he entered the service of F. A. Gammino, a Contractor, of Providence, who had extensive sewer contracts in Dedham, Mass.

Mr. Caton then decided to apply his time toward acquiring a technical education, and, in 1904, he entered the Massachusetts Institute of Technology, at Boston, Mass., studying Civil Engineering until 1908. During his summer vacations he was occupied in engineering on municipal construction work in the vicinity of Boston.

In August, 1908, Mr. Caton passed the Federal Civil Service examinations and was assigned to the Bureau of Public Works, at Manila, Philippine Islands. Here, he served for nine years, successively, as Assistant, District, Structural, and Construction Engineer, in charge of Insular Government construction and maintenance in Manila.

From August, 1917, to August, 1919, he was in the United States Army. He entered as a Captain, but soon was made Major of Engineers, becoming Company and, finally, Regimental Commander of the 33d Engineers. He had charge of quarries and road construction, at Base Section 5, American Expeditionary Forces. His record includes consulting on port work at Brest, in

---

[1] Memoir prepared by E. F. Kriegsman, M. Am. Soc. C. E.

France, the design, purchase, and installation of five rock-crusher plants, with harbor loading and unloading facilities, etc.

In September, 1919, Major Caton became an Assistant Engineer, United States Engineer Department, Office of Public Buildings and Grounds, at Washington, D. C. He had charge of the construction of the Lincoln Memorial Reflecting Pool.

In January, 1920, at the urgent request of his family, he accepted the position of Assistant General Manager of the Industrial Chemical Company, at Providence, R. I. Industrial management did not satisfy Major Caton's disposition to keep physically active, and, in November, 1920, he was designated as Director General, Bureau of Public Works, at Santo Domingo, Dominican Republic. In this position, he had charge of administration, involving the design and construction of all public works in the Republic under the American Naval Administration, the cost of which was more than \$3 000 000. He remained in this capacity after the government was returned to the elected Dominican Government.

In October, 1925, Major Caton became associated with R. W. Hebard and Company, Incorporated, New York, N. Y., as Chief Engineer and Superintendent of Construction on contracts with the Republic of Salvador for the construction of several highways centering in the capital City of San Salvador. Extensive work was done also in the city for various municipal improvements.

Near the completion of this work Major Caton was sent to the Republic of Colombia for the same Company. There, he carried out the work of the construction of the "Carretero al Mar" (Road to the Sea), from Medellin across the Andes Mountains to the Pacific Ocean. The work was an historic piece of highway construction, being the first of its kind ever carried out, under very primitive conditions, over the rugged and picturesque Andes.

With these experiences, Major Caton considered the possibility of future public works construction in Latin America as a fertile field for development. In April, 1929, when the work in Colombia was discontinued, due to the exhaustion of public funds, he became associated with Winston Brothers, of Minneapolis, Minn., which Company had contracts for railroad, highway, and other improvements in Latin America. Major Caton was engaged by this Company on highway construction, taking advantage of the opportunities afforded him. Shortly after, he was made Latin-American Representative for the Company (with general power of attorney). In this position, he developed opportunities for several large contracts for general, heavy construction, and municipal improvement work, most of which was projected in Chile and the Argentine Republic.

In June, 1932, Major Caton returned to the United States, the depression in this country having had the effect of disrupting the finances of the Latin-American countries.

In September, 1933, he was appointed Deputy Engineer Examiner for Rhode Island under L. A. Hoffman, State Engineer, for the Federal Emer-

gency Administration of Public Works, of Rhode Island and Connecticut. In this position, Major Caton developed the Emergency Public Works projects for the 1933 program for the State of Rhode Island, the cost of which amounted to $11 000 000. This program consisted largely of municipal and State buildings, schools, water-works, and sewage disposal projects.

Concurrent with this position, he was named one of the members and Vice-Chairman of the Rhode Island State Planning Board, by Governor Theodore Francis Green, in 1934, and was re-appointed in 1935.

In March, 1935, Major Caton was appointed Chief of the Division of Roads and Bridges, Department of Public Works, State of Rhode Island, and as such was engaged in carrying out the Federal Aid Highway Program for the State, including grade-crossing elimination installations and the maintenance and construction of the State Highway System. On April 24, 1936, President Roosevelt appointed Major Caton to be State Director, Public Works Administration, for Rhode Island.

On May 2, 1936, while at his camp at Wallum Lake, Rhode Island, where he had gone to spend the week-end, he was stricken, and was taken to a hospital in Providence where he died from a cerebral hemorrhage shortly afterward.

Major Caton always insisted that his most important work was done in the Republic of Santo Domingo and in the Latin-American countries, where he was well known. He spoke Spanish fluently and was popular with all who came in contact with him.

He was an engineer of exceptional ability and, in addition, he possessed those human qualities which endeared him to his associates and friends. He was a brilliant conversationalist and had that happy faculty of meeting people and enjoying social intercourse.

He was a member of Corregidor Lodge, A. F. and A. M., Manila, Philippine Islands, which affiliation he always considered a distinction. He was also a member of the following scientific and technical societies: American Society of Military Engineers; American Association of Engineers; Association of State Highway Officials; Association of State Highway Officials in North Atlantic States; Association of State Planning Officials, Rhode Island State Planning Board; Providence Engineering Society; and the National Geographic Society.

He also had membership in the following social clubs: Massachusetts Institute of Technology Club of Rhode Island; Santo Domingo Country Club; Club Union, Colombia; Club Union, Buenos Aires, Argentine Republic; and the Philippine Club, New York City.

He was married on July 18, 1908, to Sadie Wilson, of Newton Center, Mass., who survives him. He also left four sons, John H., 4th; Frederick W.; David C.; and Richard B. Caton; two sisters, Mrs. E. A. Dow, of Worcester, Mass., and Mrs. Thomas H. Roberts, of Edgewood, R. I.; and two brothers, Jesse H. and W. Stuart Caton, both of Edgewood, R. I.

Major Caton was elected an Associate Member of the American Society of Civil Engineers on June 11, 1917, and a Member on January 20, 1922.

WILLIAM BOWDOIN CAUSEY, M. Am. Soc. C. E.[1]

DIED AUGUST 10, 1936

William Bowdoin Causey was born in Suffolk, Nansemond County, Va., on June 24, 1865, the eldest child of Charles Henry Causey, a Captain of Cavalry in the Confederate Army, and Martha Josephine (Prentis) Causey. On his father's side he traced his ancestry to the Causeys who settled quite early in Delaware and to James Colvin who came from Scotland to Philadelphia, Pa., in 1817, with his wife, Jane Campbell, and their two young daughters. His mother's people had lived in Tidewater, Virginia, since 1620, when Sir George Yeardley, afterward Deputy Governor of Virginia, came to Jamestown. Colonel Causey's great-grandfather, Judge Joseph Prentis, was a member of the Virginia Legislature during the Revolutionary period and soon after became Judge of that State's first Admiralty Court. Judge Prentis' father, William Prentis, had come to Williamsburg, Va., from Norwolk County, England, about 1725, and engaged in a general merchandising business; in the restoration of Williamsburg, the shop in which Prentis and Company conducted its business in the latter half of the Eighteenth Century has been restored to its original condition. Colonel Causey loved Tidewater, Virginia, and his many associations there and, after his death, in Chicago, Ill., his body was taken to Suffolk and laid to rest in the family lot in Cedar Hill Cemetery within almost a stone's throw of the house in which he was born.

He was the eldest of eight children and, as his childhood and youth fell in the difficult period just following the Civil War, he learned early the meaning of hard work. He attended a local military academy, but his formal schooling came to an end when he was seventeen and he went to work as a Chainman with the engineers who were building the Atlantic and Danville Railroad (later, a part of the Southern Railway System). He continued with the Atlantic and Danville Railroad Company until 1889, when he had become Assistant to the Chief Engineer. Because of the death of his father and grandfather in 1889 and 1890, his presence was required at home. After affairs at home were settled, he spent a year in charge of construction forces on track elevation near Boston, Mass., for the New York, New Haven, and Hartford Railroad Company. After this, he and his brother, James C. Causey, were in the logging business at Suffolk.

In 1898, Mr. Causey became Roadmaster and Assistant Superintendent of the Milwaukee Division of the Chicago and Northwestern Railroad. In 1901, he was Division Engineer of the Chicago Great Western Railroad Company, at Des Moines, Iowa, and, in 1902 and 1903, he was Chief Engineer of the Elgin, Joliet, and Eastern and of the Chicago, Lake Shore, and Eastern Railway Companies. In 1903, he returned to the Chicago Great

[1] Memoir prepared by W. G. Atwood, M. Am. Soc. C. E.

Western Railroad Company as General Superintendent of Construction, and, from 1904 to 1908, he was Engineer of Maintenance of Way and Superintendent of the Illinois Lines of the Chicago and Alton Railroad Company. He then returned again to the Chicago and Great Western Railroad Company as Division Superintendent and remained with this Company until 1914, when he was made Vice-President of the Norwood White Coal Company. He had just left this position to become Fuel Agent for the Buick Motor Car Company when the United States entered the World War. Although past the draft age, he at once volunteered and received a commission as Captain of Engineers and was assigned to the Seventeenth Engineers (Railway).

Captain Causey sailed for France with the regiment on July 28, 1917, as Battalion Adjutant of the First Battalion. Regimental headquarters were established at St. Nazaire, France, and the Commanding Officer was in charge of all construction in Base Section No. 1, with an area not much less than that of the State of Massachusetts. Captain Causey, who was soon promoted to Major and, later, to Lieutenant Colonel, was stationed at Nantes, and represented the Section Engineer in charge of all construction in the eastern half of the Section.

Among the projects under his supervision were: The construction of the Aerial Gunnery School, at St. Jean de Monts, with a very large flying field and about 15 acres of buildings; the construction of small holding yards, and the reconstruction of the track systems, on many of the French docks in and near Nantes; the St. Luce storage yard, with 150 000 yd of grading, about 10 miles of track, and 5 acres of warehouses; a flying junction, with about 15 miles of yard tracks and an engine terminal, at Saumur; five hospitals, at Nantes and Angers, with a combined capacity of 15 000 beds; an artillery training camp, at Coetquidan, with 58 acres of buildings, many roads, and a firing range where three regiments of field artillery could fire at one time, as well as a large number of smaller projects.

Colonel Causey's tireless energy and driving force, together with his diplomatic skill and, above all, his capacity for making and holding friends, enabled him to administer this work to the great satisfaction of his superiors and great credit to himself.

After the Armistice, Colonel Causey was relieved from duty in Base Section No. 1 and assigned to duty with the American Relief Administration. He accompanied the first mission to Austria as a transportation expert. His first telegraphic report was a classic: "The Austrian railroads are worse than * * * Railroad," naming a road that was notorious for the low grade of its maintenance.

When the Relief Administration found it necessary to supervise the operation of the railroads transporting relief supplies, Colonel Causey was placed in charge of the operation of the roads from Trieste and Fiume, supplying Austria, Hungary, and Czechoslovakia. He increased the daily tonnage from 200 to 8 000 in a very short time. This did much, not only for the relief of distress, but for the pacification of Central Europe.

After the disbandment of the Relief Administration forces in October, 1919, Colonel Causey was employed as Technical Adviser by the Republic of Austria. In addition to strictly technical services he was called on to represent Austria in many international negotiations, and was one of the official representatives of the Republic at the Genoa and Rapallo Conferences.

He served Austria for about five years, and was so universally admired and loved by the people that when he left Vienna, the Imperial rooms in the station were opened, and he was sent away with all the honors that could be given him.

After his return to the United States, Colonel Causey was City Manager of Norfolk, Va., for several years, and afterward, to the time of his death, he was Vice-President of the M. E. White Construction Company, of Chicago, Ill. He had also served as United States Assistant Commissioner to the Century of Progress Exposition at Chicago in 1933.

Colonel Causey was an engineer of ability, an administrator of still greater ability, and a man who attracted and held the love and admiration of his associates to an extent that is rare. He had great opportunity for service to others in his European experience, took full advantage of it, and left a record that will be an inspiration to all who know it.

He received a citation from General Headquarters, American Expeditionary Forces, was made an Officer of the Legion of Honor by France, received the Order of St. Sava, Grade II, from the Jugoslav Government, and the Great Silver Cross of Honor from Austria.

Colonel Causey was elected a Member of the American Society of Civil Engineers, on October 11, 1920.

ROBERT CARR CHURCHILL, M. Am. Soc. C. E.[1]

Died September 9, 1936

Robert Carr Churchill was born at Roanoke, Va., on October 20, 1890, the son of the late Charles Samuel Churchill, M. Am. Soc. C. E., and Anna (Green) Churchill. His early education was received in the public schools of Roanoke. In 1909, after graduation from Mercersburg Academy, Mercersburg, Pa., with honors, he entered Yale University and, in June, 1912, was graduated from the Sheffield Scientific School, with the degree of Bachelor of Philosophy.

Upon leaving college, he was engaged in keeping cost data for Mr. David W. Flickwir, of Flickwir and Bush, which firm was then building the Nicholson (Pa.) Viaduct for the Delaware, Lackawanna, and Western Railroad Company. Mr. Churchill remained with Mr. Flickwir until 1915, when he entered the employ of the Norfolk and Western Railroad Company, as Resident Engineer on a valuation survey at Suffolk, Va. In July, 1916, he

[1] Memoir prepared by William T. Gilbert, Esq., New York, N. Y.

became Plant Engineer for the Westinghouse Machine Company, at East Pittsburgh, Pa., later being transferred to Westinghouse, Church, Kerr and Company, to supervise the layout of the Essington Plant.

During the World War Mr. Churchill served in France as First Lieutenant in the Twelfth Engineers, from September, 1917, to April, 1919, seeing active service at St Mihiel, the Argonne, and during the final drive around Toul. He was cited for exceptionally meritorious and conspicuous services in the Toul Sector, and in October, 1934, was awarded the decoration of the Purple Heart, by the Congress of the United States.

From April to August, 1919, he was in Philadelphia, Pa., as Plant Engineer for Westinghouse Electric and Manufacturing Company, at the Essington Plant, making a special study of oils. After August, 1919, Mr. Churchill returned to his native city, Roanoke, with J. F. Barbour and Sons, Building Contractors. In April, 1920, he went into business for himself operating a quarry. In 1922 Mr. Churchill took up contracting in conjunction with the quarry business, and was engaged in building streets for the Cities of Roanoke and Vinton and doing work for the Virginian and the Norfolk and Western Railway Companies.

In 1928, he built two large viaducts, the Jefferson Street and Walnut Avenue Viaducts, for the City of Roanoke. From then, until his death on September 9, 1936, Mr. Churchill was engaged in general contracting and the ready-mixed concrete business in and around Roanoke.

Throughout his life Mr. Churchill was known for his fairness and high sense of business responsibility and civic leadership He was a member of St John's Episcopal Church, the Rotary Club of Roanoke, Chi Phi Fraternity, Elks Club, Shenandoah Club, Country Club, and American Legion Post No. 3. From 1934 to 1935, he served on the School Board of the City of Roanoke.

Besides his widow, Mrs. Dorothy (Lacy) Churchill, and two children, Robert Carr Churchill, Jr., and Dorothy Fontaine Churchill, he is survived by his mother, Mrs. Charles S. Churchill, and by three sisters, Mrs. P. V. Littlejohn, Ethel Churchill, and Mrs. Cecil Bertie.

Mr. Churchill was elected an Associate Member of the American Society of Civil Engineers on November 27, 1917, and a Member on January 17, 1927.

EDWARD IVAN CLAWITER, M. Am. Soc. C. E.[1]

Died August 12, 1936

Edward Ivan Clawiter was born at Mount Eden, Calif., on December 21, 1879, the son of Edward and Anna Clawiter. His early education was received in the schools of his native city, and, later, he was graduated from the High School, at Hayward, Calif. In 1896, Mr. Clawiter entered the University of California, at Berkeley, and was graduated in 1900, with

[1] Memoir prepared by Frederick R. Muhs, M. Am. Soc. C. E.

the degree of Bachelor of Law; he was admitted to the Bar of California in the same year. He then decided on Civil Engineering as a life work, and was graduated from the Van der Naillen School of Civil Engineering in 1903.

Immediately after his graduation in 1903, he went to Manila, Philippine Islands, where he was employed as Assistant City Engineer. In January, 1904, Mr. Clawiter became Chief Engineer of the Atlantic, Gulf, and Pacific Company of Manila in which position he continued until 1909. His experience in Manila was broad, including both design and construction of breakwaters, dredging, reclamation, harbor improvements, wharves, buildings, sewers, water systems, and tunnels.

On his return to the United States, for eighteen months, Mr. Clawiter was Assistant Engineer in the field for the Contractor, on the construction of the New York Barge Canal between Whitehall and Fort Edward, N. Y.

During 1910 and 1911 he was Engineer for J. G. White and Company, at Buenos Aires, Argentine Republic, in charge of extensions and reconstructions for Ferro-Carril Central de Buenos Aires, later representing the Trussed Concrete Steel Company in the Argentine and Brazil, where he remained until the end of 1914. He was then transferred to the Los Angeles, Calif., Office of the same Company.

During the latter part of 1915 and the first six months of 1916 he was Assistant Engineer for Miller and Lux, a large land-holding Company in California, for which he designed and constructed extensive drainage and irrigation works.

In July, 1916, Mr. Clawiter became Chief Engineer of the San Francisco Bridge Company, engaged in the building of dry docks, harbor, and bridge work. He resigned from that Company in December, 1929, to become Division Engineer for the Hydraulic Dredging Company, of Oakland, Calif., which position he held until the time of his retirement in 1935.

He was married, in 1907, to Letitia Foley. His widow survives him.

Mr. Clawiter was elected an Associate Member of the American Society of Civil Engineers, on June 30, 1911, and a Member on June 2, 1920.

FREDERICK HOSMER COOKE, M. Am. Soc. C. E.[1]

Died August 28, 1936

Frederick Hosmer Cooke was born in Cincinnati, Ohio, on March 11, 1879. He came of a family long distinguished in the annals of New England. The forebears of his father, Henry P. Cooke, settled in and around Boston, Mass., as early as 1636, and his mother's family in and around Salem, Mass., between 1630 and 1640. His grandfather, the Rev. Sylvester Cooke, was a member of the first graduating class of Amherst College, while his father, together with four brothers, served with distinction throughout the Civil

[1] Memoir prepared by Commander E. C. Seibert (C. E. C.), U. S. N., M. Am. Soc. C. E.

War. Abner Hosmer, a member of the family of his mother, Mary R. (Barker) Cooke, was among those killed at the Battle of Concord Bridge.

Frederick Hosmer Cooke attended the public schools in Cincinnati, and was graduated in 1900 from the Massachusetts Institute of Technology, at Boston, with the degree of Bachelor of Science in Civil Engineering. However, before obtaining his engineering education, he had received a training in Latin, Greek, and the classics, that broadened his mind and gave him a charm of diction and a vocabulary seldom encountered in an engineer. His fluent knowledge of French later became of inestimable value to him during the periods of his work in France and Haiti.

After graduation, he held various engineering positions, in civil life, in Cleveland, Ohio, Boston, Mass., and at the Navy Yard, at Portsmouth, N. H. This was prior to his being commissioned, after competitive examinations in which he stood first (with a grade of 91.6), an Assistant Civil Engineer, United States Navy, with the rank of Lieutenant (Junior Grade), on January 1, 1904.

In November, 1906, he was given the grade of Civil Engineer, U. S. Navy, with the rank of Lieutenant; in July, 1914, he received a promotion to the rank of Lieutenant Commander; and in July, 1918, to temporary rank of Commander, and to Commander in October, 1921; and, finally, to Captain in June, 1924.

In the Naval Service, Captain Cooke had a professional career marked by interesting and important duties. From February, 1904, to February, 1906, at the Navy Yard, Mare Island, California, he was Assistant to the late Rear Admiral H. H. Rousseau (C.E.C), U. S. N., M. Am. Soc. C. E., in charge of the Drafting Room. The outstanding work then in progress was the commencement of the construction of dikes for regulating and increasing the depth of water in Mare Island Strait.

From March, 1906, to November, 1908, he was in charge of the Department of Yards and Docks at the Naval Station, Cavite, Philippine Islands, during which period a considerable addition was built to the Canacao Hospital, mostly by day labor of Filipinos and Chinese.

From November, 1908, to January, 1909, Lieutenant Cooke was en route from the Philippine Islands to the United States *via* India, Egypt, and Europe. Then followed, for a period of about three months, temporary duty at the Bureau of Yards and Docks, at Washington, D. C.; from which he went to the Naval Training Station, Great Lakes, Ill., and thence, again, for a period of one year and four months to the Bureau of Yards and Docks where he had charge of the Drafting Room.

Between October, 1910, and January, 1911, he made a voyage to Europe and return with the United States Atlantic Fleet, inspecting commercial dock yards and marine works in England, and naval establishments at Chatham, Sheerness, Portsmouth, and Devonport, in England; at Kiel and Wilhelmshafen, in Germany; and at Cherbourg and Brest, in France. His description of these dock yards and marine structures later was published, with commentary, by the Bureau of Yards and Docks.[3]

[3] *Confidential Bulletin No. 6*, Bureau of Yards and Docks, Navy Dept., Washington, D. C., September 1, 1911.

In 1911, for a ten-month period, Lieutenant Cooke was Assistant to the late Rear Admiral Frank Taylor Chambers (C. E. C.), U. S. N., M. Am. Soc. C. E., at the Navy Yard, Norfolk, Va. Late in the same year he made an inspection of coaling plants and coal-handling appliances at several points on the Great Lakes, and along the Atlantic seaboard, at the request of the Isthmian Canal Commission.

From the early part of 1912 until the end of 1916, he served with the Panama Canal on the Isthmus, first, as Assistant Engineer, and then as Designing Engineer, under Admiral Rousseau, who was a member of the Isthmian Canal Commission and, later, Engineer of Terminal Construction. Lieutenant (and before he left Panama, Lieutenant Commander) Cooke was in charge of the design, and, to some extent, of the construction, of the Cristobal Coaling Plant, the Balboa Dry Dock, the two 250-ton floating cranes, *Ajax* and *Hercules*, and of the Naval Radio Stations at Darien, Colon, and Balboa.

Once again, from March to July, 1917, after a three-month leave, Lieutenant Commander Cooke served at the Bureau of Yards and Docks. This was the formative time for the real preparation for the participation of the United States in the World War. In November, 1917, he went to Norfolk, Va., to make appraisal of the just compensation due owners of property commandeered for the Naval Operating Base at Hampton Roads, Virginia.

In the latter part of 1917, he went to the Navy Yard, at Portsmouth, for duty, and then, again, in 1918, he returned to the Bureau for duty preparatory to going to France in charge of the construction of the Lafayette (high-power) Radio Station, at Croix d'Hins, near Bordeaux.

Upon returning to the United States, Commander Cooke was made a member of a board on vacation of properties commandeered for naval purposes during the war. This Board was charged with the appraisal of numerous items of real estate all over the country, and its praiseworthy reports were largely the result of Commander Cooke's careful and diligent efforts.

This work was followed by duty at the Training Station, Great Lakes (September, 1921, to June, 1924), as Public Works Officer of the Station, and of the 9th Naval District; and from July, 1924, to August, 1928, as Engineer-in-Chief to the Republic of Haiti. In this latter capacity he did much toward the rehabilitation of the Island Republic, employing several thousand men under the guidance of American engineers in the construction of roads, telegraph and telephone systems, wharves, drainage, sanitary works, water-works, irrigation systems, hospitals, schools, public buildings, and other works necessary in laying the foundation of an orderly government.

Following his tour in Haiti, Captain Cooke went to Philadelphia, Pa., as Yard and District Public Works Officer (October, 1928 to June, 1932); thence, in July, 1932, to Pearl Harbor, Hawaii, as Station and District Public Works Officer. As such, he had charge of important and very extensive work, including a large Repair Basin at the Navy Yard.

In July, 1935, he returned to the United States *via* Europe, and made inspections of dockyards in Japan, Singapore, Italy, Malta, and France. Upon the completion of this inspection, he went to his last duty, at the Navy Yard, Boston, Mass., as Yard and 1st Naval District Public Works Officer.

He was a member of the Military Order of the Loyal Legion of the United States in succession to his father, and was also a member of the Army and Navy Club of Washington, of the Army and Navy Club of Manila, of Sigma Alpha Epsilon Fraternity, and of the Alumni Association of the Massachusetts Institute of Technology.

The Government of the Republic of France conferred on Captain Cooke the grade of Chevalier of the Legion of Honor for his work in connection with the construction of the Lafayette Radio Station near Bordeaux, during the World War; the Republic of Haiti, for his work as Engineer-in-Chief of the Republic (1924–1928), conferred upon him the rank of Commandeur of the National Order of Honneur and Merite.

He was married to Olga Faure, on December 2, 1914, at Ancon, Canal Zone. Mrs. Cooke survives him, as do their sons, Frederick A. F. and Henry J. H. Cooke, and their daughter, Olga Cooke.

Captain Cooke will be sorely missed by his associates and by many others, of divers nationalities, who came in contact with him. It can truthfully be said that his friends were myriad. His unusual understanding in all his relations with others, combined with a fine generosity, endeared him to the masses. His wit and humor, combined with his personal dignity, endeared him to his intimates. His remarkable memory served him well in recounting his experiences, in the telling of which he interjected a wealth of anecdote to the delight of his friends. His industry and thorough-going methods in his work and his vigor of attack of professional problems gained the admiration of his co-workers. Truly, he was an outstandingly capable, vigorous, and lovable character.

He died at the Naval Hospital, at Chelsea, Mass., and was buried with full military honors of his rank, at the National Cemetery, at Arlington, Va.

Captain Cooke was elected an Associate Member of the American Society of Civil Engineers on July 9, 1906, and a Member on April 26, 1921.

JOHN JOSEPH DONOVAN, M. Am. Soc. C. E.[1]

Died January 9, 1937

One of seven children of Patrick and Julia (O'Sullivan) Donovan, natives of Ireland, John Joseph Donovan was born at Rumney, N. H., on September 8, 1858. After completing his High School course he attended the State Normal School, at Plymouth, N. H., from which he was graduated in 1877.

[1] Memoir prepared by Joseph Jacobs, M. Am. Soc. C. E.

For three years thereafter (1877–1880), he taught school in New Hampshire and Massachusetts and then entered Worcester Polytechnic Institute, at Worcester, Mass., to prepare himself for the Engineering Profession which he then desired to make his life work. As Valedictorian of his Class Mr. Donovan, was graduated from that institution in 1882 with the degree of Bachelor of Science, to be followed, a few years later, by the award of the degree of Civil Engineer. In 1932, on the occasion of the Fiftieth Anniversary of the graduation of his Class, he was the Commencement Speaker and at that time he was made an Honorary Doctor of Science of the Institute. In recognition of his marked ability as a student, Mr. Donovan, together with another brilliant student, J. Q. Barlow, M. Am. Soc. C. E., who also was destined to rise high in the Engineering Profession, was selected for service with the Northern Pacific Railroad Company in the construction of its western extension to the Pacific Coast.

Mr. Donovan's initial assignment was to Missoula, Mont., where he began work as a Rodman in August, 1882. From this modest start, he rose rapidly through the grades of Levelman, Transitman, Assistant Engineer, and then Location and Construction Engineer in charge of important new work. During this early period, Mr. Donovan participated, as a young engineer observer, in the ceremonies which marked the joining of the Eastern and Western Divisions of the Northern Pacific Railroad, at Gold Creek, Mont., in September, 1883—ceremonies that were presided over by the President of the Railroad Company, Mr. Henry Villard, and which had among others of its distinguished guests, Gen. Ulysses S. Grant, former President of the United States. In 1886 and 1887, Mr. Donovan was stationed in Washington, in charge of heavy mountain work on the Cascade Division West; he also had charge of location along the Snoqualmie River approaching Puget Sound. During the latter part of 1887, he was again assigned to duty in Montana and was made Engineer in Charge of a number of Northern Pacific Branch Line Subsidiaries, as follows: Drummond and Phillipsburg Railroad, Helena and Northern Railroad, Helena and Red Mountain Railroad, Helena, Boulder Valley and Platte Railroad, Helena, Gallatin and National Park Railroad, and Helena and Madison Railroad. He also had charge of surveys for other projected branches in that region. During a brief vacation, in 1887, he made a hurried trip to Alaska and also to his home in the East.

Mr. Donovan returned to New England for his marriage in 1888 and then, with his young bride, promptly returned to Montana to resume his engineering work. Shortly thereafter, the couple moved to Tacoma, Wash., where, however, they made but a brief stay. Associating himself with certain corporations then interested in developing Bellingham Bay, Mr. Donovan and his wife, in December, 1888, moved to Fairhaven (later a part of the City of Bellingham), Wash., where they made their permanent home and where Mr. Donovan established headquarters for his extensive future professional and business activities. His initial work there, as Chief Engineer of the Fairhaven Land Company, Skagit Coal and Transportation Company, and Fairhaven and Southern Railway Company, included the building of a railroad, opening coal mines on the Skagit River, platting the town site of Fair-

haven, and constructing its first wharves. The Tacoma-Montana Syndicate, which financed these operations, began, in 1890, with Mr. Donovan again as Chief Engineer, the construction of a railroad intended to extend from Victoria, B. C., Canada, to Portland, Ore., on the south and to Spokane, Wash., on the east. With appropriate official ceremonies, in which Mr. Donovan took a prominent part, the Canadian and American Sections were joined at the International Boundary on February 14, 1891, and a short time later, when eighty miles of line had been completed, the property was acquired by the Great Northern Railway Company.

Upon the termination of this last engagement, Mr. Donovan, after his return from another hurried trip to the East Coast, served for a short time as Chief Engineer for the local Tideland Appraisers. Following this, his engineering engagements for a number of years included the following: Chief Engineer and Manager, Blue Canyon Coal Mining Company (1891–1902); and Chief Engineer and Manager, Bellingham Bay and Eastern Railroad Company (1898–1906), later a branch of the Chicago, Milwaukee, St. Paul and Pacific Railroad. An interesting sidelight on this branch line is that when it was originally built, which was prior to Mr. Donovan's connection with it, its principal owner was the late Ogden Mills and that its first locomotive, which had already seen service in California, had been brought around "the Horn" to San Francisco, Calif., by Mr. Mills who had a strong sentimental attachment for that particular locomotive. It will be noted, from what has preceded, that Mr. Donovan had served as Chief Engineer of the several lines that eventually became the terminal sections, for entry into Bellingham, of three great transcontinental rail systems, namely, the Great Northern Railway, the Northern Pacific Railroad, and the Chicago, Milwaukee, St. Paul and Pacific Railroad.

During the latter period of his more active railroad work, Mr. Donovan also became definitely identified with the logging and lumber industry—an industry which eventually claimed his major attention and became his major business concern. In 1898, in association with Messrs. Larson and Bloedel, he organized the Lake Whatcom Logging Company, Mr. Donovan serving as its Vice-President. Greatly expanding their activities, these same men subsequently organized the Larson Lumber Company and, in 1913, the Company was re-organized as the Bloedel-Donovan Lumber Mills under which name it has since then been continuously operated. Mr. Bloedel, as President, supervised the Manufacturing and Sales Departments, while Mr. Donovan, as Vice-President, handled all logging railroad and general logging operations. This Company is one of the large operators in this industry. It has extensive timber holdings, and operates large mills and logging camps in several of the northwest counties of Washington. It maintains Sales Offices in New York, N. Y., Chicago, Ill., and other large cities throughout the United States and, at times, it has employed as many as 3 000 men, with a monthly payroll in excess of $300 000. Mr. Donovan was also, in 1925, Vice-President and General Manager of the Columbia Valley Lumber Company.

His interests were by no means confined to his business and professional activities. He was an ideal citizen—charitable, public-spirited, and always helpful in civic affairs. He gave freely of his time and talents to the study of National, State, and local social and economic problems. In politics, he was a Republican and frequently attended the conventions of that party, but he never held partisan political office. In religion, he was a Roman Catholic and was ardently devoted to his church and to its affiliate organizations, such as the Knights of Columbus, its hospitals, and its other charitable institutions. The breadth of his interests and activities in matters not directly related to business is evidenced in the large number of social and civic organizations to which he belonged and the numerous public commissions upon which he had served at various times. Some of these are, as follows: Member, first two City Councils of Fairhaven; first Charter Commission of Bellingham; Trustee, Bellingham State Normal School; Member, first State Highway Commission; State Commission on Forest Legislation; Executive Committee, State Conservation Association; President, State Good Roads Association; State Chamber of Commerce; Director, Columbia Basin League; Member, State Board of Charities and Correction; National Child Labor Commission; National Municipal League; National Civic Federation; National Security League; Navy League; Adviser, St. Joseph's Hospital; President, Catholic State Federation; and Member, American-Irish Historical Society.

Among his trade association and technical society connections were the following: President, Bellingham Chamber of Commerce, Bellingham Rotary Club, Pacific Logging Congress, and Northwest Rivers and Harbors Congress; Vice-President, National Foreign Trade Council; Member, National Geographic Society, and the Montana Society of Engineers. Mr. Donovan was a frequent contributor to the press on economic questions and he had written considerably on railroading and logging. At the Summer Meeting of the Society at Seattle, in 1926, he presented a paper[2] entitled "The Engineer in the Lumber Industry." His principal social club affiliations were the Rainier Club of Seattle, and the Golf and Country Club and the Twentieth Century Club of Bellingham. His major recreations were horseback riding, tramping, climbing, and travel. Well read and exceptionally well informed on public affairs, a widely traveled man who had seen much of Europe and the Orient, he was much in demand as a speaker and as a presiding officer at public functions.

In 1888, Mr. Donovan was married to Clara Isobel Nichols, of Melrose, Mass., a lady of unusual charm and culture who trod with him, to the end, all of life's long path ahead, and she contributed her full share to his success as a man of affairs. Three children resulted from this union—Helen Donovan (Mrs. Leslie Craven); J. N. Donovan, who succeeded his father in the lumber business; and Philip Donovan, of Portland, Ore. Mrs. Donovan passed on in June, 1936, which sad event was followed only a few months later by the passing of Mr. Donovan. In consequence of his long years of heavy toil and service, and of the special demands put upon his

[2] *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 460.

time and energy during the early years of the depression, Mr. Donovan had a nervous breakdown in 1933 which compelled his retirement from active business and which, after three years of invalidism, caused his demise on January 9, 1937. He is survived by his three children and seven grandchildren. Attended by his family and a large part of the citizenry of his home city, and mourned by thousands throughout the Pacific Northwest, he was laid to rest in Bay View Cemetery, Bellingham, on January 12, 1937.

Mr. Donovan was an able engineer and a man of talent, aggressiveness, and fine business acumen. When he settled in Bellingham a half century ago that region was largely a forested wilderness waiting to be subdued and developed by just such hardy pioneers as progressively pushed the Western Frontier across the continent to the Pacific Seaboard and helped to make the United States a great nation. Mr. Donovan was of that type—"their tribe were God Almighty's men"—and he played an important part in the development of the Pacific Northwest. He will be missed by his fellows in their future counsels. The following is quoted from an editorial in the *Bellingham Herald*:

"Mr. Donovan was a man of faith and a man of action whose life of service has enriched this community and this State. His name is deeply graven in the records of the Northwest as one of our greatest builders and most influential leaders. Courage and ambition flamed in the heart of this son of Irish Emigrants and led him on to seek an education and then to throw the power of his young body and brain into the work of building the West. His intelligence, integrity, energy and initiative made him a leader in that work. He achieved wealth, position, and honor. Here is inspiration for the youth of this land, yet young and in need of leaders and doers."

Mr. Donovan was elected a Junior of the American Society of Civil Engineers on April 7, 1886, and a Member on April 4, 1888.

OTTO RAE ELWELL, M. Am. Soc. C. E.[1]

Died November 13, 1935

Otto Rae Elwell was born on August 15, 1890, in Aberdeen, Scotland, the son of Lewis M. and Martha (Kirkwood) Elwell. His parents were both American born, the father's family having been in this country since 1632. The mother was of Scotch descent.

Lewis M. Elwell was in Scotland for about ten years, in charge of a plant producing monumental granite for export to the American firm which he represented. Three sons and one daughter were born while the family was resident in Scotland. About 1898 the Elwells returned to the United States and lived for six years in Quincy, Mass., at the end of

[1] Memoir prepared by M. S. Woodin, Assoc. M. Am. Soc. C. E.

which time they moved to Zanesville, Ohio, where Otto Rae Elwell was graduated from the High School.

In 1908, he went to the State of Washington where he began his career as an engineer by joining a surveying party working in the Yakima Valley for the Union Pacific Railway Company, locating the system known as the Yakima Valley Transportation Company. In this connection, Mr. Elwell was, successively, Chainman, Rodman, and Instrumentman. In 1911, he entered the employ of the Canadian Northern Railway Company, with which for nearly three years, he was an Instrumentman and in charge of field parties on location and construction. After the completion of this work, Mr. Elwell remained in Canada as Assistant Engineer in charge of the preliminary surveys, location, and the preparation of plans and estimates for the High River and Hudson Bay Railway and for the Alberta and Great Waterways Railway.

In 1915, he returned to Ohio, and was employed as an Assistant Engineer with the State Highway Department. This service was interrupted in 1917 when, at the entrance of the United States into the World War, he enlisted in the 23d United States Engineers, at Columbus, Ohio, and was sent to Camp Meade, Maryland, for training. In November, 1917, the regiment reached France where, as a Sergeant, Mr. Elwell remained in the service until July, 1919, participating in the regiment's arduous work of constructing roads, bridges, and docks.

After the conclusion of the war, he returned to Ohio and resumed his work with the Highway Department, remaining until March, 1921. He then took a position with the Idaho State Highway Department as Assistant Engineer and was in charge of field parties on the construction of roads and highway bridges. When this work was finished, Mr. Elwell returned to Washington and for a short time was engaged as Construction Engineer for Thurston County. He then entered the service of the Washington State Department of Highways, at Olympia, in January, 1922. In this service, he was engaged for several years as Bridge Designer in connection with many important projects. Some of the structures which Mr. Elwell designed during this period were the concrete approaches to the Puyallup River Bridge, at Tacoma; the concrete bridges between Snoqualmie Pass and Easton, on State Road No. 2; and the Nooksack River Bridge, near Ferndale.

In 1927, he was placed in charge of the Bridge Division of the Department of Highways, with the title of Assistant Bridge Engineer, and later, was made Bridge Engineer, which position he held until his death. While in charge of the Bridge Division Mr. Elwell was responsible to the Director of Highways for the design of several million dollars worth of work distributed over all parts of the State.

In July, 1935, Mr. Elwell was advised to enter a sanitorium at Milwaukee, Ore., for rest and treatment. It was thought that a few months would restore him to good health and, for a time, he did apparently improve. His friends were encouraged and not alarmed when it became known that he had returned to Olympia on November 11 but this was quickly followed

by the shock of learning that he had passed away at his home, two days later.

Otto Elwell, or "Bud" Elwell, as he was more generally known, had a real talent for making friends and was held in high esteem by a host of people with whom he came in contact in his many activities. He was an ardent sportsman, interested in nearly all branches of athletics, was an active basket-ball player during his younger days, and a capable tennis player. He was an enthusiastic fisherman and hunter and became widely known in the State as an expert trap and skeet shooter. He was interested in the Boy Scouts and for a considerable time was in charge of one of the local troops.

In appreciation for his many years of service in the Washington Department of Highways, the new bridge across the Nisqually River, east of Olympia, has been designated as the O. R. Elwell Memorial Bridge.

Mr. Elwell is survived by his widow, Bess Williams Elwell, to whom he was married in Columbus, Ohio, on October 27, 1917; by his parents; by three brothers, E. W. Elwell, Lewis M. Elwell, Jr., and Roy A. Elwell; and by a sister, Olga Elwell.

He was a member of the American Legion and belonged to the Masonic Fraternity, having been affiliated with the Blue Lodge and Royal Arch Lodge of the York Rite in Zanesville, Ohio, and with the Scottish Rite Lodge, in Olympia.

Mr. Elwell was elected a Member of the American Society of Civil Engineers on October 14, 1930.

JOSEPH FIRTH, M. Am. Soc. C. E.[1]

DIED MAY 10, 1936

Joseph Firth, the son of Frederick William and Ann (Ardron) Firth, was born in Philadelphia, Pa., on October 16, 1878. Both parents died in Mr. Firth's early childhood and he was reared by his paternal grandfather. His early education began with his entrance into Girard College, where he pursued his studies until he was graduated in 1895. After two years with the Pennsylvania Railroad Company he entered Rensselaer Polytechnic Institute, at Troy, N. Y., from which he was graduated in 1901 with the degree of Civil Engineer.

Following his graduation Mr. Firth remained for one year at his Alma Mater as an Instructor in Mathematics and Surveying. In 1902 and 1903, he was with the Foundation Company, of New York, N. Y., as Assistant Engineer on pneumatic foundations in New York City and bridge piers at Omaha, Nebr. Continuing with that Company, he installed a water supply at Ardmore, Okla., in 1904, serving as Resident Engineer in full responsible

[1] Memoir prepared by a Committee of the Philadelphia Section consisting of Dudley T. Corning, *Chairman*, C. S. Shaughnessy, C. E. Myers, and W. E. A. Doherty, Members, Am. Soc. C. E.

charge. From 1904 to 1907, with the exception of one year as Instructor in Civil Engineering at Lehigh University, at Bethlehem, Pa., he was engaged by the late T. Chalkley Hatton, M. Am. Soc. C. E., on the design and construction of a number of municipal improvements—water supplies for Ridgley, Md., and Benton, Pa.; sewerage systems for Hyattsville, Md., and Mt. Carmel, Pa.; and as Mr. Hatton's Principal Assistant in charge of the design and construction of the sewerage systems at Charleston, W. Va., and Pensacola, Fla.

In 1907, the City of Charlotte, N. C., engaged Mr. Firth as its City Engineer. During his incumbency (until 1914) he re-organized the Engineering Department and practically rehabilitated the city's water supply, its streets, and its sewage disposal plant. In 1915, he was appointed Commissioner of Public Works of Winston-Salem, N. C., and there he continued his meritorious municipal work. In 1919, he took up the duties of City Manager of West Palm Beach, Fla., but after one year, he returned to Charlotte, N. C., as City Engineer to rebuild its sewage disposal plant.

Always at heart a teacher, Mr. Firth went to Oklahoma Agricultural and Mechanical College, at Stillwater, Okla., as Associate Professor of Civil Engineering, in 1927. From there, in 1929, he returned to the place of his birth—Philadelphia, Pa.,—where he was engaged in the Bureau of Highways as Engineer of Tests and Materials, until his death.

Mr. Firth's career that culminated so suddenly, was one of great personal accomplishment. He was a thorough student and had the kindly faculty of imparting his knowledge to his subordinates and associates in a way that never savored of officiousness. Many knotty problems were made easy by a suggestion from his resourceful brain. It is a tribute worthy of aspiration that he left the world a little better than it would have been without him.

At Rensselaer Polytechnic Institute, he was honored by election to Sigma Xi; and at Oklahoma Agricultural and Mechanical College by election to Phi Kappa Phi. Mr. Firth was a Thirty-second Degree Mason; and a member of the Shrine, Oasis Temple, of Charlotte, N. C. He was also a member of the American Road Builders Association.

He was married to Maud Hunt, of Germantown, Pa., on October 22, 1907, and is survived by his widow and two children, James Hunt and Marjorie Delvalere Firth.

Mr. Firth was elected an Associate Member of the American Society of Civil Engineers on June 5, 1907, and a Member on July 6, 1925.

ROBERT FLETCHER, M. Am. Soc. C. E.[1]

Died January 7, 1936

Robert Fletcher was born in New York, N. Y., on August 23, 1847, the son of Edward H. and Mary (Hill) Fletcher. His early education was obtained

[1] Memoir prepared by Frank W. Garran, M. Am. Soc. C. E., and William P. Kimball, Assoc. M. Am. Soc. C. E.

in the public schools of New York City, followed by three years' attendance at the New York Free Academy, later the College of the City of New York, where he chose the Classical Course, including Greek, Latin, and rhetoric. In August, 1864, he won by competitive examination a coveted appointment to the United States Military Academy, at West Point, N. Y., and that month he passed his entrance examination and was enrolled as a Cadet in the Class of 1868. At the New York Free Academy, and at the U. S. Military Academy, he received the liberal arts education and the technical training which were to serve as his background for directing and teaching a Civil Engineering curriculum. The technical subjects studied were physics, chemistry, mathematics, descriptive geometry, free-hand drawing, surveying, and spherical astronomy.

Upon graduation in June, 1868, he was commissioned a Second Lieutenant in the First United States Artillery, serving for one year on garrison duty at Brownsville, Tex., on the Mexican frontier. In the spring of 1869, he was transferred with his Battery to Fort Trumbull, at New London, Conn. In August of that year his active military career ended, and a remarkable life as an educator of young men was undertaken in an appointment as Instructor of Mathematics under Professor A. E. Church, at the U. S. Military Academy, at West Point.

Lieutenant Fletcher's outstanding character and ability in this position led to a meeting with Gen. Sylvanus Thayer, U. S. Army, revered "father" of the U. S. Military Academy and veteran of the War of 1812 and of the Civil War. General Thayer, a man of broad vision, keen perspicacity, and remarkable singleness of purpose, viewed with concern the tendency toward narrow technical training of engineers, and was inspired with the vision of an engineering school for students prepared for a full life by college training in humanities and social studies. A graduate of Dartmouth College, at Hanover, N. H., General Thayer naturally chose this Liberal Arts College as the place for the engineering school which he wished to endow. Quite apparently the selection of a man to organize and direct the school along the lines outlined by its founder was a delicate task. General Thayer was a man of rigid ideals, both professional and moral, and many applicants for the position were rejected for a wide variety of reasons. Faced with the collapse of his plan for the lack of a qualified leader, General Thayer was finally advised by Professor Church of a brilliant young Lieutenant serving as Instructor of Mathematics in the Military Academy. Thus, it was that Lieutenant Fletcher found the ideal that was to constitute a major portion of his life work. An excerpt from a history of the Thayer School of Civil Engineering, founded in 1871, gives this insight into the character of the 24-yr old lad who was chosen to guide the destiny of this unique experiment in engineering education:

> "On the eighth of July [1870] Fletcher arrived in Hanover. Smith's [A. D. Smith then President of Dartmouth] reaction was that the young lieutenant's good manners and evident 'moral tone' were pleasing additions to his quiet personality. He was impressed with Fletcher's classical background gained from three years of liberal college training at C. C. N. Y. In a letter to Thayer he urged Fletcher's immediate appointment.

"The following day * * * Fletcher had a seven-hour interview with Thayer. * * * Thayer approved of Fletcher's scholastic accomplishments, his earnestness and energy and was impressed with the recommendation given by Professor Church of the West Point Mathematics Department."

In December, 1870, Lieutenant Fletcher resigned his commission in the U. S. Army and moved to Hanover, N. H., where a truly amazing task awaited him. If any present-day analogy could be drawn, it would be of a third-year engineering student faced with the task of setting up a complete curriculum of civil engineering in a liberal arts college, and, having set up the course, teaching every subject. To be sure the field of engineering has broadened since the day Robert Fletcher arrived by sleigh in the snow-bound village of Hanover; but so has the available literature increased. It is no longer necessary for engineering teachers to write their own texts, compose their own problems, and outline the very essentials of the subject-matter they teach.

It is impossible to write of Robert Fletcher without seeming to write a history of the school which was his life work, just as it is impossible to write of Thayer School during that period, without emphasizing the part played by Robert Fletcher during its forty-seven years under his direction.

Director Fletcher's first accomplishment was to prepare examinations, with the aid of Professor E. T. Quimby, of the Dartmouth College Faculty, to test the eligibility of candidates for the course specified in broad terms by General Thayer. These examinations covered subjects of mensuration, trigonometry, surveying, descriptive geometry, analytical geometry, calculus, mechanics, physics, astronomy, chemistry, geology, physical geography, and meteorology.

In June, 1871, Robert Fletcher was awarded the Honorary Degree of Master of Arts by Dartmouth College, and three months later he began the instruction of the first class of the Thayer School of Civil Engineering. During that year he taught the subjects of surveying, railroad engineering, industrial drawing, topographical drawing, fortifications, stone-cutting, statics of mechanics, dynamics of mechanics, lettering, geodesy, mining, hydrography, retaining walls, arches, strength of materials, architectural, structural, and machine drawing, materials of construction, hydrostatics, hydrodynamics, and the theory of machines described in his own words as dealing with "transmission of work by machines; modulus of machines moving with uniform or periodical motion and with variable motion; velocity of machines under variable motion; coefficients of the modulus; motion about a cylindrical axis; wheel and axle; pulley; sheaves; modulus of compound machine; capstan; Chinese capstan; whim gin; friction of cords; friction brake bands; theory of the teeth of wheels; involute teeth and how to describe them; epi-cycloidal and hypo-cycloidal teeth and methods of describing them; a train of wheels; strength of teeth; teeth of rack and pinion; lantern or trundle; conical or bevel wheels and the method of describing them", and, until 1876, he continued instruction in these courses and added to this curriculum the subjects of bridge construction, analytical chemistry, construction of cranes and hoists, drainage of lands, towns and buildings, astronomy, and foundations. During his forty-seven years of active direction and teaching

in the school which he organized and led to a position of eminence in the field of Civil Engineering education, Professor Fletcher taught courses in twelve distinct branches of engineering. This breadth of scope was perhaps his greatest attribute, and distinguished him throughout his life time from his contemporaries who were outstanding in specialized fields in a world of increasingly specialized and restricted endeavor.

The influence of his personality on the students was profound. His classes were always small, so that it was possible for him to know intimately every student who attended his school. He made the most of this opportunity, and because of his keen interest in the characters as well as in the minds of his boys, his teaching was always alive. Fully appreciative of the value of technical learning as he was, he nevertheless felt that the greatest value he could give was in the development of high ideals, mental discipline, and an appreciation of human nature. He recognized that the laws of Nature are immutable, and he taught that the greatest folly of Man is disregard for or denial of these laws; but he recognized also that the laws of human behavior are variable, and he taught that eminence in engineering as in all things could be attained only by those who are able to shape and use the laws of human behavior to the accomplishment of ends not inconsistent with the laws of Nature.

Professor Fletcher was not a dogmatist; nor did he try to force on others his own convictions. His approach was indirect. He lived openly and consistently by his own lights, teaching the truth of his convictions by example rather than by the ever less effectual method of insistence. He was a sincerely religious man and rigidly temperate, never permitting himself the relaxing luxury of tobacco, alcohol, or profanity. Yet, rigorously observant of his own ideals, he recognized in these things too the variability of human behavior.

The tributes which his former students and associates have paid to Professor Fletcher are numerous and coming as they do from some of the leading engineers of the United States, they constitute the best testimonial to his true worth. The following is chosen as being as graphic as any words ever written of Robert Fletcher:

"Professor Fletcher made a deep impression on me as a young man in his classes. His sincerity, his fine and very lovable character, together with his deep knowledge of many things, made it a privilege to be in his classes. We are all, perhaps, prone to visualize a composite of groups. As the figure of Uncle Sam or John Bull is symbolical, or as the word Southerner creates an image in our mind's eye, so the old-fashioned and much abused term, gentleman, in the finest sense of the word is associated in my mind with my remembrance of Dr. Fletcher. Some years ago a man who was then President of the American Society of Civil Engineers remarked in conversation to me, 'I met a friend of yours at the Annual Meeting. I have forgotten his name, but he looked like a character from Dickens.' I knew at once that it was Dr. Fletcher. He was rare; his kind is not so easy to find these days; and it will always be a source of pride to me that I knew him and was honored with his friendship."

These thoughts are typical of the opinions expressed time and time again by those with whom Robert Fletcher had contacts, yet the love and esteem of

his fellow men were not the result of a soft or pliable nature. His early training at the U. S. Military Academy and his rigorous years in sole charge of the Engineering School at Dartmouth taught him the value of unwavering concentration, hard work, and self-discipline. That he could be severe when necessary is well remembered. He taught his students to spell the word rest, "r-u-s-t". His only criticism of contemporary Civil Engineering education was that the students are not required to work hard enough.

In 1881, at the age of 34, he was honored by Dartmouth with an Honorary Degree of Doctor of Philosophy, and thirty-seven years later, on the occasion of his retirement as Director of the Thayer School, he was awarded the Honorary Degree of Doctor of Science by Dartmouth. At this time he was appointed Director Emeritus of the Thayer School, a position which he held until his death. During this period he was also active as Clerk of the Board of Overseers of the Thayer School.

Small and slight of stature, he was physically active and energetic. He had great power of concentration and physical stamina, and he was a prodigious worker. Only a man of great determination and capability could have carried on the school duties, demanding twelve to sixteen hours' work per day over a period of many pears. Few men could add to that the pursuit of intellectual hobbies, active participation in church and public affairs, and a consulting engineering practice.

Both because of the demands of other activities and because of the somewhat remote location of Hanover, Robert Fletcher's professional accomplishments, outside the educational field, were not great as measured in terms of dollars or tons. He designed and supervised the construction of steel bridges across the Connecticut and White Rivers, and of water-works for the Towns of Hanover and Enfield, N. H., and was Consulting Engineer for water-works and reservoirs in Lebanon, N. H., and in Hartford and Woodstock, Vt. For more than forty years he was President and Engineer of the Hanover Water Company, as well as a member of the New Hampshire State Board of Health, of which he was President until 1934. In the latter capacity he performed great public services, most notably in the development of the tight, free-flowing septic tank. Owing to his work in developing and sponsoring this type of tank for homes and summer resorts, the old-fashioned, often obnoxious, cesspool has practically disappeared from the State, and the pollution of recreational streams and lakes has been greatly reduced. He was in charge of one-half the very extensive survey to determine the New Hampshire-Vermont boundary line, a notorious boundary dispute finally settled by a decision of the United States Supreme Court in 1933.

Throughout his life Director Fletcher contributed freely to technical periodicals and bulletins, and, occasionally, when the spirit moved him and the ignorance of his fellow men seemed too abyssmal, he wrote words of homely wisdom for the public press. Although these contributions covered a wide field of engineering and lay knowledge, including bridge design, water supply engineering, sewage treatment and disposal, geology, surveying, and mechanics, his outstanding work was "A History of the Development of Wooden Bridges", prepared in conjunction with the late Jonathan Parker Snow, M. Am. Soc.

C. E., and published with the voluminous discussion thereon by the Society.[3] All the work on this major contribution was carried on after Robert Fletcher had passed the age of 83, and this fact is only one of many indications that his mind was keen, his interest unfailing, and his sense of obligation to his profession as deep as ever during the last years of his life. This feeling of obligation to his fellows was expressed by Professor Fletcher himself who frequently quoted John Smeaton: "The abilities of the individual are a debt due to the common stock of public well being."

His hobbies and recreations were of a type consistent with his nature; most men would consider them intelluctual pursuits and would perhaps prefer lighter, more trivial, relaxation. One of these hobbies was an intense study of volcanology, both in delving into theoretical and technical causes and effects and in following the sometimes too apparent manifestations of these phenomena. A related hobby was archæology, and still another was scientific research in the history of the Bible lands, and the development of civilization in all parts of the world.

He enjoyed one relaxation, however, which really overshadowed all the other pleasures of his life; that is, following the fortunes and accomplishments of his former students. He found this easy to do, for the affection and esteem in which his students held him, prompted them to write often of their trials and tribulations and triumphs. In 1916, after forty-five years as Director of the Thayer School, Professor Fletcher traveled from New England to New Orleans, La., to the Pacific Coast, and back East by a northerly route, visiting at frequent intervals engineers who had formerly been his students. These visits took him to some of the greatest engineering works of the time. It was a truly rich reward to him to see these men, whom he had taught as boys, in responsible charge of such projects. This trip, with the lasting pleasure which it brought, was perhaps Robert Fletcher's major self-indulgence.

He was an active member of the Society for the Promotion of Engineering Education from the time of its organization in 1892 and served as its President in 1901–02.

He was married in June, 1872, to Ellen M. Huntington who, with their daughter, Mary A., and his two sisters, Harriet and Helen, survives him. His only son, Robert H. Fletcher, Professor at Grinnell College, Grinnell, Iowa, died in 1919.

On January 9, 1936, Robert Fletcher was buried in the Old Cemetery in Hanover, N. H., within a few blocks of the house in which he had spent sixty years of his long and noble life, and whether we knew him as Professor, or Doctor, or "Bobby", his passing leaves a gap in our lives which can never be filled.

At the time of his death, he had been associated with the Society longer than any other man—sixty-one years. This distinction, however, was not one which he would have chosen to contemplate, for he was always a little ashamed of growing old and disliked to recognize in himself symptoms of the passing years.

Professor Fletcher was elected an Affiliate of the American Society of Civil Engineers on November 4, 1874, and a Member on August 31, 1909.

SAMUEL GOURDIN GAILLARD, M. Am. Soc. C. E.[1]

DIED NOVEMBER 17, 1936

Samuel Gourdin Gaillard was born on July 17, 1853, at Hayden Hill Plantation, Upper St. Johns, Berkeley County, South Carolina, the son of Eugene M. and Camilla (Richebourg) Gaillard, both of that section of South Carolina. He was of French Huguenot descent on both sides. Following the revocation of the Edict of Nantes, his ancestors, together with many other Huguenot refugees, left France and settled on the Santee River, at Jamestown, S. C., early in the 1680's. These French Huguenot families played an important part in the history of South Carolina, and Mr. Gaillard's ancestors were no exception—one, Captain Peter Gaillard, was an Officer with the Colonial Forces during the Revolutionary War; another, the Hon. John Gaillard, was for many years, United States Senator from South Carolina. Colonel David Dubose Gaillard, the engineer in charge of the Culebra Cut of the Panama Canal and for whom that Cut was named after his death, was a cousin and close friend. During the Civil War, all the men of his family able to bear arms were in active service on the side of the Confederacy. Mr. Gaillard, himself, although only a boy of ten or eleven years, was old enough to remember some of the incidents of the latter years of the war—especially the visit, in the dead of night, of Northern troops to his family's plantation, and the complete despoiling of that place. Although still very young, he took an active part in the difficult Reconstruction Period, and was one of Hampton's "Red Shirts" Later, he obtained a scholarship at the Porter Military Academy, at Charleston, S. C., and upon graduation obtained another scholarship at Union College, at Schenectady, N. Y. There, he made many life-long friends, and was graduated as a Civil Engineer in 1881. While an undergraduate at Union College he was elected a member of Kappa Alpha Society.

Upon graduation from Union College, Mr. Gaillard obtained a position as Assistant Engineer with the Shenandoah Valley Railroad Company in Virginia. This position came to him on the recommendation of the Professor of Civil Engineering at Union College to whom the late Foster B. Morss, Civil Engineer, a graduate of the Class of 1864, had written, asking him to name a recent graduate qualified to be his Assistant on the construction of the Shenandoah Valley Railroad (now a part of the Norfolk and Western Railroad System). After about two years in this position, Mr. Gaillard accepted the offer of Mr. Morss to go with him as his Assistant with the railroad company being organized in Connecticut to purchase the New England Railroad and build connections to New York, N. Y., and Boston, Mass., and, in the capacity of Assistant Engineer, he surveyed much of the proposed line of the Hartford and Harlem Railroad. This road was not

[1] Memoir prepared by Edward M. Gaillard, Esq., New Haven, Conn., assisted by Foster G. Morss, M. Am. Soc. C. E.

built because the plans for financing failed. In 1884, he went to the Norfolk and Western Railroad Company as Assistant Engineer with the Construction Department. From this position he was promoted to be Resident Engineer, Engineer in Charge of Construction, and, finally, Assistant to the President, with headquarters in Philadelphia, Pa.

When the Norfolk and Western Railroad Company went into Receivership, the position of Assistant to the President was abolished and Mr. Gaillard was returned to the Engineering Department as Division Engineer. In 1896, at the solicitation of Arthur W. Sewall, Secretary of the Mack Manufacturing Company, of Philadelphia and New Cumberland, W. Va., Mr. Gaillard accepted the position of Superintendent of Mines and Factories of that Company at New Cumberland. This Company was engaged in the manufacture of vitrified paving brick and vitrified clay sewer pipe and although Mr. Gaillard had had no previous experience in that line, he secured every publication available on the subject and became an authority on the manufacture of clay products He held, successively, the positions of General Manager, Vice-President, and President of the Company, and continued in this last capacity until 1919 when control of the property was sold to new interests. In 1920, Mr. Sewall, then President of the Barber Asphalt Company (General Asphalt Company), now Chairman of the Board, appointed Mr. Gaillard Chief Consulting Engineer of the Uintah Railway Company, a subsidiary operating in Western Colorado and Eastern Utah, and under his supervision surveys were made for an extension of the railway into the Gilsonite fields in Utah and for a grade revision survey over the Book Cliff Mountains where a line was run with 3% grades and 16° curves to replace the existing 5% and $7\frac{1}{2}$% grades and 66° curves. For a few years before retiring. he held a position with the General Asphalt Company of Philadelphia.

In the course of his engineering work, he was the author of numerous reports on ores, and, while he was with the Mack Manufacturing Company, he made minor inventions in brick machinery and improvements in the design and construction of the plants

Mr. Gaillard was fond of all kinds of sports, especially of shooting, and most of his vacations were spent on hunting expeditions with friends in South Carolina.

In June, 1891, he was married to Esther Lynch McCrady, a daughter of Professor and Mrs. John McCrady, of Charleston, S. C. After retiring from active business about five years ago (1931), Mr. Gaillard moved to New Haven, Conn., in order to be near his sons, Samuel G. Gaillard, Jr., and Edward M. Gaillard, who, with his widow, survive him.

In addition to his business activities, Mr. Gaillard was for six years President and Commissioner of Hancock County, West Virginia. He was a life long member of the Protestant Episcopal Church. During the World War, he was a member of the Navy League. He was also a member of the National Geographic Society, Society for Scientific Research, and a Life Member of the Huguenot Society of South Carolina.

Mr. Gaillard was elected a Member of the American Society of Civil Engineers on October 1, 1912.

CHRISTOPHER LAWRENCE GATES, M. Am. Soc. C. E.[1]

DIED AUGUST 30, 1920

Christopher Lawrence Gates was born in Nüremberg, Germany, on June 13, 1848, the son of Christopher Lawrence and Anna Sibylla Goetz. His early education was gained in the common schools of that city, where, after competitive examinations, he was admitted to the Polytechnic School at the age of 12.

In 1865, Mr. Gates came to the United States, and settled in Fort Wayne, Ind., where he was engaged as a Machinist. From Fort Wayne, he moved to Milwaukee, Wis., where he was employed by the Milwaukee Bridge and Iron Works and the Chicago, Milwaukee, and St. Paul Railroad Company as a Designer of railroad bridges until 1886.

He spent a year with the Clinton (Iowa) Bridge Company, and then went to Toledo, Ohio, as Railroad Bridge Engineer for the Smith Bridge Company, continuing in that capacity after this Company sold its interests to the Toledo Bridge Company. His naturalization papers were taken out about the time he came to Toledo.

When the Toledo Bridge Company was absorbed by The American Bridge Company in 1900, Mr. Gates severed his connection with it, and for the next twenty years did occasional consultation work. He represented the Toledo Bridge and Crane Company in the erection of the United States Naval Coaling Station in Guantanamo Bay, Cuba, in 1908, and in the erection of wireless towers in Darien, Panama, in 1914. He was also Consultant on bascule bridges for the City of Saginaw, Mich., and for the Ann Arbor and Pere Marquette Railroad Companies, the Saginaw Valley Traction Company, and the City of Toledo.

He was a Director in the Toledo Bridge Company, The Toledo-Massillon Bridge Company, The Toledo Bridge and Crane Company, and The Toledo and Indiana Interurban Company.

Mr. Gates became a Mason in 1879, as a member of Independence Lodge, in Milwaukee. In Toledo, he was connected with Toledo Commandery No. 7, Knights Templars, Fort Meigs Chapter, Sanford L. Collins Lodge, Scottish Rite, Zenobia Shrine, and Fraters Club.

For many years, he was a Trustee of the Central Congregational Church, of Toledo, and represented that body on its merger with the First Congregational Church.

Mr. Gates was an active member of the Toledo Engineering Society, serving in various official capacities, and had a wide acquaintance both in and out of engineering circles. He was a man of pronounced and outspoken convictions for which he was admired by his many friends. Mr. Gates passed away in Milwaukee, his old home, where he had gone on a business trip, after a few days of very sudden illness.

[1] Memoir prepared by A. H. Smith, Assoc. M. Am. Soc. C. E.; L. M. Gram, M. Am. Soc. C. E., and W. G. Clark, Jun. Am. Soc. C. E.

He was married on May 30, 1872, to Jennie Young Walker, who passed away in 1909. Of eight children, but three survive their father: Arthur O. Gates, of Salt Lake City, Utah; and the Misses Florence A. and Louise W. Gates, of Toledo. Christopher Lawrence Gates, Jr., his youngest son, who accompanied him to the Annual Convention of the Society and the trip to the Panama Canal, in 1911, was drowned the following year at Lafayette, Ind., where he was a student at Purdue University.

Mr. Gates was elected a Junior of the American Society of Civil Engineers on December 4, 1878, and a Member on September 5, 1883.

MARTIN GAY, M. Am. Soc. C. E.[1]

Died November 23, 1935

Martin Gay, the son of Sydney Howard and Elizabeth Johns (Neall) Gay, was born on Staten Island, New York, on May 15, 1854. He came of a long line of Quaker and New England ancestry. His father was a journalist of note, whose principal work was done in Civil War times as Editor of the *Anti-Slavery Standard*, in 1844, and of the *New York Tribune*. Subsequently, he became Editor of the *Chicago Tribune* and, later, of the *New York Evening Post*.

His paternal progenitor—John Gay—came from England in 1630 and, with his wife, Joanna, located at Watertown, Mass. John Gay was one of the founders of Dedham in that State. His grandson, the Rev. Ebenezer Gay, was noted among early clergymen for his vitality and unflagging interest in his religious work at Hingham, Mass. Ebenezer Gay died in his ninety-first year on returning to his home after preaching in the Old Ship's Church. A model of this church is in the Colonial Exhibition in the Metropolitan Museum of Art in New York City, and the original is still standing and in good repair, at Hingham. From Ebenezer the line of descent is through his son, Martin, who set up in Boston, the first copper foundry in the Colonies, and the latter's son, Ebenezer, who was a lawyer, the father of Sydney Howard, who was the grandfather of Martin Gay. The ancestral home of the Gays, which was built by the Rev. Ebenezer Gay, still stands in Hingham. For the last thirty years of his life, Martin Gay with his family spent the summers in this old home, which was occupied by the Gays for more than 200 yr. He loved the old home, its furniture, and environment, and liked to work there maintaining it.

From the maternal side of his family, all of whom were Quakers, Martin Gay inherited a patience and tolerance seldom found in the swift tempo of life to-day. A straight line of descent may be drawn from the Mifflins, Nealls, and Justices, all of whom were early settlers in and about Philadelphia, Pa. Warner Mifflin, son of John Mifflin, "before God and my con-

[1] Memoir prepared by J. A. Knighton and Arthur W. Tidd, Members, Am. Soc. C. E., and Robert Ridgway, Past-President and Hon. M. Am. Soc. C. E.

science, feeling it wrong to enslave my fellow man * * *", was the first man to liberate his slaves, and this action took place nearly one hundred years before the Civil War and many years before such action was taken in England. His original deed of manumission remains a cherished heirloom of the family. The site of the old Mifflin homestead is marked with a tablet and comprised, what is now a substantial part of Fairmont Park, in Philadelphia.

Martin Gay was educated first in private schools in Chicago, Ill., and on Staten Island. In 1877, he was graduated from the Massachusetts Institute of Technology, at Boston, Mass. During vacation periods he had his first professional work in Nebraska in railroad surveying. It was pioneering work, sleeping in sod houses, posting sentries against Indians, and long distances to go for a water supply. He was in nowise appalled by these hardships and liked to tell of them retrospectively. Later, he did some work in connection with the construction of the Second Avenue Elevated Railroad in New York City.

On September 17, 1877, he was appointed an Axeman with the Department of Public Works of the old City of New York, serving on the work in the Croton Water-Shed under the Chief Engineer, George W. Birdsall, and was promoted through the various grades until he reached the rank of Assistant Engineer on November 20, 1883. He was in charge of the construction of a section of the Bronx River 48-in. pipe line and of the Williamsbridge Reservoir. Then, about 1894, he was in charge of the construction of Macomb's Dam Bridge over the Harlem River for the Department of Parks, which was designed by the late Alfred P. Boller, M. Am. Soc. C. E. Mr. Gay remained on this work until its completion. During this period he was also Engineer in charge of the completion of the Third Avenue Bridge, over the same waterway, for the Department of Public Works, under the late George W. Birdsall, Chief Engineer. This bridge was designed by the late Thomas Curtis Clarke, Past-President, Am. Soc. C. E.

With the consolidation of the City of New York into its present form, on January 1, 1898, Mr Gay was transferred to the Department of Bridges, later, called the Department of Plant and Structures, with which he remained for twenty-three years until he retired on January 1, 1921. His outstanding work was with that Department. At first, he was assigned to the preparation of a plan designed to make the City's newly created Department of Bridges function smoothly and to co-ordinate its various activities. The Brooklyn Bridge, formerly under the supervision of a separate commission, was naturally the focal point of his plan, that structure being the largest bridge in the jurisdiction of the Department, and the only one in operation at that time over the East River.

Among other bridges over the Harlem River the construction of which he supervised were those at Willis and Madison Avenues. While thus employed, Mr. Gay was also in charge of the maintenance of the Harlem River bridges. It has been stated, and is a fact worth noting, that all his bridge work was so carefully planned and the construction co-ordinated with such vigilance and care that no man was ever killed in the operations. He

took much pride and satisfaction in this record. His creditable and faithful service with the Department of Bridges and the Department of Plant and Structures was identified principally with these Harlem River bridges with which construction and maintenance he had so much to do, and the details of which he knew so well. One who went to Mr. Gay's office was sure of a courteous and kindly welcome and received the information he came for if it was possible to give it to him. He was a cultivated gentleman, a scholarly Engineer, and a loyal friend, greatly beloved by all who had the privilege of knowing him, and was withal a real man.

On his retirement from active service on January 1, 1921, the Department of Plant and Structures by formal resolution, sent to his widow on his death, testified that he had endeared himself to his associates by his devotion to the City's welfare and by his justice, kindness, cheerfulness, and humanity. Following his retirement, Mr. Gay's interest in the work continued, and he kept up his visits to the office as long as his health permitted. He often gave lectures illustrated with lantern slides, intended for engineers, but in which there was a keen popular interest. In the leisure of his retirement he made an exhaustive study and prepared a history of the bridges of New York City—not including the East River bridges. He had the literary and historic sense as well as the technical talent to do justice to his topic, and spent many hours of investigation of old records, newspapers, and reports. This history is said to be practically the only account that is available of the "birth" of the earlier bridges and is a valuable document. He was a man of infinite patience and loved to do any such work that required research. He upheld the ideals of his profession and was a credit to the Engineering Service of the City he served so long, efficiently, and unostentatiously.

Mr. Gay was domestic in his tastes, and was not an active club man. He was fond of reading and was never at a loss for occupation. He liked carpentry. He had watches that had been in his family for six generations, and he made a box to fit them. He knew his grandfather clocks and could mend them and make them keep correct time when they were the despair of the modern clockmaker. Out of such things and indeed out of life in general, he extracted much of humor and sunshine for he had the genial gayety that goes with a mind at rest because he was always just and considerate. His was a beautiful character. He lived up to the favorite maxim of his grandfather, "Be good, do good, and be ever mindful of the rights of others." He was a close reader of current events, a student of economics and history, and an earnest advocate of the single tax theory, being a personal friend of its chief exponent, Henry George.

Mr. Gay died in New York City on November 23, 1935—a kindly compassionate man of unusual altruism who gave freely and quietly to private charities and whose personal probity was above reproach His body was taken to his ancestral home in Hingham, and, with a simple and impressive service, was buried in the cemetery there.

On September 5, 1895, he was married to Julia DeWitt Stone, of Staten Island, New York. She survives him, as do two daughters, Mrs. Martha

(Gay) Whiting, of Hingham, Mass., and Mrs. Elizabeth Neall (Gay) Pierce, wife of William Curtis Pierce, of New York City.

Mr. Gay was elected a Junior of the American Society of Civil Engineers on June 4, 1884, and a Member on June 5, 1889. He was also a member of the Municipal Engineers of the City of New York.

GEORGE ARCHIBALD GRAHAM, M. Am. Soc. C. E.[1]

Died February 11, 1937

George Archibald Graham was born on October 2, 1878, at Fort Ricasolia, Valetta, Malta, in the Mediterranean Sea, the son of the late Captain W. J. Graham, of the British Army, and Huldah (Barnes) Graham. He received his early education at Oxford, England, later attending Oxford University, where he took a Civil Engineering Course.

Soon after leaving college, Mr. Graham became Town Engineer for Whitney, Oxfordshire, England, where he remained for eight years. He then emigrated to Canada, and became connected with the Trans-Continental Railway, having been engaged in exploration, surveying, and construction for a number of years. Attracted by the lure of the South, he went to Jacksonville, Fla., in September, 1911, where for six and one-half years, he was Assistant Engineer in the City Engineering Department. During this time, he assisted in the preparation for a complete survey of the city, besides aiding in the remodeling of the water-works and underground electrical construction.

At the outbreak of the World War, Mr. Graham volunteered for active service, and was commissioned a First Lieutenant in the United States Corps of Engineers. He served at Camp Humphreys, in Virginia, and, for nearly two years, at Camp Dix, in New Jersey. After his discharge from the Army he went to Daytona Beach, Fla., in November, 1922, and immediately began to practice his profession. Among the subdivisions in the Halifax country which Mr. Graham surveyed may be mentioned the following: El Pina Parque, Kahnway Heights Seabreeze Park, and about one hundred others. He also prepared more than three hundred maps of the Halifax country.

Throughout his life Mr. Graham was noted for his fairness and high sense of business responsibility. He was a member of the American Association of Engineers and the American Water Works Association. He was also associated with the Institution of Civil Engineers of Great Britain. Locally, he was a member of the Chamber of Commerce and of the Masonic Fraternity.

For the last three years of his life, Mr. Graham was employed by the Government as Chief of Party No. 13, of the United States Coast and Geodetic Survey of Clay County, in Florida.

---

[1] Memoir prepared from information on file at the Headquarters of the Society and from data from "A History of Volusia County, Florida".

Besides his widow, Mrs. Alice Isobel Graham, and two children, Edgar J. and June Graham, he is survived by his sister, Rose Graham, of Oxford, England, and a brother, Professor Richard Graham, of McGill University, at Montreal, Que., Canada.

Mr. Graham was elected an Associate Member of the American Society of Civil Engineers on August 9, 1920, and a Member on April 12, 1926.

PAUL EVANS GREEN, M. Am. Soc. C. E.[1]

DIED MARCH 12, 1937

Paul Evans Green was born at Richmond, Ind., on April 23, 1879, the son of George Donaldson and Carrie Belle (Evans) Green.

He attended public and private schools in Wheeling, W. Va., and received his technical education at the State University of West Virginia, at Morgantown, W. Va., from which he was graduated in 1899 with the degree of Bachelor of Science in Civil Engineering. He was a member of the Kappa Alpha (South) Fraternity.

Mr. Green's first engineering work was with the Illinois Central Railroad Company as Rodman and Inspector. From 1900 to 1906, he was employed as Instrumentman, and, later, as Assistant Engineer in charge of new construction, and masonry and steel bridges, in Minnesota, the Dakotas, and Wisconsin. During 1906, he was Assistant Engineer on the New York State Barge Canal as Designer of reinforced concrete bridges, spillways, locks, dams, and other hydraulic works.

After 1906, Mr. Green made his home in Chicago, Ill. He was Division Engineer for the City, in charge of street improvements on the North Side. For the last thirty years of his life, he had been in private practice as a Consulting Engineer. The firm of Marr, Green, and Company was formed in 1908, but twenty years later, the name was changed to Marr, Green, and Opper. With these firms Mr. Green served more than one hundred cities and villages in the Middle West, as Engineer on water supply, sewerage, paving, and other municipal works.

As a citizen, Mr. Green was actively interested in the betterment of civic affairs. His abilities, as an independent consultant, were recognized. He made an investigation and report for the State's Attorney of Cook County on the operations of the Sanitary District of Chicago. He also served as a member of the Advisory Board of Engineers for the West Chicago Parks, on the proposed super-highway, and was Consultant on the design of the double-decked Wacker Drive improvement. The Finance Committee of Chicago engaged Mr. Green as its adviser on cost examinations.

---

[1] Memoir prepared by L. K. Sherman, M. Am. Soc. C. E.

During the World War, he was in Washington, D. C., with the United States Bureau of War Housing and Transportation, under the Chief Engineer, John W. Alvord, Hon. M. Am. Soc. C. E. Mr. Green had charge of about fourteen projects connected with munition plants.

In 1934, he served as an Associate Consultant for the National Resources Board on the inventory of water resources of the Great Lakes District. Mr. Green also served as Assistant Chief Engineer with the Civil Works Administration for the State of Illinois in 1933, and as Chief Engineer in 1934.

Much of Paul Green's work as an Engineer had to do with men, rather than materials. His genial personality won him many friends. When he was a subordinate, he was loyal, dependable, and free from envy. As a leader, he was respected for his calm judgment, integrity, prompt decision, and kindly interest in the welfare of his associates.

He was an enthusiast at golf, a member of the Evanston, Ill., Golf Club, and did considerable work in the layout, drainage, and sprinkling systems of golf courses.

Mr. Green was the author of a number of technical papers. One of his latest was a study of the cause of failure of a water supply storage dam near Herrin, Ill. He was a member and Past-Director of the Western Society of Engineers. He was also a member of the American Water Works Association, American Society for Testing Materials, and the Illinois Society of Engineers, and served as President of the latter for the year 1936.

In 1911, he was married at Fort Wayne, Ind., to Jessie Godfrey Winslow. Mrs. Green, his mother, a sister, and a brother survive him.

Mr. Green was elected an Associate Member of the American Society of Civil Engineers on July 10, 1907, and a Member on October 1, 1912.

JOHN HERBERT GREGORY, M. Am. Soc. C. E.[1]

Died January 18, 1937

In the passing of John Herbert Gregory in the midst of an active and eminent career, the profession has lost one of its pioneers in modern sanitary engineering, that branch of engineering in which the great advances in the art of water purification and sewage treatment have taken place during the last four or five decades.

John Herbert Gregory was born in Cambridge, Mass., on August 7, 1874, the son of John P. and Mary C. (Stone) Gregory. His early education was obtained in the public schools, and his technical education at the Massachusetts Institute of Technology, from which he was graduated in Civil Engineering in 1895.

[1] Memoir prepared by the late Harrison P. Eddy, Past-President, Am. Soc. C. E., and J. Trueman Thompson, M. Am. Soc. C. E.

In college, he was recognized, by teachers and students alike, as a leader in scholarship and an exceptionally able, orderly, and neat worker. Mr. Gregory always remained deeply interested in the Institute and took just pride in his Class, many members of which have attained distinction.

His early work was chiefly in Massachusetts, where he was employed by the Metropolitan Sewage Commission during college vacations and, later, by the Metropolitan Water Board upon problems of design relating largely to the Wachusett Dam and the Wachusett Aqueduct under the Chief Engineer, the late Frederic P. Stearns, Past-President, Am. Soc. C. E.

Mr. Gregory was intimately associated with early water purification practice in the United States. At Albany, N. Y., while in the employ of the late Allen Hazen, M. Am. Soc. C. E., he was Assistant Engineer and, later, Resident Engineer on the design and construction of the slow sand-filter plant, the first large covered plant of its kind in this country. Thus, in less than five years after graduation, Mr. Gregory held a position of responsibility in design and construction.

From 1900 to 1902, he was Assistant Engineer in Charge of Designs upon a project for the improvement, extension, and filtration of the water supply of Philadelphia, Pa., including the City's first four water filter plants, of which the Torresdale Plant, with a capacity of 100 000 000 gal per day, was then the largest in the world.

In 1902, Mr. Gregory was Division Engineer in charge of building the 22-mile conduit from Boonton, N. J., to Jersey City, N. J., for the new water-works of that city. Following this, he was Principal Assistant Engineer in the Filtration Department of the Commission on Additional Water Supply of the City of New York. In 1903, for the late Rudolph Hering and George W. Fuller, Members, Am. Soc. C. E., he personally made the designs for the rapid sand-filter plant built by the Hackensack Water Company, at New Milford, N. J., with a capacity of 24 000 000 gal per day. This was the second large rapid sand-filter plant built in the United States.

In some ways, Mr. Gregory's most noteworthy professional work was for the Water Department of the City of Columbus, Ohio, which he served intermittently for a period of 33 yr. Beginning in 1904, he was, successively, Engineer of Design, Principal Assistant Engineer, and Engineer in Charge. His first undertaking was the design and construction of the Julian Griggs Dam and Reservoir. He then designed and put in operation the first large sewage testing station built by an American city. In addition to the testing of various methods of sewage treatment, extensive research was carried on in the field of water softening. As Engineer in Charge of Improved Water and Sewage Works, Mr. Gregory was in charge of both the design and construction of the water purification and softening works (30 000 000 gal per day) and of the sewage treatment works (20 000 000 gal per day). The water treatment plant was the third large rapid sand-filter plant in the United States, and the largest water-softening plant then built. The trickling filters at the Sewage Treatment Works were the first large trickling filters designed and placed under construction in the United States. In 1910, Mr. Gregory was awarded the Thomas Fitch Rowland Prize by the Society

for his paper entitled "The Improved Water and Sewage Works of Columbus, Ohio."[2]

From 1920 to 1925, Mr. Gregory served as Consulting Engineer to the City of Columbus, in connection with the design and construction of additional water supply works which had been recommended by him in a report made to the City in 1919. These additions included mainly the enlargement of the water-purification and water-softening works from a capacity of 30 000 000 to 54 000 000 gal daily, and the construction of the O'Shaughnessy Dam and Reservoir on the Scioto River. For a paper entitled "The O'Shaughnessy Dam and Reservoir"[3] written by Mr. Gregory in collaboration with C. B. Hoover and C. B. Cornell, Members, Am. Soc. C. E., the James Laurie Prize was awarded them by the Society.

From 1926 to the time of his death Mr. Gregory served the City of Columbus as Consulting Engineer, in connection with the design and construction of many miles of relief and separate sewers and storm drains, and the new intercepting sewers and sewage treatment plant. The storm stand-by tanks which were built in connection with the sewage treatment works were the first to be built in the United States. The Rudolph Hering Medal of the Sanitary Engineering Division of the Society was awarded in 1935 for the paper entitled "Intercepting Sewers and Storm Stand-By Tanks at Columbus, Ohio"[4], written by Mr. Gregory in collaboration with Robert A. Allton, Orris Bonney and the late R. H. Simpson, Members, Am. Soc. C. E. In recognition of Mr. Gregory's services well and faithfully performed over a long period of years, first, in the regular employ of the City and, subsequently, in the capacity of Consulting Engineer, the City Council of Columbus passed a resolution of appreciation on January 25, 1937.

On the Passaic Valley Sewage Project in 1909 and 1910, he was Resident Engineer in charge of surveys and designs for the 20-mile Passaic Valley trunk sewer. He then entered the employ of the Metropolitan Sewerage Commission of New York, and was engaged primarily on investigations and studies relating to the collection, treatment, and disposal of sewage of the City of New York. One of the sites selected by him for sewage treatment works was the northeasterly end of Ward's Island, where the City now has nearly completed an activated-sludge treatment plant.

From 1911 to 1917, Mr. Gregory was a member of the firm of Hering and Gregory. Consulting Engineers and Sanitary Experts. After Mr. Hering's retirement from active practice in 1917, Mr. Gregory continued the practice until 1919, except for a period in 1918 when he was a Captain in the Sanitary Corps, United States Army. During the period devoted exclusively to private practice, he was Consulting Engineer to a large number of cities and towns, being engaged particularly upon problems relating to water, sewage, and municipal refuse.

Mr. Gregory became a member of the Faculty of the School of Engineering of The Johns Hopkins University, at Baltimore, Md., in 1919. In 1920,

[2] *Transactions*, Am. Soc. C. E., Vol. LXVII (1910), p. 206.
[3] *Loc. cit.*, Vol. 93 (1929), p. 1428.
[4] *Loc. cit.*, Vol. 99 (1934), p. 1295.

he was appointed Professor of Civil and Sanitary Engineering, occupying at the same time a similar Chair in the School of Hygiene and Public Health. Both these offices he held until his death. His wide experience in the management of affairs not connected with University life brought to the Advisory Boards of both these Schools many practical suggestions of great value. His services were also much in demand by other committees of the University.

Aside from his work-a-day relations with his students, his principal interest of an extra-curricular nature was that which he showed for many years in the Johns Hopkins Student Chapter of the Society. He was responsible for its establishment in 1921, and served as its Adviser for a number of years. A day or two before his death, he generously assumed the financial responsibility of a trip by the Senior members of the Chapter to the Annual Meeting of the Society in New York City.

During his connection with the University, he continued to act in a consulting and advisory capacity in so far as his teaching obligations would permit, and a large proportion of his most important work was done in this period. A few of his notable engagements, in addition to his work at Columbus, may be selected for special mention.

For about ten years Professor Gregory served as Consulting Engineer to the Sewer Department of the City of Baltimore in connection with the design and construction of large sewers and the enlargement of the sewage treatment works. For many years he served, and was serving at the time of his death, as Consulting Engineer to the Public Improvement Commission of the City of Baltimore on water supply matters. Among the works built and planned were the Prettyboy Dam and the Prettyboy Reservoir which was created by the construction of the dam. He served from 1932 to 1935 as one of three advisory engineers named to make an investigation and report on the need of an additional water supply for Baltimore. Professor Gregory was serving as one of the same group in an advisory capacity in connection with carrying out one of the steps recommended, namely, a duplicate water-works tunnel, 12 ft in diameter and 6 miles long, from the existing source of supply to the city. A resolution appreciative of his services to the City of Baltimore was adopted by the Public Improvement Commission on January 25, 1937.

In 1925, he served as one of the twenty-eight members of the Engineering Board of Review of the Sanitary District of Chicago, Ill., in connection with the controversy over diversion of water from Lake Michigan and the lowering of the levels of the Great Lakes which was alleged to have resulted therefrom.

In the same year, he served as one of three consulting engineers appointed by the Special Committee on Sewage Disposal of the City of Detroit, Mich., to advise as to the collection and disposal of the sewage of that city. The Board recommended the building of intercepting sewers and sewage treatment works. In 1936, Professor Gregory and his former associates were retained to advise upon the design and construction of these works.

He was chosen in 1933 as one of the three consulting engineers to make an investigation of the sewage disposal problem of the National Capital. Subsequent to their report, they were again retained in connection with the design and construction of remedial works.

At the time of his death, Professor Gregory was serving as Consulting Engineer to Samuel A. Greeley and Paul Hansen, Members, Am. Soc. C. E., on the design of the sewage disposal works at Buffalo, N. Y.

His services as expert witness were sought in important Court cases. Among those in which he participated were the States of Wisconsin, Minnesota, Ohio, Pennsylvania, Michigan, and New York *vs.* the State of Illinois and the Sanitary District of Chicago, in which an injunction was sought to prevent the diversion of water from Lake Michigan through the Main Drainage and Calumet-Sag Channels, Des Plaines River, and Illinois River to the Mississippi River; the State of Connecticut *vs.* the Commonwealth of Massachusetts, in which an injunction was sought to prevent the diversion of water from the Ware and Swift Rivers, tributaries of the Connecticut River, for use in the Metropolitan District of Boston; and the condemnation proceedings brought by the Passaic Valley Water Commission of New Jersey to acquire the water supply works of the Montclair Water Company, then supplying water to Paterson, Passaic, and other cities and towns in Northern New Jersey.

In 1932, Professor Gregory was appointed and served for a year as one of the five members of the Engineers' Advisory Board of the Reconstruction Finance Corporation. The function of the Engineers' Advisory Board was to advise the Board of Directors of the Corporation as to the merits of the applications made for funds to build so-called self-liquidating public works, for the financing of which Congress had appropriated $1 500 000 000. Professor Gregory's appointment was due to his wide experience in the design and construction of water supply and sewerage works. Of the loans made, 58% were for such projects.

The technical papers and discussions written by Professor Gregory are numerous and have appeared in various publications. The most important are the three papers presented to the Society, for which Society prizes were awarded as previously noted. Another literary field in which he participated was the reviewing of technical books, especially those dealing with Hydraulics and Sanitary Engineering.

Thus, for more than forty years, Professor Gregory had devoted his time, energy, and skill to the practice of Sanitary Engineering. His work as designer, supervisor of construction, teacher, consulting engineer, author, and collaborator in professional society activities was at all times marked by accuracy, refinement of detail, and fidelity to the highest standards and ideals of the Engineering Profession.

In the course of his professional career, Professor Gregory accumulated a comprehensive reference library of more than 5 000 volumes, pertaining to sanitary and municipal engineering and allied subjects. In accordance with his wishes, this library has been presented to the City of Columbus, Ohio,

as an expression of appreciation of the confidence placed in him during his many years of service to that city. The library is now established in the City Hall Building, where it is available to any one who desires to make use of it.

Professor Gregory's participation in professional society activities, his voluminous correspondence in quest of information, and his contacts with teachers and students gave him a wide acquaintance and a large circle of close friends who recognized his sterling qualities.

He was married, in Boston, on July 16, 1900, to Sarah Ann James. Mrs. Gregory and one son, Richard Sears Gregory, survive him.

He held membership in the Boston Society of Civil Engineers, American Society for Testing Materials, American Public Works Association, American Public Health Association, American Water Works Association, New England Water Works Association, California Sewage Works Association, Maryland-Delaware Water and Sewerage Association, Engineers' Club of Baltimore, and the Society of Sigma Xi. He was an Honorary Member of Tau Beta Pi.

Professor Gregory was elected a Junior of the American Society of Civil Engineers on January 3, 1899; an Associate Member on April 3, 1901; and a Member on December 4, 1906. He was a Director for the 3-yr term, 1932-34, serving on the Publication Committee, of which he was Chairman during his last year on the Board of Direction.

GEORGE TILLINGHAST HAMMOND, M. Am. Soc. C. E.[1]

Died August 9, 1936

George Tillinghast Hammond was born in Newport, R. I., on August 14, 1863, the son of George Tillinghast and Mary Elizabeth (Shipman) Hammond, His father was the publisher of the *Newport Daily News* and also served as Deputy Collector of Customs, New York, N. Y., during the administration of President Grant. His grandfather, William G. Hammond, had been Collector of Customs of Newport, R. I. The Hammonds were among the earliest of the settlers in Rhode Island and were among the most conspicuous of the earliest families. His Grandfather Shipman was the Chief Engineer of the Long Island Railroad during the early development of that road between 1836 and 1848.

Mr. Hammond prepared in his youth to enter the field of medicine and studied at the College of Physicians and Surgeons, in New York City, and was Assistant to his cousin, Dr. George Tillinghast Bull, who was a noted surgeon of a generation ago.

[1] Memoir prepared by J. C. Riedel, M. Am. Soc. C. E.

Leaving the field of medicine in 1888 to enter the profession of Civil Engineering, he was engaged by the Aerated Fuel Company, a subsidiary of the Standard Oil Company, in connection with the design and installation of some of the earliest oil burners for steam generation. He became Chief Engineer of the Aerated Fuel Company and remained in this field until 1891, when he became an Assistant Engineer in the Department of City Works of the former City of Brooklyn, N. Y., in which position he was engaged upon the design and construction of water-works, aqueducts, and pumping equipment. He then became an Assistant Engineer in the Department of Sewers in the newly created Greater City of New York. During this period, he also designed the sewerage system of Ceballos, Cuba.

From 1898 until 1906, Mr. Hammond was attached to the Department of Sewers and then to the Bureau of Sewers in the Borough of Brooklyn, as Assistant Engineer in charge of the building of some the largest sewers which had been constructed to that time.

In 1906, he obtained a leave of absence from the City of New York and was appointed Division Engineer in charge of the design of the storm-water sewers of the City of Baltimore, Md. Upon completing the design of this system, he returned to Brooklyn, and was appointed Engineer of Design, in the Bureau of Sewers, which position he held until his retirement from active service in 1933. As such, he designed the Classon Avenue Relief Sewer System, as well as the sewerage systems of other parts of the Borough. The value of the work for which designs were made under the supervision of Mr. Hammond was more than $100 000 000.

During his connection with the Bureau of Sewers of Brooklyn, Mr. Hammond was in charge of the experiments performed in 1913 to 1918 at the 26th Ward Sewage Disposal Works, upon all known methods and processes of sewage treatment and disposal. His work resulted in the development of processes now accepted as standard. Mr. Hammond was in charge of the design of the pumping station erected at the head of Gowanus Canal, which cleared the waters of that Canal twice daily, the capacity of the plant being 30 000 cu ft per min.

Mr. Hammond was one of the foremost experts on sewage disposal in the United States. In 1912, he visited Europe with the late Rudolph Hering, M. Am. Soc. C. E., who was then the Dean of American engineers specializing in Sanitary Engineering, and inspected all the important sewage treatment works there.

During the World War, Mr. Hammond entered the United States Public Health Service, was appointed a Surgeon, and, as such, designed and supervised the construction of sewage treatment works in the camps of the Army in the United States. He was in charge of the health and sanitation of thirty-eight shipyards between Boston, Mass., and Philadelphia, Pa., which employed about 100 000 men. He also served in the Housing and Transportation Division of the Shipping Board.

Mr. Hammond also acted as Consultant upon sewerage projects and water supply systems for Batavia, Java, Dutch East Indies, other cities in the

Orient, and for a number of cities in the United States. He was frequently consulted by agencies of the Japanese and Chinese Governments on these related matters.

He was a member of the American Society for Testing Materials and was Chairman of one of its committees for many years.

In his early career he wrote frequently on scientific subjects for the *New York Tribune*, the *New York Sun*, and the *New York World*, and was a member of the Press Club in the City of New York.

Mr. Hammond studied law from 1900 to 1903, after office hours, at the Law School of New York University, and was admitted to the Bar in 1904. He served as Arbitrator and Counselor in many engineering matters.

He was a member of the Delta Chi Fraternity, the Long Island Historical Society, the Kings County Historical Society, Altaire Lodge 601, F. and A. M., and the Washington Club, and was a Fellow of the American Association for the Advancement of Science.

Mr. Hammond had an encyclopedic mind, was deeply interested in scientific developments, was an ardent research worker, and kept in contact with the most recent developments in the fields of physics, chemistry, and engineering. He possessed high artistic ability and in his youth painted many fine portrayals of landscapes of the country about his early homestead.

He possessed a charming and interesting personality and was always highly regarded and highly respected by his countless friends and associates.

He was never married, and is survived by four brothers: John F. Hammond, M. Am. Soc. C. E., Henry B. Hammond, a member of the New York Bar; William G. Hammond, the famous organist and composer, all of New York City; and Charles F. Hammond, a lawyer, of Watch Hill, R. I.; and a sister, Mrs. Mary K. Smith, of New York City.

Mr. Hammond was elected a Member of the American Society of Civil Engineers on February 7, 1906.

THEODORE HENRY HINCHMAN, M. Am. Soc. C. E.[1]

Died July 16, 1936

Theodore Henry Hinchman, the son of John Marshall Hinchman and Ella (Cropsey) Hinchman, was born in Detroit, Mich., on June 24, 1869. His forebears were important people in Detroit back in the days when it began to develop from a town almost exclusively French in character, into an American city. His great-grandfather, Dr. Marshall Chapin, was one of Detroit's early physicians, having left his home in New York State in 1809 to settle there. In 1819, his grandfather, Theodore Henry Hinchman, established a wholesale drug business, which, after the founder's death, was carried on by his sons under the name of T. H. Hinchman's Sons, and which ultimately became The Michigan Drug Company of the present time. With such a back-

[1] Memoir prepared by William R. Kales, M. Am. Soc. C. E.

ground, the subject of this memoir may well be called a "Detroiter", since he and his relatives have taken an active part in the growth and development of the city for more than one hundred and twenty-five years.

As a boy, Mr. Hinchman attended the Detroit Public Schools, and was graduated from the Old Detroit High School in 1887. He then entered the University of Michigan, at Ann Arbor, Mich., from which he was graduated from the Liberal Arts Department, in 1891, with the degree of Bachelor of Arts, and from the Engineering Department, in 1893, with the degree of Bachelor of Science. While acquiring his training as an engineer, he had the good fortune to study under Mortimer E. Cooley, Hon. M. Am. Soc. C. E., beginning a friendship which continued for the remainder of his life.

During college vacations he worked on the Engineering Staff of the Michigan Central Railroad Company, and under Mr. Henry M. Leland, with the Leland, Faulkner, Norton Company. After his graduation, in 1893 and for a part of 1894, he served under Professor Cooley and under Mr. Jesse M. Smith, on consulting engineering work.

In the latter part of 1894, the partnership of Field and Hinchman, Consulting Mechanical and Electrical Engineers, was formed. Times were hard in those years immediately after the panic of 1893; and it took real courage to start a new business, venturing all one's small financial resources. Fifteen hundred dollars was the paid in capital with which the new firm started. Of this amount, Theodore Hinchman contributed \$1 000 which had come to him through a legacy from his maternal grandfather, Mr. John G. Cropsey, of Chittenango, N. Y. Mr. George H. Field of the firm had also been recently graduated from the University of Michigan.

As can be seen by the dates, this was long before the development of the automobile industry in Michigan. Detroit was a slow, easy-going city of about 250 000 people—approximately one-sixth of its present size. It was a pleasant, clean place in which to live, being largely a jobbing center with comparatively little manufacturing. The first steel-frame office building was constructed about this time. There was very little work for the consulting engineer in such a community, and it was very difficult to secure enough of it "to keep the wolf from the door."

A year later, on October 24, 1895, Theodore Hinchman was married to Emma MacAllan Ballentine, at her home in Port Huron, Mich.

When war was declared against Spain in 1898, Mr. Hinchman temporarily left his work in Detroit to enlist in the Navy as Chief Machinist on the U. S. S. *Yosemite*, serving under his old friend and professor, Mortimer E. Cooley, who was Chief Engineer of that ship. The *Yosemite* served in the blockades of Santiago, Cuba, and of San Juan, Puerto Rico. At one time, while alone on the latter station, she was attacked simultaneously by several gunboats and from Morro Castle. Dean Cooley gives the following account of this naval action:

"While on the blockade off San Juan, the *Antonio Lopez*, flagship of the Lopez Line, crept by us in the dark the night of June 27–28, 1898, missed the port and sailed westward. Discovering her mistake in the early dawn, she was returning when we saw her about four-thirty A. M.

"We immediately cleared ship for action, and intercepted her. To escape she turned toward the shore, and we ran in between her and the port. This brought us within range of Morro Castle, which began to fire at us with her nine-inch guns. Simultaneously, several torpedo boats came out from the harbor, one of them armed with a gun from the fort. Also the *Antonio Lopez* was armed and took part in the engagement. We drove the gunboats back into the harbor; and as the shots from the fort were dropping closer and closer, we went back out of range. This part of the engagement lasted from about four-thirty A. M. to about eight A. M.

"After breakfast we went in to destroy the *Lopez*, which was on the shore. The fort and the torpedo boats attacked us again. We drove the latter back into the harbor a second time, and went back and played safe. The fort did some clever firing. The flashes from the heliograph in the hills helped them find the range. One shot came so close as to splash water in on the gun deck. Another barely grazed the top of our smoke pipe. Most of the shells fell astern, as we kept up the speed of six or eight knots an hour.

"I timed the flight of a shell from the flash until it struck—31 seconds, which would mean the range was about six miles. One torpedo boat, armed with a Hontura from the fort, fired one shell that went lengthwise of the bridge, and so low that everybody dropped flat, including the Captain. Had one of the plunging shells from the fort struck us on the deck, it would have gone straight on through us. The nearest land was about a mile and a half below. The water there is very deep.

"In the Spanish War, we were the only ship in the Navy to fight against superior odds. As a result of it we received double prize money, a considerable sum by the way. The law awarding prize money was later done away with. We were the last ship to receive it."

After the war, Mr. Hinchman resumed his work as Consulting Engineer; and by hard, faithful, and effective service, built up his reputation.

The advent of the automobile business, and the increase in manufacturing in Detroit after 1900, brought more demand for the services of a man who had proved his ability and reliability during the preceding years. There was a great increase in the use of structural steel, and reinforced concrete construction was introduced. Building work required the services of the engineer as well as those of the architect. On March 30, 1903, an Architectural Department was added to the firm's activities; and the business was incorporated under the name of Field, Hinchman, and Smith.

In an old city like Detroit, many of the down-town office and commercial buildings occupied the best sites, and were hopelessly inadequate for the requirements. Obviously, they would soon have to come down, and be replaced by modern structures. New factories, embodying up-to-date manufacturing methods of production, were constantly going up. In planning the construction and equipment of such buildings, the harmonious and co-operative work of engineers and architects was necessary.

At the end of 1906, Mr. Field left the organization; and the present name—Smith, Hinchman and Grylls—was adopted early in 1907.

The following are some of the important pieces of work planned and carried to completion under Mr. Hinchman's supervision; Buhl Building (26 stories); Union Guardian Building (34 stories); Penobscot Building (44 stories); J. L. Hudson Co. Department Store; Crowley Milner Co. Department Store; Second National Bank of Saginaw, Mich.; the University Club (Detroit); the Detroit Country Club; Dodge Brothers Automobile Plant;

Hiram Walker & Company's great distillery recently completed in Peoria, Ill.; the Mistersky Power Plant and Transmission System for the Public Lighting Commission of Detroit; the High-Pressure Fire Protection System of Detroit; the Fairview Sewage Pumping Plant for Detroit; and the Power Plant, the Chemistry Building, Sub-Station, Power House, East Engineering Building, Yost Field House, Intramural Building, and Graduate School, of the University of Michigan.

In 1905, Mayor George P. Codd recognized the ability of Theodore Hinchman, and the need the City of Detroit had for his services, by appointing him a member of the Public Lighting Commission. He was also a member of the Michigan State Planning Commission, receiving his appointment from Governor Fitzgerald, in January, 1935. At the time of his death, he was President of the Village of Grosse Pointe Farms, where he had his home.

Soon after starting in business in 1894, Mr. Hinchman assisted in organizing the Detroit Engineering Society. For several years he served as Secretary of this Society; and held this office until it had become firmly established as a factor in the Detroit community. Later, he became, successively, Vice-President and President of the Engineering Society.

He joined the American Society of Mechanical Engineers as a Junior Member shortly after his graduation from college; and, when his age and experience justified his doing so, became a Member. His affiliations also included membership in the Detroit Board of Commerce, of which he was at one time a Director, the Detroit Country Club, the University Club, and the Detroit Club, of which a few years ago, he was President.

Coming from an old Presbyterian family, Mr. Hinchman was always a member and consistent worker in that church, and, at the time of his death, he was President of the Board of Trustees of the Grosse Pointe Memorial Presbyterian Church.

Theodore Hinchman is survived by Mrs. Hinchman and their three sons, Theodore Henry Hinchman, Jr., David Ballentine Hinchman, and John Marshall Hinchman, II. The second son, David, is married and has two children, one of whom bears the name of Theodore Henry Hinchman. He was a loving and much loved husband and father.

In writing this memoir, the attempt has been made very briefly to sketch the career of one who represented the highest type of American citizen. He was fortunate in having back of him an ancestry that stood for the best things in life—integrity, reliability, and honor He was endowed with an exceptionally bright and logical mind, and the capacity for unflagging industry, so that year by year he became more useful and more efficient. His education only began in his school and college days. It ended only with his death, which occurred at his home in Grosse Pointe Farms, a suburb of Detroit, on July 16, 1936.

Mr. Hinchman had a cheerful friendly disposition that inspired in all with whom he came in contact, feelings of confidence, trust, and loyalty. He began his professional career at the "bottom of the ladder", relying for success on his own ability and industry. By consistent hard work, he progressed until he built up one of the finest engineering and architectural organizations in the United States.

When his services were needed by his friends, his church, his city, his State, or his country, they were freely given; he never shirked his responsibilities. It is an honor to have been his friend.

Mr. Hinchman was elected a Member of the American Society of Civil Engineers on February 25, 1924.

JOHN HISLOP, M. Am. Soc. C. E.[1]

Died February 22, 1901

John Hislop was born at Strasburg, Waterloo County, Ont., Canada, on February 1, 1856. He entered McGill University, at Montreal, Que., Canada, in September, 1881, and was graduated therefrom in April, 1884, with the degree of Bachelor of Applied Science.

During his vacation of 1882, he was engaged in making surveys on the Great Eastern and Pontiac Pacific Railways, in the Province of Quebec, Canada. In 1884, he served as Rodman on the Canadian Pacific Railway; in 1885, on surveys on the Burlington and Missouri River Railway; and afterward on construction work for the Burlington and Northern Railway Company.

In 1886, Mr. Hislop was employed as Transitman on the Burlington and Northern Railway; and, in 1887, as Transitman and Track Engineer, and, in 1888, as Assistant Division Engineer, Maintenance of Way, on the Chicago, Santa Fé and California Railway.

During February and March, 1889, he served as Assistant Engineer on Construction, on the Carbon Cut-Off, for the Union Pacific Railway Company. Later, he was appointed First Assistant Engineer, on the exploration and surveys of the Colorado River of the West, for the Denver, Colorado Canyon, and Pacific Railway Company. This work proved his courage and efficiency beyond all question.

Mr. Hislop was engaged in general engineering practice, in Denver, Colo., in 1890, and in the winter and spring of 1891, he was Resident Engineer in charge of construction on the Denver, Lakewood, and Golden Electric Railway. Later, he was appointed Chief Engineer of the Colorado Grand Canyon Mining and Improvement Company.

From January to April, 1892, he was Acting County Surveyor of Weld County, and City Engineer, of Greeley, Colo., and while holding this position he made surveys and estimates for the proposed Highline Reservoir, in South Park. He then became Assistant Engineer of the Payette Valley Irrigation and Water Power Canal, in Idaho, in charge of location and construction of twelve miles of canal, including head and waste-gates, flumes, bridges, siphons, etc.

[1] Memoir compiled from information supplied by the late C. LeR. Annan, M. Am. Soc. C. E., and from data on file at the Headquarters of the Society.

In January, 1894, Mr. Hislop became Assistant Engineer of the Castaica and San Feliciana, and Hocumac Mining Companies, with headquarters at Los Angeles, Calif. Later, he went to Alaska, where he had charge of the construction of the White Pass and Yukon Railroad. This road was between Skagway and the interior, 110 miles in length, and required the most expert work under very difficult conditions. At this time, he also served as Mayor of the City of Skagway.

Mr. Hislop had great athletic skill, and was able to keep his poise under all circumstances. Although very reserved, he was considered a good fellow among his associates, and was ever ready to assist in any arduous undertaking.

He was accidentally killed in Chicago, Ill., on February 22, 1901, by falling beneath the wheels of a moving train which he was trying to board.

Mr. Hislop was elected a Member of the American Society of Civil Engineers on May 1, 1895.

RICHARD CARMICHAEL HOLLYDAY, M. Am. Soc. C. E.[1]

Died November 17, 1936

Richard Carmichael Hollyday, Civil Engineer and Naval Officer, the son of Richard Carmichael and Marietta Fauntleroy (Powell) Hollyday, was born at Ratcliffe Manor, in Talbot County, Maryland, the ancestral home of the fine old Southern family from which he sprung, on November 13, 1859.

Educated in private schools, the Shenandoah Valley Academy, and Washington and Lee University, at Lexington, Va., Mr. Hollyday subsequently completed the necessary course of study and was admitted to the practice of law; but, because of an inclination for an outdoor life, he sought and obtained a position on a railroad survey and, thereafter, followed the profession of civil engineering.

Beginning his professional career on preliminary and location surveys of the Philadelphia Branch of the Baltimore and Ohio Railroad, he was employed, successively, on bridge construction—foundations and superstructure erection—for crossing of the Susquehanna River, at Havre de Grace, Md., the Schuylkill River, at Gray's Ferry, Philadelphia, Pa., and the Christiana River for the City of Wilmington, Del. After a short period at the Baltimore Headquarters of the Baltimore and Ohio Railroad Company, he was transferred to the Ohio Division of the System as Engineer of Maintenance of Way, with headquarters at Newark, Ohio. Upon the termination of this connection, he resigned from the railroad service and was variously employed on a gasholder project, in Philadelphia, Pa.; blast furnaces, at Bristol, Tenn., and Radford, Va.; a pipe foundry, at Bristol; an inclined railway, at Lookout Mountain, Chattanooga, Tenn.; and on the construction of an ore plant, at Shelby, Ala.

[1] Memoir prepared by Leonard M. Cox, Captain (C. E. C.). U. S. N. (*Retired*), M. Am. Soc. C. E.

On March 15, 1894, Mr. Hollyday was appointed by President Cleveland as a Civil Engineer, United States Navy, with the relative rank of Lieutenant, Junior Grade, and served on active duty continuously thereafter in the Corps of Civil Engineers, until he reached the statutory age for retirement.

In April, 1894, Civil Engineer Hollyday began his naval career as Assistant to the late Civil Engineer, U. S. G. White, U. S. N., then attached to the Puget Sound Navy Yard. In December of the same year, through the detachment of his superior, Civil Engineer Hollyday became head of his Department in charge of Public Works. Thence, until May, 1897, he played a most important part in the building of the then new station, a part that included superintendence of construction of the timber dry dock, general lay-out for the Yard, design and construction of water system, shops, and officers' quarters.

From May, 1897, to August, 1901, Civil Engineer Hollyday was Yard Civil Engineer—corresponding to the present position of Public Works Officer—at the Mare Island Navy Yard, in California. During this duty the disastrous earthquake of March 30, 1898, afforded opportunity for the display of his exceptional abilities. He virtually rebuilt the Yard—and in what was considered record-breaking time. Many of the Yard shops and storehouses were either demolished, or badly damaged, all officers' quarters had to be condemned for use, and Yard operations were virtually suspended. Civil Engineer Hollyday wired estimates and a request for funds, and secured a special appropriation. Work was started immediately and, by January, 1900, the Yard was to all intents and purposes rebuilt. Undoubtedly, the record then made for handling such an emergency was the deciding factor in his later selection as Chief of Bureau of Yards and Docks. He was the officer who inaugurated the methodical study of the hydraulics of Mare Island Strait, which culminated during his administration as Chief of Bureau of Yards and Docks, in the appointment of the so-called Biddle Board and, by that Board's recommendations, in the adoption of the dike layout which has proved so successful in maintaining the desired depths of channel.

From August, 1901, to January, 1903, he was assigned to duty at the Boston (Mass.) Navy Yard, in charge of all new construction and of Yard maintenance; and from the last-mentioned date until March, 1907, he held the corresponding position at the then ranking naval shore station, the New York Yard, in Brooklyn, N. Y.

In March, 1907, Commander Hollyday—he held that rank at the time—was commissioned Chief of Bureau of Yards and Docks of the Navy, with the relative rank of Rear-Admiral during incumbency. Within the term of his administration many important—some serious—problems were solved satisfactorily, and many improvements effected in Bureau procedure. One of the most important advances in Bureau policy was the elimination of irresponsible bidders and the issuance of "invitations to bid" to selected contractors of known ability and financial standing in the case of Dry Dock No. 3, at the New York Yard.

He administered the highest office in his Corps during the trying period when the ambition to re-organize the Navy Department, among newly

appointed Department officials, assumed something like epidemic proportions. Boards and commissions were charged with the planning of procedure changes affecting nearly every phase of the Department's activity from filing systems to works management and supervision. Carried away by the unquestioned need for improvement in the way of reduction of plant and supervisory duplication, attempts were made to consolidate the Naval Staff Corps—a project which, had it been put into effect, would have resulted in placing authority over one class of technical work in the hands of men trained for entirely different work. Admiral Hollyday saved the situation—for his Corps and for the best interests of the Navy—not by the militant methods advocated by many able officers, but by a calm demeanor throughout the period, by a willingness to concede the merit of the plan within limits of practicability, and by the unanswerable logic of his arguments.

In January, 1912, Admiral Hollyday, his term of office having expired, was detached from duty as Chief of Bureau of Yards and Docks, and automatically reverted to his permanent rank of Captain. As Dean of his Corps he served from this date until retirement as Public Works Officer of the Washington, D. C., Norfolk, Va., and New York Navy Yards, and successfully administered the expenditures of large amounts of public funds in naval shore construction.

In November, 1923, while stationed at the New York Yard—with additional duty as Public Works Officer of the Third Naval District—Captain Hollyday reached the retirement age and was relieved from active duty.

He was recalled subsequently to active duty for temporary service on selection boards for the promotion of civil engineer officers, but his active professional and naval career ended with retirement. Until his death, he and Mrs. Hollyday resided in New York City, or at his family home in Easton, Md.

Captain Hollyday was married, on April 28, 1894, to Mary Holton King, of Newark, Ohio, and enjoyed an exceptionally happy married life. Of their two sons one, Richard Carmichael, educated for his father's profession, but preferring a business career, is a member of the firm of Culver, Hollyday and Company, Realtors, of New York City; the other, King, like his Colonial ancestors, is an agriculturist, residing at St. Michaels, near Easton, Md. He is also survived by his sister, Mrs. William P. Semple, of Louisville, Ky.

Captain Hollyday entered the Naval Service with the rank of Lieutenant, Junior Grade. On June 2, 1897, he received his first promotion—to the rank of Lieutenant. He was commissioned with the rank of Lieutenant Commander on April 6, 1902; Commander, on November 26, 1906; Chief of Bureau of Yards and Docks, with the rank, during incumbency, of Rear-Admiral, on January 18, 1908; and Captain (regular list), on March 13, 1911.

His social clubs were the Army and Navy, Chevy Chase, and University, of Washington, D. C.

Captain Hollyday was an able engineer, a naval officer of the highest type, and a gentleman of the old school—true to the traditions he inherited from a long line of Virginia and Maryland ancestors who played their part in

American history from early Colonial days. In times of stress, he was cool and deliberate; ever kind and considerate to his subordinates; to those who failed to measure up to his own standards of professional or naval ethics, he was slow to forgive—but never vindictive. Those who were fortunate enough to serve under or with him in close association, loved him, and will not soon forget their "Old Chief."

Captain Hollyday was elected a Member of the American Society of Civil Engineers on September 3, 1903.

LAURENCE COOPER HOUGH, M. Am. Soc. C. E.[1]

DIED JANUARY 13, 1937

Laurence Cooper Hough, the eldest child of Elida C. and Pamelia (Rice) Hough, was born on December 5, 1891, at East Falls Church, Fairfax County, Va. He was of straight English Colonial stock on both sides of his house. His direct ancestor, William Hough, of Westchester, England, came over to the Plymouth Colony in 1640. William Hough soon moved to Connecticut, and family tradition has it that he built the first house at what is now the City of Meriden, in 1642, and settled there.

Mr. Hough's great-grandfather, Dr. H. G. Hough, moved over into Northern New York State and practiced medicine as a pioneer in the Black River country. Dr. Hough's son, Dr. Franklin B. Hough, was elected to Phi Beta Kappa Fraternity while a student at Union College, at Schenectady, N. Y., about 1842, and, later, studied science at Case Institute in Ohio, walking from Albany, N. Y., to Cleveland, Ohio, for the purpose. He practiced medicine at Lowville, N. Y., served as Surgeon and Major with the 90th New York Volunteers during the Civil War, being present at the battles of Fredericksburg, and Antietam, and in other campaigns. In 1875, he was appointed United States Commissioner of Forestry, and, as such, established the office which is now the United States Forest Service.

Mr. E. C. Hough, the father of Laurence Cooper Hough, was born at Lowville, N. Y., was graduated from Cornell University, at Ithaca, N. Y., in 1885, with the degree of Bachelor of Arts, and spent almost his entire working life as Examiner for the United States Patent Office, in Washington, D. C.

Laurence Cooper Hough attended the public school at Falls Church, Va., and was also a student at Force School, Washington, D. C. He spent one year at the Western High School and three years at the McKinley Manual Training School, in the District of Columbia, and was graduated from the latter in 1910.

In 1914, he was graduated from Cornell University with the degree of Civil Engineer. His summers during his college course were spent in engi-

[1] Memoir prepared by Edgar K. Wilson and Egbert D. Case, Members, Am. Soc. C. E.

neering work. In 1911, he was a Draftsman, in Washington, on Patent Office drafting. During the summer of 1912, he acted as Transitman at the Cornell University Engineers' Camp on a topographical survey. The following summer he was employed as Chainman for the United States Land Office, on a surveying project in the Swan River country of Western Montana.

The summer after his graduation, Mr. Hough worked for The Whitney Company, in New York City, as Estimator on Construction. Later, he was employed for a short time by the late James H. Fuertes, M. Am. Soc. C. E., after which he served as Chief of Party on subway construction in New York City for the Public Service Commission, until June, 1917. During this latter engagement, part of his duties was to check the elevations of buildings adjacent to the construction work to determine whether they were sinking.

In June, 1917, he became connected with The Pitometer Company, Engineers, and this proved to be the engagement to which the remainder of his life was devoted. With the exception of a period from August, 1917, to November, 1918, when he served in the World War, he was engaged in making water-waste surveys and other investigations for water-works distribution systems, first as Assistant and then as Engineer in Charge in surveys of Buffalo, N. Y., Boston, Mass., and Providence, R. I., as well as of many smaller communities.

In 1924, due to his thorough knowledge of this work, his pleasing personality, and his growing acquaintance with water-works officials, Mr. Hough was appointed a District Manager of the Company, first with headquarters at Boston, Mass., covering the New England States; but, later, with an office at Albany, with New York State, part of New Jersey, Georgia, and Florida, added to his territory.

During the years following his appointment as District Manager Mr. Hough almost literally lived in his automobile, driving long distances to call on his clientele, or to attend meetings of officials, and he was known to hundreds of water-works men, including many with whom he had no direct business contact, as a man of character, genial and kindly in all his relations with his fellows.

Mr. Hough always had a taste for music and as a boy rather seriously studied the violin. In later years, he derived much pleasure from a piano.

He was always greatly interested in military matters, and during his fourth year in preparatory school served as Captain and Regimental Adjutant of the Cadet Corps. When the United States entered the World War, Mr. Hough promptly applied for admission to the First Officers' Training Camp and was bitterly disappointed when he failed to receive an appointment. However, he was appointed to the Second Camp at Plattsburgh, N. Y., and received a commission as Second Lieutenant of Coast Artillery. After a brief assignment at Fortress Monroe, Virginia, he was sent to France, and assigned to I Battery, 51st Coast Artillery. This outfit was using 14-in. naval guns on railway mounts. Unfortunately, or perhaps fortunately, Mr. Hough saw little action, although he underwent frequent aerial bombard-

ments. On one occasion a severe attack of the mumps, on another a quarantine against measles suffered by a tent mate, and on a third a school assignment removed him from his outfit when it was in combat. His education and talent as a Civil Engineer were made use of in laying out the curved trackage for new positions, by which means the guns were trained to left or to right, and, at other times, he was responsible for the supply of ammunition to the guns. One of his war stories is to the effect that while moving their guns it was found that one gun with its car would not enter a tunnel by a scant 2 in. This was remedied after considerable delay by changing to smaller car wheels. When the gun train finally passed through, a Rear Admiral was in the locomotive cab, in his jubilation holding down the whistle cord. After the war, Mr. Hough became a member of the Coast Artillery Reserve and served until 1934 when he retired with the rank of Captain.

Mr. Hough's pioneering ancestry showed itself in his insatiable interest in people, historical places, and things around him. His accurate knowledge of the happenings of former days in the cities and countryside within his reach was amazing. Not only did he have a store of interesting knowledge about such places, but he was always eager to tell about them and show them to his friends, even at considerable inconvenience to himself.

However, inconvenience was not in his vocabulary, when there was a question of doing a favor for a friend or an associate. By all who knew him Mr. Hough was recognized as a man of the highest character, upright and fair in all his dealings, an able engineer, a true friend, and a valued associate.

He was married on October 7, 1922, to Jennie Marion Ponti, who survives him. Mr. and Mrs. Hough were members of the Old South Church, of Boston.

He was also a member of the Cornell Society of Civil Engineers, American Water Works Association, New England Water Works Association, Maine Water Utilities Association, and of the Joseph Warren Lodge, A. F. and A. M., of Boston.

Mr. Hough was elected an Associate Member of the American Society of Civil Engineers on July 11, 1921, and a Member on October 7, 1929.

JOSEPH MILTON HOWE, M. Am. Soc. C. E.[1]

Died March 22, 1937

Joseph Milton Howe was born on July 30, 1874, in Houston, Tex., the son of the late Milton Grosvenor Howe, M. Am. Soc. C. E., and Jessie (Briscoe) Howe. His grandparents were pioneers of Texas. His grandfather, Captain Andrew Briscoe, fought at the Battle of San Jacinto; he

[1] Memoir prepared by A. J. Wise, M. Am. Soc. C. E.

was one of the signers of the Texas Declaration of Independence and was the first Judge of Harris County. His father built the Houston and Texas Central Railway, and, later, became its Chief Engineer. Mr. Howe was a descendant of John R. Harris, founder of Harrisburg, which is now a suburb of Houston, and for whom Harris County was named.

He was educated in private schools, at Phillips Academy, at Andover, Mass., and received his degree from the Massachusetts Institute of Technology, in Boston, Mass., in 1896. Later, he attended the Law School of the University of Texas, at Austin, for a year.

Mr. Howe ended his academic career to enter the Engineering Department of the Santa Fé Railway Company in 1897, joined the Engineering Staff of the Houston and Texas Central Railway Company in 1899, and became Acting Engineer, Maintenance of Way, and Assistant Engineer, Maintenance of Way, of the Company before he resigned to become Principal Assistant Engineer, Maintenance of Way, of the Southern Pacific Railroad Company (Atlantic System). He resigned this position in January, 1904, to enter private practice in Houston, and was engaged in the location and construction of short-line railroads and drainage. Among his achievements were the Montana Panuco y Monclova Railroad, in Mexico; the design and construction of Drainage District No. 1, Liberty County, Texas; the location of storage tanks and pipe lines for various oil companies; and the design of a sewage disposal plant in Estacion Monclova, Coahuila, Mexico.

In July, 1909, he formed a partnership with A. J. Wise, M. Am. Soc. C. E., and organized the firm of Howe and Wise which association continued until his death. During the period of this partnership Mr. Howe devoted most of his time to road construction, paving, and other municipal engineering work, and to hydraulic and railroad engineering. He personally supervised design and construction for the Gulf Coast Irrigation Company, the Texas Exploration Company, as well as the Dayton-Goose Creek Railroad Company, as Cousulting Engineer of the Brays Bayou Drainage District, one of the most important projects in Houston and Harris County.

The firm of Howe and Wise served as County Engineers of Harris County from 1911 to 1915 and again in 1917 until 1929. The bridge and road improvements that brought national attention to this area were designed under its supervision. In 1935 and 1936, Mr. Howe again acted as Consulting Engineer for Harris County. From 1911 to 1936, about \$20 000 000 was expended on road and bridge construction in that County under his supervision.

He was prominent in professional and business movements throughout the United States. He was Vice-President of the Houston National Bank, a Director of the Trust Company of Texas, President of the Houston Realty Syndicate, Oakland Realty Company, and the Brookline Development Company. He was a member of the State Board of Health and a Trustee of Hermann Hospital Estate. He belonged to the Museum of Fine Arts, University Club, Rotary Club, and Sigma Chi Fraternity.

The high regard in which Mr. Howe was held in the City of Houston and the State of Texas was expressed editorially by the *Houston Post,* on March 24, 1937, as follows:

"America's modern industrial civilization is largely the creation of engineers.

"Business men, promoters and politicians get much of the credit, but the engineers furnish the brains.

"Because of their technical skill railroads have been pushed across rugged mountain ranges, automobiles dash around curves in highways at sixty miles an hour in perfect safety, and huge bridges span the Mississippi River and San Francisco bay, bodies of water once considered unconquerable.

"Look behind any modern triumph of construction or invention and you will find an engineer bent over a desk, pipe in mouth, scanning blueprints, filling pages with figures.

"His name does not appear on the bronze plates or marble cornerstones, but without him and his knowledge it would be impossible to build a three-story building that would not topple down on the heads of its occupants.

"J. Milton Howe, who was born in Houston and who died here Monday, was an engineer who had won recognition throughout America. He was known for two outstanding characteristics that dominated his entire professional career—technical skill and unswerving honesty.

"In a long and brilliant engineering career, he spent his lifetime above all usefully. He leaves behind him railroads in Mexico, highways in the United States, and scores of other projects as monuments to his constructive genius. Many of the fine highways which bear traffic of Harris County and Houston were built under his supervision and his name has been associated with notable construction projects throughout the country.

"He was honored repeatedly by the American Society of Civil Engineers and by the Texas chapter which he helped organize. Nearly every honor that can come to an engineer as a reward for proficiency in his profession came to Mr. Howe. Throughout his career, he was as interested in the advancement of engineering as a science as in his own affairs.

"As a man he was kindly, sincere, honorable and wholly lovable. He made friends who clung to him because of his genuine worth, his lack of pretense and his unconquerable spirit.

"His friends and surviving members of his family will miss him sorely. The engineering profession has lost a man who followed in his work and his every day life its highest idealism."

And, again, by the *Houston Chronicle,* of March 25, 1937, as follows:

"J. Milton Howe leaves an enduring record of achievement in the field of civil engineering. Internationally known both as railroad and highway builder, he applied to his work not only the time-tested sound principles of engineering but also an originality that produced new methods and gained him wide recognition.

"Mr. Howe followed in the footsteps of his ancestors, who were builders and pioneers. His great-grandfather was John R. Harris, founder of Harrisburg and the man for whom Harris County was named. More remote forebears of his founded Harrisburg, Pa. Other of his ancestors figured largely in Texas History. His grandfather was Capt. Andrew Briscoe, who fought at San Jacinto and was the first judge of Harris County. His father, Capt. Milton G. Howe, was one of the engineers who built the Houston & Texas Central Railroad.

"With such a background it is not surprising that he became a well-known engineer and that he figured prominently in the civic life of his county and state.

"His long service as Harris County engineer, in connection with his partner, A. J. Wise, was preceded by a number of years in the railroad building field in this country and in Mexico.

"The work he and Mr. Wise did along irrigation and drainage, road and bridge building lines gained national recognition. They pioneered the present method of settling highway embankments within a few weeks time, soaking the roadbed throughout its depth by means of long pipes, supplemented by ponding on the surface. This method produced in a short time a more compact foundation, without the usual soft spots, than the old method of traffic-packing obtained in months or even years. The plan is now standard in Texas and other States with similar soil conditions.

"Mr. Howe's death is a blow to a number of civic organizations as well as to the engineering profession. His passing will be widely mourned over the nation as well as in his home community."

A fitting tribute and appreciation of his likable personality was expressed in the *Houston Press*, of March 22, 1937:

"There was something in the appearance of J. Milton Howe that gave you the impression of rugged honesty. That was his outstanding characteristic. He was fair and square in all his dealings and thousands in Houston held him in high esteem. His death Monday was not a shock to his friends, for his serious illness was known to them, but it caused much sadness."

And, again, on March 23, 1937:

"J. Milton Howe's friends will miss his sparkling smile, his quiet humor and the stories of his adventures when he was a young railroad engineer in Mexico.

"At 62 he was still young in spirit and body and he had more zest for living and greater interest in the people and things about him than most men of 25. It's hard to believe that yesterday he died.

"Behind him he left many evidences of his engineering skill. As county engineer from 1911 to 1914 and from 1917 until 1929, he supervised the building of many of the county's important roads and bridges. As a consultant, his advice was sought widely.

"He was a native of Houston. His forebears were among the pioneers of Texas. Their spirit was strong in him, and it never grew dim."

From his partner, A. J. Wise, M. Am. Soc. C. E.:

"Mr. Howe was more than a business associate, he was a companion. His charming personality and many delightful characteristics contributed much to ease us over the rough spots which were encountered during our twenty-eight years of partnership. He was always honest and reasonable with his employees as well as myself. He was sociable, he loved parties and his pipes. In going through his desk we found six full-fledged smoke pipes. His son, Knox, informed me that he had about that many more at home."

Mr. Howe was married to Rowena Thomson, of Cleburne, Tex., in 1901, and is survived by one son, Knox Briscoe Howe.

He took a leading part in the formation of the Texas Section of the Society and never missed a meeting of that organization. He served a term in all its offices.

Mr. Howe was elected an Associate Member of the American Society of Civil Engineers on February 4, 1903, and a Member on January 7, 1908. He served as a Director of the Society from 1924 to 1926, and as a Vice-President—the first Texan ever to hold that office in the organization—in 1930 and 1931.

LAURENCE BRACKETT HOYT, M. Am. Soc. C. E.[1]

DIED JUNE 1, 1936

Laurence Brackett Hoyt, the son of Frank Murray Hoyt and Mary Ellen (Brackett) Hoyt, was born on September 10, 1891, at Greenland, N. H., the home of his mother's people. He was a descendant of John and Priscilla Alden, his great-grandmother being an Adams, a descendant of Joseph Adams, an uncle of President John Adams.

The boy was educated in the public schools of Melrose, Mass., and was graduated from the High School in 1909. He then entered the Massachusetts Institute of Technology, at Boston, Mass., from which he was graduated in 1913 with the degree of Bachelor of Science in Civil Engineering. In 1913 and 1914, he did graduate work in Civil Engineering at the Massachusetts Institute of Technology. In 1922, he returned to the Institute for graduate work in Engineering Administration and Highway Engineering, including business management, statistics, mathematical laboratory, hydrology, highway materials testing, and chemistry of road materials.

During his summer vacations as a Student at Massachusetts Institute of Technology, Mr. Hoyt served as Rodman for the Boston Elevated Street Railway Company; he was also engaged as Rodman for the Power Construction Company on the Hoosac Tunnel, and as Instrumentman for the Directors of the Port of Boston, Mass.

He served as Instructor at the Technology Surveying Camp, at Gardiner's Lake, Maine, during the summer session in 1913, following which he was appointed Assistant in the Civil Engineering Department at the Institute and served during the school year of 1913 and 1914. This included private work for Charles M. Spofford, M. Am. Soc. C. E., on bridge and masonry designs.

For the next ten years (1914–1924), Mr. Hoyt was with the Massachusetts Department of Public Works on the various highway engineering projects being carried out by that Department.

He served as Director of Public Works, of Manchester, N. H., in 1925 and 1926. In this position he was in executive charge of highways, bridges, sewers, refuse disposal, street cleaning, traffic regulation, and of the various Engineering Departments of the City.

Returning to Boston, Mr. Hoyt entered the employ of the firm of Metcalf and Eddy, Consulting Engineers. During 1927 and 1928, he made investigations and reports on work carried on by that firm for Braintree, Mass. He was also engaged on studies on the feasibility of the extension of Riverside Drive from New York City to Tarrytown, N. Y., for the Westchester County (New York) Park Commission.

[1] Memoir prepared from information supplied by the family and on file at the Headquarters of the Society.

In October and November, 1928, Mr. Hoyt was engaged by Mr. John D. Rockefeller, Jr., as Consulting Engineer on highways for the Town of Seal Harbor, Me. In February, 1929, he was appointed as Assistant Professor of Civil Engineering at the University of Maine, at Orono, Me., to fill a vacancy of a teacher on leave. He remained in this position until June, 1929, and was offered a continuance of the work, but declined it to accept another offer in Indiana. During the summer of 1929, he served as Special Engineer with the State Highway Department of Maine, with headquarters at Solon, Me.

In the fall of 1929, Mr. Hoyt went to Evansville, Ind., to accept the position of Director of Engineering and Professor of Civil Engineering, at Evansville College. He remained in this position until the fall of 1931, at the time the College was re-organized as a part of Purdue University.

After leaving Evansville College in September, 1931, he was engaged until March, 1932, on an industrial investigation at Columbia, S. C., for Meade Johnson Company, of Evansville, Ind. For the remainder of 1932 and during 1933, he was again engaged with the State Highway Department of Maine, with headquarters at Bangor.

In 1934, Professor Hoyt entered the employ of the State Highway Department of New Hampshire, as Resident Engineer on jetty construction, including shore dikes and hydraulic fill, for Hampton, N. H., Harbor. He continued in this position until his sudden death from a heart attack on June 1, 1936.

Professor Hoyt was a member of the Boston Society of Civil Engineers, the Canopy Club of Massachusetts, the Boston Chess Club, and the Society of American Magicians. He was a Mason, a member of Fidelity Lodge, A. F. and A. M., and the Waverly Royal Arch Chapter, of Melrose Mass.

He had taken and passed with high marks all the Civil Service examinations given to Civil Engineers in Massachusetts.

In writing of Professor Hoyt and his work, the President of Evansville College stated:

"In his relation to the work of teaching I have discovered that he has a keenly analytical mind, and that either in writing or in speech he expresses himself with crystal clarity. He always has the courage of his convictions about matters professional or academic, but being a reasoning man, he is always reasonable in debate and discussion. He is therefore a most satisfactory person to deal with.

"In the few contacts he has had during his period here, * * * he has won the undeniable respect of professional men in the city. In the course of a very thoroughgoing survey of our college and its work, particularly in the field of engineering, made by five of the leading officials of Purdue University, the impression settled upon these men that 'Professor Hoyt is a man who knows his business thoroughly,' to speak in the terms used by one of the men."

He is survived by his widow and seven children, and by his father, Frank M. Hoyt, of Melrose, Mass.

Professor Hoyt was elected an Associate Member of the American Society of Civil Engineers on May 8, 1922, and a Member on July 7, 1925.

EDWARD SHERMAN JACKSON, M. Am. Soc. C. E.[1]

DIED APRIL 4, 1935

Edward Sherman Jackson was born in Walden, Vt., on August 3, 1865, the son of Marshall Dexter Jackson, a farmer, and Jane Elizabeth (Johnson) Jackson. He was educated in the public schools of Walden, later attending the University of Vermont, at Burlington, from which he was graduated as an Honor Student, with the degree of Civil Engineer, in the Class of 1890.

Immediately upon graduation, Mr. Jackson accepted employment with the Chicago, Burlington, and Quincy Railroad Company and was assigned as Assistant Engineer on Maintenance of Way at McCook, Nebr., and Denver, Colo. In March, 1894, he was appointed Assistant Division Engineer on Construction in Wyoming and Montana, which marked the beginning of his steady advancement through the grades of Resident Engineer, Location Engineer, Superintendent of Construction, and Train Master, to Engineer, Maintenance of Way, for the Wyoming District, in 1906. During this period, his engineering responsibilities included the construction of the Big Horn River Bridge, near Fort Custer, Montana; the location of lines in the North Platte Valley, in Nebraska; and heavy railroad construction between Alliance and Bridgeport, Nebr., and between Northport, Nebr., and Guernsey, Wyo.

In September, 1906, Mr. Jackson became Chief Engineer of the Intermountain Railroad, at Boise, Idaho, where he supervised the preliminary surveys, location, plans, and specifications for one hundred miles of railroad lines north and east of that city. He also had charge of extensive repairs on the Barber Dam across the Boise River. These activities led to his appointment as Superintendent of Construction and Operation of the Idaho Southern Railroad, and Engineer of Construction and Superintendent and Chief Engineer, of the Milner and North Side Railroad. He remained with these Companies until February, 1916.

Following a year on construction at the Bremerton Navy Yard, at Seattle, Wash., he became associated with the Great Northern Railway Company as Maintenance Engineer, on the Great Falls (Mont.) Division, later, being identified with the relocation and double-tracking of the main line through the main range of the Rockies in the vicinity of Glacier National Park. Mr. Jackson was assigned as Engineer, in charge of location and construction, on the Eastern Section of the Cascade Tunnel, on the Great Northern Railway, at Berne, Wash., including the Mill Creek shaft and headings. At the conclusion of this work, in July, 1927, he was transferred to resident charge of the Chumstick cut-off and approach to the Cascade Tunnel, which is considered the most important single refinement of the Great Northern Railway's Transcontinental Line attempted since 1912. He continued with the Great Northern Railway Company in various capacities until November, 1933, including location work on the proposed

[1] Memoir prepared by R. H. Willcomb, Assoc. M. Am. Soc. C. E.

New Rockford cut-off, in the vicinity of Sand Springs, Mont., the Klamath Falls Line, between Bend and Klamath Falls, Ore.; and the location of rail connections with the Grand Coulee Dam, in Washington.

Mr. Jackson relinquished his more arduous responsibilities incident to railroad engineering in 1933, but did not retire entirely from his chosen work. He took charge of the location of a section of the Great Falls-Fort Peck Dam high-power transmission line for the United States Government.

Completing this work, he became associated with the Montana State Highway Commission as Project Engineer and Bridge Inspector, which positions he held at the time of his sudden death.

He was married on October 8, 1902, to Ruth Ethelwyn Bogue, at Alliance, Nebr. Mrs. Jackson died on April 14, 1916. He is survived by two daughters, Mrs. Harry B. Ward, of Garden City, Long Island, N. Y., and Mrs. Alfred P. Shepherd, of Winchester, Mass.; a son, Edward S. Jackson, Jr., of Jackson, Mich.; a brother, Elmer Jackson, of St. Johnsbury, Vt.; and one grandchild.

Among Masonic circles he was a member of the York Rites, receiving his degrees in McCook, Nebr. He later affiliated with the Masonic bodies at Alliance, Nebr., and, at the time of his death, was a member of Lincoln Lodge No. 59, A. F. and A. M. and King Solomon Chapter, R. A. M., both of Gooding, Idaho. He served as Excellent High Priest of the latter body in 1914, and was appointed and installed as Grand Master of the Third Veil of the Grand Chapter of Royal Arch Masons of Idaho in May, 1916. He demitted from Bunah Commandery No. 26, Knights Templars, of Alliance, Nebr., in 1913.

Mr. Jackson was singularly proficient and exacting in any work which he undertook. Quiet and unassuming to the point of reticence, he went ahead with each responsibility confidently and without hesitation. The many engineering projects which were completed under his guidance and supervision attest to his accuracy, thorough dependability, and unfailing integrity as an Engineer. He was a gentleman, unusually considerate and helpful, particularly toward his younger professional brothers, and a trustworthy friend to all his associates. He was a member of the Association of Railway Superintendents from 1908 to 1916.

Mr. Jackson was elected a Member of the American Society of Civil Engineers on March 4, 1915.

JOHN QUENTIN JAMIESON, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 28, 1932

John Quentin Jamieson, the son of John and Mary (Duncan) Jamieson, was born in Pittsburgh, Pa., on April 19, 1855. Both his parents were of Scotch ancestry. His grandfather, Quentin Jamieson, was a Captain in the

[1] Memoir prepared by J. P. Newell, M. Am. Soc. C. E.

Yeomanry, in the time of George III. His father, John Jamieson, came as a boy, from Maybole, Ayrshire, Scotland, to Pittsburgh, and was engaged in the manufacture of iron.

Thomas and Helen Duncan, great-grandparents of Mary Duncan Jamieson, left Peebles, Scotland, and settled in York, Pa., before the Revolution. One of their sons, James, was a minister of the United Presbyterian Church, noted for his learning. Late in life he was put out of the Church for heresy, preferring to break off the association of a lifetime rather than sacrifice his convictions. Thomas, a son of James, and the father of Mary, was a Quartermaster in the American Army in the War of 1812.

John Quentin Jamieson received his technical education at the Western University of Pennsylvania, at Pittsburgh. He served his apprenticeship under that master of the art of railroad location, the late William Harlin Kennedy, M. Am. Soc. C. E. From 1879 to 1883, Mr. Jamieson was Topographer and Assistant Engineer for the Oregon Railroad and Navigation Company, on the line then being built along the Columbia River and over the mountains of Eastern Oregon, from Portland to the Idaho line. From 1884 to 1887, he was Assistant Engineer on the Northern Pacific Railroad, in charge of the construction of the two-mile Stampede Pass Tunnel at the summit of the Cascade Range and of the six miles of very heavy work on each approach to the tunnel.

Through 1888, 1889, and 1890, he was Division Engineer in charge of location and construction of the Oregon Railroad and Navigation Company's line from Tekoa, Wash., over the mountains to Coeur d'Alene Lake, and thence along the river of the same name to Wallace, Idaho, In 1891, Mr. Jamieson served as Division Engineer on the Portland and Puget Sound Railroad for the Union Pacific Railway Company. In 1892, he had charge of surveys for the San Francisco and Great Salt Lake Railroad from Oroville, Calif., through the Sierra Nevada Mountains to Beckwith Pass, at the Nevada line, along the route later followed by the Western Pacific Railroad.

Following the lull in railroad construction in 1892, Mr. Jamieson turned to another field and for eighteen months was in charge of the construction of the head-works and part of the pipe line of the Portland, Ore., Water-Works, in a feat then unprecedented, the drawing of an urban water supply from the heart of a snow-capped mountain range.

Back to railroad work again, he was for four years Engineer in Charge of Construction of the Astoria and Columbia River Railroad from Goble to Astoria, Ore. An incident illustrates the ingenuity of the pioneer: A large part of this line consists of tunnels and heavy cuts through rocky promontories and embankments across deep bays filled to a little above high tide with fine sediment brought down by the Columbia River and deposited in the tidal stretch from Bonneville, Ore., to the sea. Material borrowed from the mountain sides was used for these fills, and the subsidence was excessive. In order to secure reliable measurements of pay quantities, Mr. Jamieson devised a plan of placing heavy wooden platforms cross-wise at suitable intervals in the base of the fill, to which upright pieces were attached. Careful watch was kept, and as the fill sank into the soft bottom the uprights were extended

and the heights noted. When equilibrium was finally reached, the settlement was known within reasonable limits. The estimates thus obtained were acceptable to the contractors.

For the succeeding five years Mr. Jamieson was again with the Oregon-Washington Railroad and Navigation Company, on location and heavy construction work in the Snake River Valley, or on miscellaneous examinations and reports.

In 1905, he went to Alaska to report on the development of extensive copper deposits, but finding that the interests of his employer were in conflict with those of a former client for whom he had made a reconnoissance in the same territory a short time before, he declined to continue the engagement.

In the same year (1905) the construction of the Western Pacific Railroad was begun, and Mr. Jamieson was among the first in the field. His Division comprised the entire crossing of the Sierra Nevada Mountains from the Sacramento Valley to the Nevada line, and was more than four years in building. In those tremendous canyons and among those mighty peaks there was ample opportunity for the exercise of the skill and knowledge he had acquired in thirty years of struggle with mountain, desert, storm, and flood. In all this there was nothing of the romance which a later generation may see. Among the last survivors of that mighty race of engineers who led the "iron horse" from the great plains through pathless wilderness to the Western Sea, to him it was all part of the day's work.

With the construction of this line, Mr. Jamieson's professional work was ended. Engineers to-day will look with something of envy on his record of thirty-one years of work of a kind necessarily discontinuous yet with a total of only sixteen months between engagements.

On November 22, 1910, he was married to Kathleen Ward, who survives him, together with two sisters, Maria and Agnes D. Jamieson, all of Portland, Ore. Following his marriage, he retired to a small farm near Oswego, Ore., a few miles from Portland, saying, that with only twenty-five acres he could loaf afternoons. In later years he was wont to remark, with a twinkle in his eye, that one acre would have been more nearly his size. The career of the citizen Jamieson was marked by the same faithful performance of duty as that of the engineer. From spending millions in building railroads, he came down, without loss of dignity, to the position of Treasurer of a local Farmers' Telephone Company. He served on the District School Board. Finding the neighborhood lacking in good water for domestic use, he persuaded his neighbors to form an Assessment District and obtain water through an extension of the Portland mains. In every community matter, he bore his part.

The affection and esteem in which he was held are evidenced by many expressions, of which a few are quoted.

W. D. Clarke, M. Am. Soc. C. E., states:

"My association with him, beginning as a mere boy on the Bull Run Pipe Line and continuing through our service together on the Western Pacific, gave me an appreciation of him as a gentleman, an engineer, and a friend, that brought me to a respect and love for him second only to that for my own father."

From Richard Sachse, an Engineer with the Western Pacific Railroad Company, comes the following:

"At first, he appeared to me as a very severe, almost hard, superior, who did not welcome any personal or friendly relations with employees under his direction. Later on, I learned that this was the outward shell only, and that underneath that shell there was an understanding and sympathetic note and a staunch and loyal friend who could be depended upon under all conditions."

Mr. Robert E. Duniway, a friend and neighbor, writes:

"I was well acquainted with Mr. Jamieson from 1920 until his death, and often visited at his home. On these occasions he was a charming and genial host, though more inclined to listen to the conversation of his guests than to contribute from his own experiences.

"In 1920, he became interested in the problem of securing City water for the rural district where his home was located. A large part of the remainder of his life was devoted to this project; first making the plans and tediously raising the necessary funds, later in superintending the installation, and finally reading the meters and collecting rentals to keep the system on a business basis. For all of this work he received no compensation whatever, save the esteem and appreciation of those neighbors who knew him best. * * * His loss is deeply mourned by all who knew him."

Mrs. Charlotte Boykin Parker, a friend of many years, states:

"In the death of John Quentin Jamieson there passed from this world one of the best men and citizens, one of the rarest spirits. He was a man of unusual dignity, which came from his utter sincerity and modesty. This quiet, simple manner never concealed, from those who knew him, the big heart and soul, the high idealism.

"There was another quality almost hidden beneath these gentle ways—kept in the background through modesty, but always there as the thing on which life was founded—a strength of character like iron. Fidelity, conscientiousness and integrity were not merely laws with him, but parts of his human fabric."

True to his Covenanter ancestry, Mr. Jamieson was a deeply religious man. Soon after coming West, he joined the First Presbyterian Church of Portland and was a faithful member for fifty-two years. In a friendship of more than forty years, the writer has been aware of nothing inconsistent with his profession of faith. His outstanding characteristic was his absolute integrity. He had a keen sense of the responsibility of the engineer as an impartial judge between employer and contractor, and was as scrupulous in maintaining the rights of the one as of the other. The late Mr. Kennedy once said: "There are times when I would lose faith in the honesty of human beings if it were not for John Jamieson."

Reserved, a man of few words, yet he had a keen sense of humor, and was a warm and constant friend. A great engineer, a faithful citizen, a good neighbor, nothing affords deeper insight into the heart of the man than that little children ran to meet him, climbed into his lap, chattered of their affairs, and minded not his silence nor his brief replies, content to be with him.

Mr. Jamieson was elected a Member of the American Society of Civil Engineers on November 6, 1889.

ALBERT FREDERICK JOHNTZ, M. Am. Soc. C. E.[1]

Died October 17, 1936

Albert Frederick Johntz was born in Abilene, Kans., on July 3, 1887, the son of Frederick and Louisa P. (Muskopf) Johntz. On both sides of the family he was descended from a line of Swiss stock which came to the United States in 1830 and settled in Ohio. He was one of two children. His brother, Harry, later became a distinguished engineer, dying in service as Engineer of Maintenance and Way for the Missouri, Kansas, and Texas Railroad Company.

Albert Frederick Johntz received his preliminary education in the public schools of Abilene. He entered the University of Kansas, at Lawrence, Kans., in 1906, from which he was graduated in 1910 with the degree of Bachelor of Science in Civil Engineering.

After his graduation from college, he was employed by the City Engineer of Kansas City, Mo., and, later, by the firm of Worley and Black, on designs for municipal improvements in Middle Western cities. From the service of the Winnipeg, Salina, and Gulf Railway Company, he entered the employ of the Kansas City Terminal Company and, during the planning and construction of these terminal facilities, was advanced to the position of Assistant Resident Engineer, and, later, as Assistant Engineer a sumed the supervision of the construction of the viaducts, subways, retaining walls, sewers, and track work of this project.

In 1915, Mr. Johntz returned to the University of Kansas as a Graduate Student and candidate for a higher engineering degree, but left in August of the same year to accept the position of Assistant Engineer in the office of the Chief Engineer of the Cuba Railroad Company, at Camagüey, Cuba.

His duties during the three years he was in the employ of the Cuba Railroad Company were varied and were performed with distinction. They included the survey and construction of two lines to the coast, the replacement of main-line bridges under traffic, the \$1 000 000 improvements to the terminal, and the construction of the new shops and gravity yards in Camagüey. In addition to the engineering problems faced with the assistance and direction of the Chief Engineer, Mr. A. C. Reed, the construction problems were met in the field by Mr. Johntz with great credit to his ability. The success that attended his efforts in this connection, requiring the apt handling of all types and nationalities of labor, proved a measure of the man.

[1] Memoir prepared by Mason Garber, M. Am. Soc. C. E.

Due to the World War, he returned to the United States in 1918 and, later, was commissioned a Captain in the Reserve Corps of the Construction Division of the Army. During his tour of duty—1918 to 1925—he served, successively, as Civil Engineer, Supervising Engineer of Construction, later acting as Principal Assistant to the Constructing Quartermaster in Maryland. His principal services during this time included the supervision of the construction of buildings, gun emplacements, roads, sewers, and railroads, at the Aberdeen Proving Grounds, in Maryland. Later, at Fort Benning, Georgia, he assisted in the design and construction of many of the buildings and facilities at that post.

In 1925, Mr. Johntz resigned from the Government service to become associated as Engineer with the Southern District Office of the North-Eastern Construction Company. For several years his work was that of planning, designing, and supervising, in the field, the construction of some of the more important projects which that Company had under way. These assignments included the terminal facilities and Union Passenger Station at Winston-Salem, N. C., the Winston-Salem City Hall, the Winston-Salem Young Men's Christian Association building, and other similar projects.

In 1928, he was placed in charge of the construction of the grade-elimination program of the Southern Railway Company and the City of Greensboro, N. C., for the North-Eastern Construction Company. This contract approximated $1 500 000 and contemplated the construction of twelve underpasses and over-passes. In spite of unexpected soil conditions, this program was carried through to successful completion, with great credit to Mr. Johntz personally and to his Company. Most of the work was constructed under traffic and required the underpinning and care of adjacent buildings. On the completion of his work in Greensboro, he returned to his position as Chief Engineer of the Company's Southern District Office, in Winston-Salem. His work, in this capacity, required direct field supervision of the Company's more important projects in North Carolina, South Carolina, and Virginia. Among the more recent projects completed under Mr. Johntz's direct supervision was the Engineering Group for the University of Virginia, at Charlottesville, Va.

His engineering ability, together with a forcefulness as a leader of men, is best attested by his completed works. They stand as fitting monuments to his memory.

In February, 1916, Mr. Johntz was married, at St. Augustine, Fla., to Keene Fones, of Lyons, Kans. He is survived by his widow and three sons, Frederick Fones, Robert Fones, and William Fones.

He was a member of the Twin City Country Club, the Masonic Fraternity, and the Officers Reserve Corps, U. S. Army.

Mr. Johntz was elected an Associate Member of the American Society of Civil Engineers on October 9, 1917, and a Member on January 13, 1933.

WILLIAM DATUS KELLEY, M. Am. Soc. C. E.[1]

Died January 21, 1936

William Datus Kelley was of New England ancestry. The first generation of which there is a definite record was located in Norwich, Conn., in 1690, and the third generation immigrated to Lowville, Oneida County, N. Y., about one hundred years later. Here, the family occupied an outstanding position in the business, educational, and religious life of the community.

Early in the Nineteenth Century, in that period of international disturbance that resulted in the War of 1812, began the migration to the "Far West", as the Western Reserve of Connecticut was then considered. As a part of this movement in 1811 went Datus Kelley, grandfather of William, to Cleveland, Ohio. Fifteen years before an uncle, Joshua Stow, had accompanied the surveying party of Moses Cleaveland who had been one of the original members of the Connecticut Land Company, which purchased the Western Reserve from the State of Connecticut. Others of the family, including two of his brothers, Alfred and Irad Kelley, settled in Cleveland, or the vicinity, about the same time.

Datus Kelley settled just west of Rocky River on a large tract of land extending from Lake Erie to the North Ridge where he resided for thirty-five years. In 1833 he, with his brother Irad, purchased what is now Kelley's Island (then Cunningham's Island) of about 3 000 acres, one of the group of islands in Western Lake Erie. It was in the bay on the south side of this island that Commodore Perry assembled his fleet for the historic and successful naval battle with the Lake Erie Naval Forces of Great Britain in 1813. In 1836, Datus Kelley moved with his family to the island where he developed the valuable limestone deposits as well as the forest and agricultural resources, shipping in 1834 the first cargo of limestone from the island. Since that time a large tonnage—in the year 1912 alone more than 500 000 tons—of limestone has been quarried and shipped from the island for use in the steel industry as well as for construction purposes. The stone for the first locks at Sault Ste. Marie came from Kelley's Island. Datus Kelley was a patriarch in the community and with his descendants exercised a lasting influence on its members. Among his other activities, he served as a Land Surveyor both on the island and on the mainland.

The activities of others of this generation of this family seem of sufficient interest to engineers to record here, particularly those of Alfred Kelley, due to his active participation in transportation facilities, more notably canal and railroad building. In 1815, Alfred Kelley was elected the first President of the recently incorporated Village of Cleveland, and, in 1816, with his two brothers, Irad and Datus, he incorporated the Cleveland Pier Company which was formed to build the first pier at Cleveland for the accommodation of vessels navigating Lake Erie.

[1] Memoir prepared by Charles H. Splitstone and Wendell P. Brown, Members, Am. Soc. C. E.

Known as the "Father of Ohio Canals", Alfred Kelley as the first State Canal Commissioner was the dominating force in the building of the Lake Erie and Ohio Canal, completed in 1832. In 1847, he became President of the Cleveland, Columbus, and Cincinnati Railroad (the "Big Four"), and is credited with turning the first shovel of earth and with laying the last rail. Records of 1850 note him as President of the Cleveland, Painesville, and Ashtabula Railroad (later, the Lake Shore and Michigan Southern Railway), now with the "Big Four", a part of the New York Central System.

The brother, Irad Kelley, a prominent merchant in Cleveland, was interested in lake transportation and operated a sailing vessel between Cleveland and Detroit, Mich. He is said to have acted as a pilot for Commodore Perry's fleet. Horace Kelley, a nephew of Alfred and Datus, was another member of this capable and aggressive family, who contributed a considerable portion of his fortune, more than $500 000 for the founding of an art gallery and school. This, later, with contributions from other sources, provided for the establishment of The Cleveland Art School and the building of the Cleveland Museum of Art.

William Datus Kelley was born on Kelley's Island, on May 11, 1859, son of William Dean and Marcella (Dean) Kelley. He was a grandson of Datus Kelley and a grand-nephew of Alfred and Irad Kelley. In this inspiring and interesting environment he passed his boyhood years, receiving there his first impressions and early education in public and private schools. While waiting for his age to permit him to enter Cornell University, at Ithaca, N. Y., he went to Wooster University, later, Wooster College, at Wooster, Ohio. He later attended and was graduated from Cornell University, in 1880, with the degree of Bachelor of Science. In 1881, he acquired a degree in Civil Engineering.

In 1880, Mr. Kelley served as a Rodman on the New York and New England Railroad, later a part of the New Haven System, and as a Transitman and Leveler on the Catskill Mountain Railroad. In 1881, he was Assistant Engineer on the surveys for the South Penn Railroad from Harrisburg to Brownsville, Pa., and also Assistant Engineer on the Somerset Division until the construction work was stopped by the sale of the road to a competing line.

The year, November, 1885, to November, 1886, was spent in France and Germany in travel and study. From 1886 to 1890, he was Special Assistant Engineer on the New Croton Aqueduct for New York, N. Y., with headquarters at Tarrytown, N. Y.

In 1891 and 1892, Mr. Kelley was Engineer in Chief of the Third Corps of the International Railway Commission in Ecuador and Peru, under the sponsorship of the United States War Department, where he ably displayed the characteristics and ability of his pioneering family. The outstanding feature of this engagement was the running of a continuous back-sight line with stadia and topography from the equator near Quito, Ecuador, to Lake Titicaca, on the Bolivian boundary, perhaps the longest transit line—3 000 miles—ever produced with one instrument and by one party, crossing the main range of the Andes Mountains at nine different water divides and also the head-

waters of the Amazon River 500 miles above navigation limits. This feat required living in encampments under varying conditions from the extreme tropical temperature of the Amazon Valley to the frigid regions of ice and snow 2 000 ft above the perpetual snow line of the Andes.

In addition to the survey of the railroad line, the authority involved reporting on the mineral and agricultural resources as well as the animal and vegetable life. The complete report of this project required the preparation of two large volumes of maps, estimates, and data which were published by the United States War Department.

In 1892 and 1894, Mr. Kelley was engaged in general engineering practice, designing and constructing a sewerage system for North Tarrytown, N. Y.

From January, 1894, to 1927, he was engaged in contracting on sewers and public utilities in New York City and Cleveland, as President of the firm of James R. F. Kelly and Company, later Kelly and Kelley, Incorporated, of New York City, and also of the Kelley Demarest Company, of Cleveland. During this period he developed and patented a hinged arch center providing for the renewal of sewer arch supports without demolishing the supporting centers, with a consequential major saving of labor and material.

He owned and maintained a summer home on Kelley's Island where he was interested in fruit growing, and after his retirement from active business, in writing a genealogy of the Dean family, who with the Kelley family were prominent in the history of New England and the Western Reserve.

Mr. Kelley will be remembered as a loyal, conscientious, and dependable engineer and a gentleman possessing an interesting and agreeable personality with a deep sense of duty to his friends and associates. He died in Cleveland, on January 21, 1936, and his remains were interred on the Island in Lake Erie named for and developed by this family of exceptional ability and character of which he was a worthy representative.

He was married to Isabelle Silver, of Tarrytown, N. Y., who survives him, as does a son, William D. Kelley, Jr.

Mr. Kelley was elected a Member of the American Society of Civil Engineers on November 2, 1887, and was a Past-President of the Cornell Society of Civil Engineers.

GEORGE BERTRAM de BETHAM KERSHAW, M. Am. Soc. C. E.[1]

DIED JULY 30, 1935

George Bertram de Betham Kershaw, the third son of the late Rev. G. S. W. Kershaw and Isabella Marie (Fitz-Hardinge) Kershaw, was born at Boughton, Nottinghamshire, England, on August 22, 1874. His father was Rector of the Parish of Fledborough, England. He was educated at Malvern, England, and obtained his early experience of sewerage, sewage disposal, and

[1] Memoir prepared by H. P. Kaufman, Esq., Westminster, London, England.

water supply as Assistant to Messrs. John Taylor and Sons and Santo Crimp, of Westminster, London, England.

At the inception of the Royal Commission on Sewage Disposal, appointed in England in 1898 to inquire into the methods of disposing of sewage and trade effluents, Mr. Kershaw was appointed Engineer to the Commission, in which capacity he did excellent and most noteworthy work for sixteen years. The work which he accomplished during these years can be appreciated to some extent by those who have studied the voluminous reports presented by the Commission.

When the Commission was dissolved in 1914, Mr. Kershaw engaged in private practice as a Consulting Engineer, and the experience he had gained while acting as Engineer to the Royal Commission proved of inestimable value to him in the many sewerage, sewage disposal, trade waste, and water supply projects he designed and carried out for a large number of important local authorities and manufactories in England. Mr. Kershaw also visited Egypt, India, and Bermuda to advise the Towns of Khartoum, Bombay, and Hamilton, on their sewerage and sewage disposal problems.

In 1911, he published his well-known book, "Modern Methods of Sewage Purification", and, in 1914, a further work entitled "Sewage Purification and Disposal", of which a Second Edition appeared in 1925. He was also the author of several other publications and a number of articles written by him on the subject of the treatment of trade wastes were published in technical journals from time to time.

He was a member of the Institution of Civil Engineers, the Association of Consulting Engineers, a Fellow of the Royal Sanitary Institute, a Fellow and a Past-President of the Institution of Sanitary Engineers, a member of the Institution of Water Engineers, and of other learned bodies connected with the Engineering Profession.

Mr. Kershaw was a man for whom all who knew him had the deepest regard, a man of gentle actions, and loved by his friends. He was held with the greatest esteem in his profession.

He was married, in 1900, to Edith, daughter of the late John Charles Pickin, of Fledborough Manor, Nottinghamshire, and is survived by his widow.

Mr. Kershaw was elected a Member of the American Society of Civil Engineers on April 2, 1913.

BURDETT KIPP, M. Am. Soc. C. E.[1]

Died January 23, 1937

Burdett Kipp was born in New York, N. Y., on August 4, 1874. He was the son of Lieut.-Col. William H. Kipp, associated with the 7th Regiment, New York National Guard, since the Civil War, and Emily

[1] Memoir prepared by R. Prosper Gustin, Assoc. M. Am. Soc. C. E.

A. Kipp, both of whom were descended from old New York families. After his preparatory education in New York schools, he entered the School of Mines, Columbia University, and was graduated from its Civil Engineering Course in June, 1898.

In September, 1898, Mr. Kipp became an employee of the City of New York as Topographical Draftsman and Transitman, and did drafting, computing, and surveying in the five Boroughs. In September, 1900, he was transferred to the Rapid Transit Commission as Assistant Engineer. From September, 1903, until September, 1906, he was Engineer in responsible charge of construction, for the Rapid Transit Commission, of the Interborough Rapid Transit Railroad Subway under Broadway from south of Battery Place to Vesey Street (approximate value, \$2 000 000).

From September, 1906, to September, 1919, he was with the Degnon Contracting Company as Principal Assistant Engineer and, later, as Engineer in Charge of Construction of the following work in New York City: Hudson-Manhattan Railroad Subway from 12th Street to 33d Street (value \$4 000 000); construction of the foundations for the Gimbel Building and the McAlpin Hotel (value, \$500 000); New York Municipal Railroad, under Broadway, from Park Place to Walker Street (value, \$2 500 000); Interborough Rapid Transit Railroad Subway, under Greenwich Street and West Broadway, from Vesey and Franklin Street, and under Varick Street to Beach Street (value \$3 100 000); and under 14th Street from Irving Place to Avenue B (value, \$2 000 000).

From 1922 to 1928, Mr. Kipp was employed by Niewenhous Company as Chief Engineer and Superintendent of Construction on the following work: The Bronx Wholesale Terminal Market (largest of its kind; value, \$3 000 000); Concourse Plaza Hotel (value, \$2 225 000); Mount Saint Michael's Institute (value, \$660 000); Rockland State Hospital, Orangeburg, N. Y. (value \$8 000 000); Biological Plant, Brooklyn, N. Y. (value \$560 000); Hall of Records and Power House, Newark, N. J. (value, \$2 200 000); also, banks, schools, and industrial buildings.

From February, 1928, to September, 1936, he was Chief Engineer with Atwell-Gustin-Morris, Incorporated, on the following work: Independent Subway System in Nott Avenue and Jackson Avenue, from Van Alst Avenue to Harris Avenue, Long Island City (value, \$5 000 000); and Independent Subway System under Broadway from Northern Boulevard to Baxter Avenue, Elmhurst (value, \$8 000 000).

From September, 1936, to time of his death, Mr. Kipp was employed by the G. A. M. Construction Corporation (successors to Atwell-Gustin-Morris, Inc.), as Chief Engineer on the Queens Construction Shaft of the Midtown Tunnel.

On June 2, 1913, he was married to Georgina Sullivan. Mrs. Kipp, with his daughter, Emily, survives him.

He will be remembered for his pleasing personality and for his dependability both in business matters and socially. He was a man of fine character, always cheerful, and always kindly. By those who knew him well, he was beloved.

Mr. Kipp was elected a Member of the American Society of Civil Engineers on August 9, 1920.

AUGUST GUSTAVE KLEINBECK, M. Am. Soc. C. E.[1]

Died February 8, 1936

August Gustave Kleinbeck, the son of Peter and Fredericka (Best) Kleinbeck, was born on February 17, 1852, in Württemberg, Germany. He received his education in the Royal Technical School, of Stuttgart, Germany, from which he was graduated in 1869, with the degree of Building Technic.

From 1869 to 1872, he was in the service of the German Government on the construction of a railroad through the Black Forest in the Valley of the Nagoldie River. Following this, until 1875, Mr. Kleinbeck was in the military service of Germany. From 1875 to 1878, he was employed on the construction of the Hohenzollern Railway running from Tubingen, Württemberg, to Sigmarigen, Hohenzollern, Germany. In 1879, he passed the State Examination in Stuttgart, and received the title of Building Master.

In 1880, prospects in the United States attracted Mr. Kleinbeck and he came to Chicago, Ill., and was immediately employed by Mr. Jennings, an Architect. From 1881 to 1882, he was engaged on the construction of a narrow-gauge railroad running from Toledo to Cincinnati, Ohio, and to St. Louis, Mo. While with this Company he designed wooden trestles for a bridge across the Okaw River. The following two years he served as Draftsman for the Columbus and Cincinnati Midland Railroad Company, and the next four years found him employed as Chief Engineer for a railroad running from Peoria, Ill., to St. Louis. It was at this time that he superintended the sinking of a shaft and the construction of a coal mine north of Mt. Olive, Ill. From 1885 to 1892, he served as Civil Engineer on the Tuscaloosa, Montgomery, and Bainbridge Railroad, in Georgia.

In 1893 Mr. Kleinbeck deserted railroading and was engaged in other lines of engineering work until 1897. During this time, he supervised the laying of gas mains in New York, N. Y., for the East River Gas Company, and, later, managed the Litchfield Mining and Power Company, of Litchfield, Ill.

Returning to railroad work, in 1898, he was appointed Civil Engineer on the construction of a line from Columbia, Mo., to the Missouri River, and from 1900 to 1904, he was Chief Engineer in charge of all bridge work for the Frisco Railroad Company. The years 1905 and 1906 found him acting as Chief Engineer for the St. Louis, Brownsville, and Mexico Railroad Company. He made extensive soundings for bridges across the Brazos River and the Rio Grande, in Texas.

One of Mr. Kleinbeck's most important accomplishments was the design and construction of a bridge across the Brazos River, consisting of one draw-

[1] Memoir prepared by A. G. Kleinbeck, Jr., Esq., Litchfield, Ill.

span of 235 ft, two girder spans of 100 ft, the pivot and end pier of the draw-span resting on caisson foundations. The other piers rested on piles. He also designed and built a draw-span and two end spans, each 60 ft long, for the St. Louis, Brownsville and Mexico Railroad Company.

In 1907, because of ill health, he gave up his professional work and lived a retired life in Litchfield. Mr. Kleinbeck died of necrosis of the jaw bone, at St. Francis Hospital, in Litchfield, on February 8, 1936.

On July 14, 1887, at Litchfield, he was married to Matilda Lange who, with two sons, J. C. Kleinbeck, of Chicago, and A. G. Kleinbeck, Jr., of Litchfield, and a daughter, Mrs. R. J. Blank, of West Palm Beach, Fla., survives him.

Mr. Kleinbeck was elected a Member of the American Society of Civil Engineers on February 3, 1897.

CARL GUSTAF EMIL LARSSON, M. Am. Soc. C. E.[1]

Died April 1, 1936

Carl Gustaf Emil Larsson was born in Geddeholm, Sweden, on February 29, 1864, the son of Lars Larsson and Anna Lovisa Larsson. He was a student in the higher Elementary School, in Westerås, and in the Reål School, in Stockholm. After having been graduated from the latter institution he entered the Royal Institute of Technology, in Stockholm, from which, after three years of study, he received the diploma of Mechanical Engineer and, after an additional year, was given the diploma of Civil Engineer in 1887. He came to United States in the autumn of 1887.

From January, 1888, to July, 1889, he was a Draftsman with the Wrought Iron Bridge Company, at Canton, Ohio, the Edge Moor Bridge Works, at Edge Moor, Del., and the Hilton Bridge Company, at Albany, N. Y. In July, 1889, Mr. Larsson returned to the Edge Moor Bridge Works as a Designer, holding that position until the organization of the American Bridge Company, in May, 1900.

On July 17, 1900, he was transferred to the Pencoyd Office of the American Bridge Company as a Designing Engineer, and, in March, 1901, was appointed Division Engineer in charge of the designing offices and drawing rooms of the Company in the eastern part of the United States. In January, 1904, Mr. Larsson was made Assistant Chief Engineer of the Company, with office first at Ambridge, Pa., and, later, in New York City. For a short time in 1927 he was Acting Chief Engineer of the Company, and, in September, 1927, he was appointed Chief Consulting Engineer which position he held until he retired on June 30, 1933.

In 1918, he visited France on an important mission for the Ordnance Department of the United States Army.

His scholastic training in Sweden was thorough and differed from contemporaneous methods in the United States. One illustration of this is that

[1] Memoir prepared by Otis E. Hovey, and William M. White, Members, Am. Soc. C. E.

the teaching of theoretical and applied mechanics began in the preparatory school before entering the Royal Institute of Technology and was continued in some form for a period of seven years. Mr. Larsson acquired an unusually thorough fundamental knowledge of theory which remained outstanding throughout his long service in engineering work.

During an association with him of more than thirty years, he and the senior writer had discussed many difficult problems in analysis. His methods of approach were so different from those commonly in use in this country that his verification of the results of analysis were most valuable.

His early work as a designer demonstrated that he was logical and original in his methods, that he had a keen sense of the economics of engineering, and was quick to take advantage of local conditions favorable to simplicity in design and construction. He was ingenious in devising simple and efficient methods of erecting bridges under unusual circumstances and in developing economical designs to meet difficult conditions.

Mr. Larsson came in close contact with many younger engineers, was much interested in their progress, and was glad to advise them, to give them the benefit of his experience, and to assist them to acquire direct and effective methods in analysis and design.

It frequently happens that an engineer employed by a corporation does not become so well or so favorably known as he would have been, had he been in practice under his own name. Mr. Larsson was an exception in this respect. His work brought him in contact with the building of many of the important bridges in America and his skill and resourcefulness contributed much to the design and construction of these structures.

Some of the most difficult problems in bridge design and construction are encountered where an old bridge must be rebuilt without interrupting traffic. Mr. Larsson had unusual skill in devising safe and economical means to carry out such work. Sometimes, a new bridge is designed so that it is difficult or nearly impossible to build it as originally planned. Some of his most brilliant work was done in overcoming such conditions. A long list could be given of bridges to the construction of which Mr. Larsson made important contributions. A few of them are the Hell Gate (arch) Bridge, of the New York Connecting Railroad; the renewal of the Ohio Connecting Railroad Bridge, at Brunot's Island, Pittsburgh, Pa.; the Bessemer and Lake Erie Railroad Bridge across the Allegheny River; the Cincinnati Southern Bridge over the Ohio River at Cincinnati, Ohio; and others of comparable magnitude. On the Bessemer and Lake Erie Bridge he originated the modern method of jacking the continuous spans of fixed bridges to the desired reactions, a method that had long been in use for fixing the reactions and designing the end lifts of continuous swing spans.

In addition to the structural problems of bridge construction, Mr. Larsson contributed to the improvement of the materials of the art. He was an early advocate of the use of silicon steel as a high-strength material for bridges. Also, he was largely responsible for the development of heat-treated eye-bars which have been used for the tension members of many large bridges. Heat-

treated eye-bars of high strength also were used in the suspension chains of the Florianopolis Bridge, in Brazil.

On April 26, 1893, Mr. Larsson was married to Eliza Gano, who survives him. Mrs. Larsson is a daughter of Charles K. Gano and Anna E. Bartram, of Wilmington, Del. Their only son, Gano Larsson, who was a student at Massachusetts Institute of Technology, died in Sweden in 1919.

He was a member of the American Iron and Steel Institute, the American Society for Testing Materials, the American Railway Engineering Association, and the Army Ordnance Association.

Mr. Larsson was elected a Member of the American Society of Civil Engineers on April 1, 1903.

EDWARD HERVEY LEE, M. Am. Soc. C. E.[1]

Died January 11, 1937

Edward Hervey Lee was born in Dayton, Ohio, on January 29, 1863, the son of the Rev. Dr. John Newton and Julia (Sheldon) Lee, members of a noted Ohio family of ministers and educators. Mr. Lee, the eldest of a family of four, was educated at Ohio University, and the University of Wooster, at Wooster, Ohio.

In 1880, he entered the railroad service, being employed, successively, as a Rodman on the Scioto Valley Railway from April, 1880, to January, 1881; Rodman and Instrumentman on the New York, Chicago, and St. Louis Railway from January, 1881, to January, 1882; Instrumentman on the Ohio Central Railway from January to August, 1882; Instrumentman on the New York, Chicago, and St. Louis Railway from August, 1882, to January, 1883; Resident Engineer, in charge of construction, on the Ohio River Railway from January, 1883, to January, 1884; Instrumentman on surveys in West Virginia from January to July, 1884; Resident Engineer on the construction of the Wisconsin Central Railway, from August, 1885, to January, 1886; Division Engineer, in charge of construction, on the Omaha and Republican Valley Branch of the Union Pacific Railway from January, 1886, to March, 1887; Resident Engineer on the Wisconsin Central Railway from March to September, 1887, in charge of the construction of ore yards, engine-houses, tracks on dock, etc.; and Draftsman, Office Engineer, and Chief Engineer of the Elgin, Joliet and Eastern Railway Company from September, 1887, to June, 1893.

In January, 1894, Mr. Lee left the railroad service to take charge of a field party on the construction of the Sanitary District of Chicago and continued in that work until March, 1898. He also acted as Contractors' Engineer, superintending steam-shovel work, and concrete masonry and sewer construction from June, 1896, to June, 1897. He returned to railroad

[1] Memoir prepared by F. E. Morrow, M. Am. Soc. C. E., and W. F. Krahl, Assoc. M. Am. Soc. C. E., in collaboration with Committees of the Am. Ry. Eng. Assoc., and the Western Soc. of Engrs.

work as Principal Assistant Engineer on joint grade separation for a number of railroads at 16th and Clark Streets, in Chicago, Ill., from March to December, 1898.

In December, 1898, Mr. Lee entered the service of the Chicago and Western Indiana Railroad Company and The Belt Railway Company of Chicago as Engineer and General Roadmaster. He advanced, successively, to the positions of Chief Engineer, and Vice-President and Chief Engineer, acting as President during the period of Federal Control. On January 1, 1927, he was made President of these roads, remaining in that position until April 1, 1932, when he retired with the title of "President, Retired."

Almost all of Mr. Lee's active life was devoted to the construction, maintenance, and operation of steam railroads. During the time of his employment by the Chicago and Western Indiana Railroad Company and The Belt Railway Company of Chicago, he had charge of a large amount of grade-crossing elimination between the railroad lines and highways, and between railroads. He was a pioneer in the development of methods and means of eliminating grade crossings in Chicago and was considered an authority on such work. He was also in charge of considerable work in connection with the development and enlargement of these properties. He devoted much time and study to the development and improvement of steam railroad terminal facilities and terminal operations, and his opinions and judgments on many phases of these problems were highly valued by railroad engineers and executives.

Mr. Lee always had an active interest in the well-being and advancement of the Engineering Profession. He became a Charter Member of the American Railway Engineering Association upon its organization in 1899 and was quite prominent in the affairs of that Association, serving as a member of the Committee on Uniform General Contract Forms from 1908 to 1921, inclusive, being Chairman from 1917 to 1920, inclusive. He served as a Director, of the Association in 1918, 1919, and 1920, as Vice-President in 1921 and 1922, and as President in 1924. He became a member of the Western Society of Engineers on November 7, 1899, and contributed much to the success of that Society serving as President in 1914. For many years, Mr. Lee was an active member of the Chicago Engineers Club, of which he was President in 1919. He was also an active member of the Traffic Club of Chicago.

Mr. Lee was married, in 1916, to Ruth Sheldon Brooke, eldest daughter of the late Bishop of Oklahoma, the Rt. Rev. Francis Key Brooke. He died on January 11, 1937, at his home in Chicago at the age of 73. He is survived by his widow, a sister, Mrs. Mary Lee Stewart, and one brother, John H. S. Lee. His youngest brother, Dr. W. George Lee, died in 1927.

From his very early youth, Mr. Lee was an accomplished pianist and a lover of music. During his active life his principal recreations were handball and golf. In his younger days, he was an expert handball player and rated as one of the best players in Chicago. Until his retirement, he had been for many years an active member of the Chicago Athletic Association, the Edgewater Golf Club, and the Olympia Fields Country Club.

He was possessed of a fine quality of humor and was widely known for his ability as a story-teller. He was admired and respected by all his associates and friends on acount of his sterling character, his ability as an engineer, his good judgment, and for his human qualities that made him liked by all with whom he came in contact, and loved by those who knew him best. In spirit and memory, Edward Hervey Lee will continue to live in the hearts of a host of warm and loyal friends, for he, himself, was the very embodiment of the spirit of fine and genuine friendship wherein association with him was always delightful.

Mr. Lee was elected a Member of the American Society of Civil Engineers on June 6, 1900.

GEORGE CASPER DOERING LENTH, M. Am. Soc. C. E.[1]

Died May 11, 1936

George Casper Doering Lenth was born in Garrett, Ind., on February 1, 1882, the son of Charles L. and Anna (Doering) Lenth. Both his parents were born in Germany.

George Lenth received his early education in the public, Grammar, and High Schools of Chicago, Ill. He was graduated from the Massachusetts Institute of Technology at Boston, Mass., in 1903, with a degree of Doctor of Science in Civil Engineering.

Following his graduation Mr. Lenth returned to Chicago, and was engaged, for a short time, with the Chicago and North Western Railroad Company and in the Assessor's Office of Cook County. Later, he entered the service of the City of Chicago, in the Bridge Division of the Department of Public Works. In 1905, he was in the employ of the Board of Local Improvements as a Rodman. The following year, he became an Assistant Engineer in the Sewer Division and, later, Assistant Chief Sewer Engineer. Sewerage work and special assessments became his specialty for the remainder of his life. In the absence of the late C. D. Hill, M. Am. Soc. C. E., during 1910 and 1911, Mr. Lenth was appointed Engineer of the Board of Local Improvements, serving in that capacity until Mr. Hill's return. During the World War, he was engaged in construction work at Camp Knox, in Kentucky.

In 1921, Mr. Lenth was granted leave of absence by the Board of Local Improvements, to take the position of Secretary of the Clay Products Association. He was also engaged in private practice as Consulting Engineer, which included service in that capacity for the City of Chicago on many important projects. He was a member of the Subway Commission appointed by the Mayor of Chicago to make plans for a subway in State Street.

[1] Memoir prepared by Loran D. Gayton, M. Am. Soc. C. E.

Mr. Lenth was a member of the Illinois Society of Engineers, American Ceramic Society, Chicago Engineers' Club, Municipal Employees Society of Chicago, Chicago Municipal Employees Credit Union, Lake Shore Athletic Club, and the Royal League Club.

In 1905, he was married to Lillian Julien Holton, and is survived by his widow and two sons and two daughters.

Mr. Lenth was elected a Member of the American Society of Civil Engineers on July 9, 1912.

CLIFFORD SHERRON MacCALLA, M. Am. Soc. C. E.[1]

Died February 4, 1936

Clifford Sherron MacCalla was born in Wallingford, Pa., on March 31, 1876, the son of Clifford P. MacCalla, who was an attorney, writer, and prominent Mason, in Philadelphia, Pa., and Helen (Arrison) MacCalla. His parents were both of American ancestry dating back for several generations. His great-great-great-grandfather, John MacCalla, born in 1712, came from the Island of Islay, one of the Hebrides off the southwestern coast of Scotland, to settle in America. This ancestor became a "Prominent Rebel" during the Revolutionary War, and on account of his work in encouraging the cause of the Revolution was confined for a time in the "Jersey prison ship" by the British. He was buried in the churchyard at Roadstown, N. J.

Many of Clifford Sherron MacCalla's most admirable traits were inherited from his father. In a resolution offered June 8, 1892, by the Bethlehem, Pa., Lodge No. 283, F. & A. M., the Right Worshipful Past Grand Master, Clifford P. MacCalla, was eulogized as "a man of noble and sincere soul", of whom it can truly be said that, "as a man, a scholar and a Mason, he lived respected and died regretted, having performed his labours with honor and reputation."

Clifford Sherron MacCalla was educated at the Friends' Central High School, in Philadelphia, and prepared for college at Ulrich's School, in Bethlehem, Pa. He was graduated from Lehigh University, in Bethlehem, in 1896 with the degree of Electrical Engineer. While maintaining a good scholastic standard, he took an active interest in class affairs and social events. He was a Charter Member of the revived Alphi Rho Chapter of the Sigma Chi Fraternity and was instrumental in the acquisition of the present Chapter House, at Bethlehem. He was also a member of the Sophomore Cotillion Club. In athletics, his favorite sport was lacrosse. His eastern rearing was reflected throughout his life by his clipped speech and precise manner which, however, was tempered by considered and genuine friendliness for others.

---

[1] Memoir prepared by W. A. MacCalla, Esq., Mt. Lebanon, Pa.

After his graduation from Lehigh Mr. MacCalla's initial work was in the Installation Department of the Philadelphia Bell Telephone Company. After a few months, he quit a $7 per week job with that Company to take a $5 per week job as "trouble shooter" with the Edison Electric Light Company of Philadelphia, as he thought there was a greater future in the electric industry. Having made this choice, his rise within the industry was rapid at every place he worked. In 1897, he went with the Edison Electric Illuminating Company of Brooklyn, N. Y., as Draftsman. He was then moved to the Construction Department installing machinery and, in three years, was advanced to be Construction Boss and General Foreman of Construction.

One of his colleagues in this early work, now (1936) an engineer for the United States Government with the Works Progress Administration, writes concerning Mr. MacCalla:

"Mac and I began our real work together in the Brooklyn Edison Company. I departed from the industry and became a sort of 'beloved vagabond.' Mac stayed with it and became a pillar of industry. I wish that men would say of me when I am gone the sort of tributes paid to Mac."

In 1901, Mr. MacCalla was engaged in experimental and structural work for the General Electric Company, at Schenectady, N. Y. Upon hearing that the Company proposed to construct a large electrical installation for the New South Wales (Australia) Government, he asked to be transferred to the Foreign Department and was sent as Principal Assistant Engineer in charge of construction. This installation consisted of three 1 500-kw steam-driven generators, together with sub-stations and distribution system. This was the largest three-phase transmission plant south of the equator. In addition, he put in a complete installation of five rotary converter sub-stations and railway equipment for the Sydney tram lines of the New South Wales Government.

In the spring of 1903, after the completion of this job, Mr. MacCalla returned to the Schenectady Factory to conduct steam turbine and special tests. That summer he rejoined the Edison Electric Illuminating Company of Brooklyn as Assistant Electrical Engineer in charge of the Operating Department, including two main steam-generating plants and fourteen distributing sub-stations.

In the fall of 1903, he went to Spokane, Wash., as Assistant to the General Manager of the Washington Water Power Company. In this position he set a mark for others to follow, for in the fifteen years that he was associated with this Company he was advanced to Assistant General Manager, Chief Engineer, General Manager, and finally, Vice-President and General Manager, which position he held during his last five years with that Company.

In his first capacity, he was in charge of engineering and construction, practically all of which the Company did with its own organization. From 1904 to 1906, Mr. MacCalla designed and had charge of the construction of the Post Falls Hydraulic Power Plant, the approximate cost of which was $1 000 000, including electrical, hydraulic, and construction features. From 1907 to 1908, he directed the electrical design, erection of buildings, and installation of all machinery for the $900 000 steam turbine plant in Spokane.

Following this, he directed the electrical, mechanical, and hydraulic design and construction of the \$2 000 000 Little Falls Plant. From 1913 to 1915, he designed and built the Long Lake Hydro-Electric Plant on the Spokane River. This plant had the highest spillway dam in the United States, being 227 ft from bed-rock to forebay level, and designed for 19 ft of water on the crest of the spillway. It had the four largest hydraulic turbines built at that time, each developing 22 500 hp.

As Vice-President and General Manager, Mr. MacCalla had full charge of all operations, including engineering, sales, rates, etc. The Company, with a load of 55 000 kw in 1918, served Spokane and thirty-three smaller towns within a radius of 100 miles, and also distributed power to the Coeur D'Alene mines in Idaho. It had about 33 000 accounts in a population of 150 000, and employed 1 400 persons, including the construction force. It owned the city street and interurban railways. Mr. MacCalla had charge of equipping the city railway system with one-man cars, Spokane being the first city in the United States with a population of 100 000 or more to have complete one-man operation. This change was accomplished with the cordial co-operation of the street railway employees.

During the time that he lived in Spokane, he was very active in civic affairs and was particularly interested in the activities of the University Club.

In 1918, Mr. MacCalla returned to the General Electric Company in Schenectady. While on the staff of the Vice-President in charge of manufacturing he was Chairman of the Furnace Committee of the Schenectady Works and devoted his attention also to the development of a number of miscellaneous lines of manufacturing, including high-voltage insulators, overhead line materials, and X-ray tubes. Later, he had charge of organizing a new factory in Rochester, N. Y., designed for an output of 8 000 small motors per week and employing from 1 000 to 1 400 hands. He was then made the first Manager of the Rochester Works of the General Electric Company.

In 1920, he joined the Virginia Power Company, at Charleston, W. Va., as Vice-President and General Manager in responsible charge of all operations. This Company had an installed generating capacity of 60 000 kw in steam turbines. At the time he took over the management of this Company the post-war period of high prices was having an adverse effect on its earning power. Within the next two years Mr. MacCalla secured two rate increases for his Company and, later, had dismissed an attempt to reduce rates before the Public Service Commission of West Virginia.

In addition to his office with the Power Company, Mr. MacCalla was Vice-President of the Coalburg Colliery Company, at Ronda, W. Va., from 1922 to 1923. While in Charleston, he was appointed Chairman of the State Board for Registration of Engineers by the Governor of West Virginia. He was also appointed by the Governor as a Delegate to represent West Virginia at the Water Power Conference at New York, N. Y., in February, 1922.

Mr. MacCalla's first contact in Youngstown, Ohio, where he was located during the remainder of his career, was in 1923 when he became Vice-Presi-

dent and General Manager of the Pennsylvania-Ohio Power and Light Company, under R. P. Stevens and the late John T. Harrington, the former of the Republic Railway and Light Company. In addition, he became President and General Manager of the Youngstown Municipal Railway Company and the Pennsylvania-Ohio Coach Lines Company; President and General Manager of the Pennsylvania Power Company; Vice-President of the Penn-Ohio Edison Company; and President and General Manager of ten subsidiaries of the Penn-Ohio System. Later, the ownership of the Penn-Ohio System passed to the Allied Power and Light Company, with Mr. MacCalla still occupying the same positions. In 1926 and 1928, under his management, the Penn-Ohio property received the Charles A. Coffin Gold Medal for distinguished contribution to the development of electric light and power for the convenience of the public and the benefit of industry. This is the only instance in which this award was made twice to the same organization. The Pennsylvania-Ohio Power and Light Company received the award in the Forbes Competition in 1927 for outstanding performance in the line of public relations. In 1928, the Penn-Ohio System won the Anthony N. Brady Gold Medal awarded by the American Museum of Safety, in conjunction with the American Electric Railway Association. The inscription on the gold medal reads: "Awarded to the Penn-Ohio System for achievement in safety and sanitation by electric railway organizations in the United States—1927." Always active in national affairs in the industry, Mr. MacCalla was for a time President of the East-Central Division of the National Electric Light Association and presided at the convention in Louisville, Ky., May 7 to 10, 1929.

On July 1, 1930, the Ohio Edison Company was formed by a merger of the Pennsylvania-Ohio Power and Light Company with electric properties in Akron and Springfield, Ohio, and Mr. MacCalla then became Vice-President and Division Manager and a Director of the Ohio Edison Company. He was also named a Director of the Pennsylvania Power Company, at New Castle, Pa., a subsidiary company. He continued in this capacity until his death in Youngstown on February 4, 1936. He was buried in Mt. Moriah Cemetery, Philadelphia, Pa.

Besides his widow, the former Mrs. Anna Lanter Clark, of Olathe, Kans., to whom he was married in 1922, he is survived by two children by a previous marriage in 1906 to Agnes Wilson Purves, of Sydney, N. S. W., Australia. The children are Sylvia (MacCalla) Ryder, of Cleveland, Ohio, and Willard A. MacCalla, of the West Penn Power Company, Pittsburgh, Pa.

A statement of facts such as the foregoing may seem tedious and uninteresting, but Clifford MacCalla's life and career were anything but that. He had a capacity for leadership and a joy for work that were outstanding. Few executives were better liked by employees. His influence and character touched the most remote employee, making him his friend. Humble employees were "Bob, Jim, and Dick", just as were the many important men he numbered among his friends. He often "went to bat" against higher officers of the Company on behalf of his employees, and frequently stated that the hardest job he was given was to lay off men during the depression. He had

learned every step of the utility business from the ground up, and when his employees encountered problems which they were unable to solve, Mr. MacCalla would show them exactly how the job should be done. Then he would add, "You know I've done it and I know."

The feeling of his employees toward their Chief was expressed editorially in the February number of the *Ohio Edison Magazine*, in these words:

"The loss of a capable executive and cooperative business associate is a misfortune to any organization, but when that person was also endowed with the rare talent of making and keeping friends, his passing is mourned as a real tragedy. C. S. MacCalla was such a man. He possessed a genuine liking for his fellow men. Their occupation or station in life made no difference in the cordial word he always gave them. In return he was held in highest esteem and respect by his close friends and employees alike. He inspired a friendship that lives—and to live in the hearts of friends left behind is not to die.

"His success in his chosen field was the result of progressive endeavor combined with a generous personality. He never progressed so far that he outgrew his friends.

"Those who were present at the Safety Dinner in Youngstown will always feel honored that theirs was the privilege of being with Mr. MacCalla at his last group gathering; they will remember him at his best—a cordial host, a brilliant speaker and master of ceremonies, and best of all a genuine friend."

During the week following his death, a memorial window in the Youngstown Electric Shop, of the Ohio Edison Company, was appropriately arranged with a photograph of Mr. MacCalla, beneath which were inscribed these words: "To those who knew him best he leaves the memory of countless loving deeds, the richest legacy that man can leave to man."

In addition to his duties as Vice-President of the Ohio Edison Company, Mr. MacCalla had a wide variety of interests and because of a magnetic personality, he possessed countless friends wherever he went. As Director of the Youngstown Chamber of Commerce and Chairman of the Allied Industries Committee of the Mahoning Valley, he was intimately known and liked by many business men. Hs was an active Rotarian, having served as a member of the Board of Directors and on various committees. He was also a member of the local Torch Club and took a leading part in its activities. He organized and was elected President of the Youngstown Alumni Chapter of Lehigh University and kept an active interest in Sigma Chi, his college fraternity. He was a member of the Youngstown Club, the Youngstown Country Club, the Bankers Club, of New York City, and the Academy of Political Science. He was also a Fellow of the American Institute of Electrical Engineers.

Describing his personality, Esther Hamilton, Columnist of the *Youngstown Telegram*, writes:

"Mr. MacCalla 'got around.' He would be seen dancing in costume at the Youngstown Players ball one evening and presiding at a civic group the next. He knew everybody and everybody literally knew him.

"Quite frequently in later years Mr. MacCalla walked to work, swinging down Fifth Avenue in the early morning. Of a Sunday he liked to carry a cane which he did handsomely.

"He was a member of the First Presbyterian Church and was active in the men's group of that church. In politics, he had always been a Republican.

Mr. MacCalla played hard and he worked hard. He liked to play golf and he liked to swim. He was attached to the theater and no first night was complete in Youngstown without Mr. MacCalla and his wife.

"He was especially interested in the Youngstown Players and on one occasion took time out of his busy life to play a rôle in one of the shows, never missing a rehearsal. He was seldom ill and his constant flow of energy amazed his closest associates. 'He never goes to bed', one of his friends said of him recently."

Upon learning of his death, civic leaders and associates of Clifford MacCalla united in praising him as a gentleman and "one of the outstanding electrical engineers of the United States."

J. E. E. Royer, Vice-President and General Manager of The Washington Water Power Company wrote: "His work in helping to build the physical properties of The Washington Water Power Company, especially the hydro-electric plants, is outstanding and will stand through the years as a memorial to his engineering genius and ability."

A. C. Blinn, Executive Vice-President of the Ohio Edison Company, said:

"Ohio Edison Company and I, personally, feel deeply the loss of Mr. Clifford S. MacCalla who for more than twelve years had been in active charge of our Youngstown properties.

"Mr. MacCalla was not only active in the affairs of our own company, but was generally known and respected in the public utilities field, contributing materially to its development. He was respected and admired by his associates not only for his business capacity and leadership, but also for his genuine personal work. His family and friends have suffered an irreparable loss."

John Rowland, President of the Mahoning National Bank, stated: "He was one of the greatest authorities on electric power in the country. In his death, Youngstown loses a master of business and a civic-minded gentleman. I lose a close friend."

Attorney Charles F. Smith said::

"I have known Mr. MacCalla since he became manager of the Pennsylvania-Ohio Power & Light Company in 1923. He was an affable gentleman and one of the most skilled men I have ever known in the operation of an electric power and light company. He knew the business in all phases from the ground up, as well as being an expert in management and public relations. He always was interested in giving patrons the greatest service possible.

"Ohio Edison has lost one of its most valued employees, this community one of its best citizens, and I, a fine and loyal friend."

R. N. Graham, of the Youngstown Municipal Railway, wrote: "I worked directly with Mr. MacCalla until the railway was segregated. He was a wonderful man, intensely loyal to men who worked for him in big and small matters. I have never known a man so thoughtful and interested in the welfare of the men who worked for him."

Charles F. Owsley, Architect, stated: "I am very much shocked at his death. In Mr. MacCalla's death, I lose a close personal friend for whom I have the highest esteem. He was a civic-minded man of science and business with high intellectual attainments."

According to the *Youngstown Telegram*:

"The sudden death of Clifford S. MacCalla came as a shock to his community because of the part he has played in public and private life ever since he came to the city.

"He was an outstanding figure as an Ohio Edison executive. He was almost equally prominent as an enthusiastic participant in other community affairs, such as activities of The Youngstown Players and of the Rotary Club.

"A succession of promotions and advancements in all phases of the Engineering Profession preceded his appointment here. His connection in an executive and advisory capacity with many social and industrial groups testified to his ability and the confidence placed in him by other leaders.

"He was an aggressive business man and at the same time a charming gentleman whose graciousness in serving those in his own organization and his community endeared him to many.

"Clifford MacCalla had that happy faculty of differing with acquaintances and friends in and out of business relationships without permitting those differences in opinion to become personal differences.

"Youngstown has suffered a great loss in the death of a leader among its corporation executives, and in social activity; in the death of a personal friend."

According to the *Youngstown Vindicator*:

"Youngstown has to thank Clifford S. MacCalla for its dependable light and power service. When he came here a dozen years ago these indispensable utilities were still in the experimental stage. While he exaggerated a little when he said that 'the lights went out whenever it thundered', it is true that both light and power were interrupted with every high wind or heavy rain. Mr. MacCalla gave Youngstown the great boon of electric service so dependable that we no more expect it to be interrupted than we are in doubt as to whether we shall get water or not when we go to a faucet.

"Improvement of the irregular service of the early 1920's was Mr. MacCalla's purpose in coming to Youngstown. He brought modern ideas and a new standard of ability to the management of the local plant. Thoroughly grounded in his profession, and with his technical training reinforced by wide experience in its various phases, both in this country and abroad, he at once gave the city the impression that he knew what he was about.

"The years of the company's greatest development followed. One improvement succeeded another, until his plans reached their culmination in the building of the great power plant at Toronto and the construction of substations and service lines to replace the old ramshackle system and assure service as nearly continuous as man has been able to make it.

"It is not too much to say that any one who can do for Youngstown what Mr. MacCalla did is a public benefactor. He did not look upon himself in that light, and what he did came from pride in his profession and delight in achievement. Personally, he was keen and wide awake, well informed on the rapidly changing developments in the electrical industry and eager to adopt whatever he found helpful. His mind was intent on his work, and his habit of concentration was revealed both in his manner and his crisp mode of expression.

"In the little time Mr. MacCalla found for recreation he made many friends. He brought to his social life the energy and ability which made him a leader in his profession, and he added life and interest to any gathering which he joined. As a man as well as an engineer he was an asset to Youngstown."

Mr. MacCalla was elected a Member of the American Society of Civil Engineers on March 1, 1910.

ROBERT WENTWORTH MACINTYRE, M. Am. Soc. C. E.[1]

Died May 30, 1936

Robert Wentworth Macintyre was born in London, England, on July 14, 1867, the son of John Stevenson and Emily Sarah (Wiggins) Macintyre.

After completing his school education in 1884, some years of which were spent at Redland Hill House, Clifton, Bristol, England, and some in Germany, Mr. Macintyre began the study of engineering as a pupil under E. Wilson and Company, Consulting Engineers, of Westminster, London, England. His experience with this Company was of the greatest value in his future career, giving him an insight into harbor, bridge, and railway construction and maintenance, and also roads and sewers.

In 1888, he went to Canada, and after spending one year on a farm, he entered the service of the Lethbridge and Great Falls Railway Company. At this time in the history of Western Canada, there was a marked movement toward the development of large areas under irrigation systems, and from 1892 to 1904, Mr. Macintyre, except for an autumn's work with the Red Deer Valley Railway Company, was engaged under the Dominion Government in subdivision and contour surveys, hydrographic work, preliminary location of the Red Deer and Rosebud Canals, and the distribution system of the proposed Bow River Canal, later covering also the investigation of water rights' applications and the inspection of works.

From 1904 to 1905, Mr. Macintyre was Assistant Chief Engineer of the North West Territories, with headquarters at Regina, continuing, on the formation of the Provinces of Saskatchewan and Alberta, in the same position for the latter Province until 1911. This position necessitated constant traveling, as it included charge of outside public works, such as bridges, ferries, and roads—both maintenance and construction—and the holding of arbitration proceedings for the expropriation of necessary lands.

Moving still farther west to the Pacific Coast, he spent a couple of years (1911–1913) as Assistant Engineer in the Sewer Department of the City of Victoria, B. C., Canada. During the following two years Mr. Macintyre was engaged in private practice, before becoming, in 1915, Assistant to the late Francis Clarke Gamble, M. Am. Soc. C. E., Chief Engineer of Railways for the Government of British Columbia; on Mr. Gamble's retirement in 1918, Mr. Macintyre served in the same position under Mr. A. F. Proctor until the latter's retirement in 1922, when he became Engineer of Railways for the Province.

In 1921, torrential rains in the mountains of Northern Vancouver caused unprecedented floods that did much damage to roads and bridges; Mr. Macintyre then introduced the use of wire netting in the construction of training groynes of rock, and was very successful in the protection works built in this manner.

[1] Memoir prepared by E. G. Marriott, Esq., Victoria, B. C., Canada.

From 1924 to 1928, Mr. Macintyre was again engaged in private practice, and then spent a couple of years as Municipal Engineer for the Municipality of North Cowichan, on Vancouver Island. It was at this time that he first became aware of that insidious enemy, diabetes, which brought his engineering activities to a close.

While not engaged at any time on works of great magnitude, in the light of developments of to-day, Mr. Macintyre's wide experience, coupled with a capacity for hard work, and an unfailing perseverance that refused to be beaten, enabled him to render extremely useful service to his fellow men.

He was elected Secretary of the Victoria Branch of the Canadian Society of Civil Engineers (now the Engineering Institute of Canada) at its formation in 1911, and by his personal interest, and the giving of much time, he not only infused life into the conduct of local affairs, but took a leading part in obtaining greater recognition for engineers in Western Canada; later, he filled the position of Chairman of the Victoria Branch.

When, in 1920, there was obtained from the British Columbia Legislature an Act to incorporate the Association of Professional Engineers of the Province of British Columbia, by which the practice of professional engineering was to be regulated, Mr. Macintyre was duly registered as a "Civil Engineer", and continued as a member of the Association until his retirement in 1931.

Apart from his garden, his chief relaxations were books and music, and many of his friends took advantage of his generous invitation to make use of his library; organ music was particularly his delight, and G. Jennings Burnett, Organist of St. John's Anglican Church, which Mr. Macintyre attended, often played special compositions at his request.

When the men from the front began to return to Victoria during the World War, he took a vigorous part in obtaining for them the recognition he felt they deserved, and the following extract from the local press by a leading member gives him the credit through his friendly encouragement and cheerful persistence of having a leading part in the founding of the Great War Veterans' Association:

"Mr. Macintyre was the first person in Canada to offer assistance to the organizers of the veteran movement.

"At the second meeting of the eleven members of the Returned Soldiers' Association held May 16, 1916, * * * Mr. Macintyre appeared as an unknown and uninvited guest, * * *. The bare walls, broken plaster, and candles stuck in bottle necks, roused his ire, * * * before the next meeting he arranged with the late Mr. C. T. Cross for their spacious, well-furnished rooms in Belmont House to be at the Association's disposal. * * *

"A social gathering, held in the Belmont House board room was organized by Mr. and Mrs. Macintyre, and in a few weeks the little band of veterans was the centre of a host of friends, and Canada's first organization of veterans of the Great War was firmly established. * * *".

Speaking before the Canadian Club in the Empress Hotel, at Victoria, B. C., on July 7, 1919, Colonel Purney, Dominion President of the Great War Veterans' Association, said: "This powerful organization, of which I am proud to be the head, had its birth in your city."

Mr. Macintyre was married, at Fort Saskatchewan, Canada, on November 24, 1907, to Marion Ada Sharpe, who, with their daughter, Ruby M. R. Macintyre, survives him. Another daughter, by a previous marriage, Mrs. W. E. Huntington, resides in Vancouver, B. C., Canada.

Mr. Macintyre was elected a Member of the American Society of Civil Engineers on October 10, 1916.

CHARLES PATTERSON McCAUSLAND, M. Am. Soc. C. E.[1]

Died November 4, 1936

Charles Patterson McCausland, the son of William H. and Laura B. (Hoop) McCausland, was born at Lonaconing, Md., on August 27, 1881. His early days were spent at Phillipsburg, Pa., where he was educated in the public and high schools.

He began his career as a Civil and Mining Engineer in Clearfield County, Pennsylvania, and, in 1898, was engaged in surveying and railroad construction work as a Rodman on the preliminary surveys for the West Branch Valley Railroad from Clearfield to Williamsport, Pa. In 1900, Mr. McCausland was employed as Axeman on the New York Central and Hudson River Railroad on construction work at Clearfield.

In 1901, he turned his activities to mining, and was employed by the Sharon Coal and Coke Company on construction work, sinking two mine shafts and building the Town of Ronco, Pa.

He then became associated with A. V. Hoyt, Civil Engineer, at Phillipsburg, as Transitman on mining and all classes of general engineering. In 1903, Mr. McCausland became a partner of the Lorain Engineering Company, of Phillipsburg, and was associated with this firm from September, 1903, to August, 1905, and from September, 1907, to May, 1910.

Returning to railroad work, he was employed from August to December, 1905, as Resident Engineer, and from March, 1906, to September, 1907, as Locating Engineer by the Pittsburgh, Binghamton and Eastern Railroad Company. For a short period, from December, 1905, to March, 1906, he was Assistant Engineer in charge of preliminary surveys for the Kentucky Railroad, along the Big Sandy River.

In April, 1910, Mr. McCausland entered the service of the Western Maryland Railway Company as Field Bridge Engineer. With the exception of a short period from 1914 to 1916 when he was engaged in private practice as a Civil and Mining Engineer in Canton, Pa., his service was continuous with the Western Maryland Railway. His ability was well recognized by the Company, and he served as Locating Engineer from 1911 until 1919 when he became Engineer of Surveys. He took a keen interest in the development of coal properties along the line. Throughout this long period of service with the

[1] Memoir prepared by E. M. Killough, Assoc. M. Am. Soc. C. E.

Western Maryland Railway Company, Mr. McCausland made many friends who will long remember his genial personality.

On February 17, 1913, Mr. McCausland was married, in Canton, Pa., to Aileen M. Hickey, and is survived by his widow and a son, Charles Patterson McCausland, Jr.

During the last year or more of his life, he hid from his closest associates a heart affliction which ultimately was the cause of his death, on November 4, 1936.

He was a member of the American Railway Engineering Association, and served on its Yards and Terminals Committee. He was also a member of the Masonic Order.

Mr. McCausland was elected an Associate Member of the American Society of Civil Engineers on December 6, 1910, and a Member on July 2, 1913.

CHARLES ALBERT McKENNEY, M. Am. Soc. C. E.[1]

DIED MARCH 23, 1935

Charles Albert McKenney was born in Washington, D. C., on October 14, 1870, the son of James Hall and Virginia Dorcas (Walker) McKenney. He was descended from those McKenneys who came from the north of Ireland and settled in Maine in 1668. His Great-Grandfather McKenney moved to Maryland in 1791, since which time the family has remained in Maryland and the District of Columbia. His father was Clerk of the Supreme Court of the United States from 1880 until his death in 1913.

His preliminary schooling was received at Emerson Institute, in Baltimore, Md., and at the Columbian Preparatory School of Columbian College (later, George Washington University), at Washington, D. C.; his college preparatory work was done at the Lawrenceville School, in New Jersey, and his technical education was obtained at Princeton University, at Princeton, N. J., from which he was graduated in 1892 with the degree of Civil Engineer.

A few months after his graduation Mr. McKenney entered the service of the District of Columbia and, thereafter, for the next twenty years, he was intimately associated with the major engineering problems of the Nation's Capital and many of its monumental projects bear evidence of his energy and skill. Beginning as an Axeman in the Sewer Department, he advanced through the grades of Chainman, Rodman, Draftsman, Instrumentman, and Assistant Engineer in that Department. Entering upon this work with enthusiasm and continuing to apply himself to his books and endeavoring to absorb the experience of his associates, he made rapid progress and, in 1896, was selected to take charge of the construction of a sewerage system for Fortress Monroe, Virginia. For this purpose he was furloughed from his regular employment and loaned to the United States War Department. On

[1] Memoir prepared by L. M. Gray, M. Am. Soc. C. E.

the successful completion of this work Mr. McKenney returned to the District of Columbia and, in 1897, was made a Special Assistant to the Engineer Commissioner. He was placed in charge of the surveys for the bridge across Anacostia River, and of the preparation of plans for the elimination of railway grade crossings in the District. He afterward served as Engineer of Roads and Bridges and, later, as Engineer and Superintendent of Construction of the Water Department. In this latter capacity he had charge of the construction of the 30 000 000-gal Brightwood, or Sixteenth Street, Reservoir, which at the time it was built was a new departure in reservoir types. He also built the Bryan Street pumping plant, including the installation of pumps and other equipment. When the new Municipal Building was constructed (1904–1908), he served as Engineer for the Municipal Building Commission in charge of the construction of this monumental structure. Shortly after the completion of this assignment, Mr. McKenney resigned his position with the District Government and established an Office as Consulting Engineer, in Washington.

His professional service was interrupted by the World War, but shortly after his discharge from the Army, he joined with the late Major-General William M. Black, U. S. A. (*Retired*), M. Am. Soc. C. E., formerly Chief of Engineers, and John Stewart, M. Am. Soc. C. E., in the organization, at Washington, of the firm of Black, McKenney, and Stewart, Engineers, and thus began an association which lasted until General Black retired in 1930, and the firm was dissolved. During this period, Colonel McKenney was engaged on work for which he was peculiarly adapted and which he thoroughly enjoyed. Gifted with a personality of rare charm he made friends easily and readily established the basic contacts essential for his firm's success. He was a convincing talker and, possessed of a keen and ready yet kindly wit, he was ideally fitted for carrying on the negotiations preliminary to the making of contracts. Combined with a rare facility of expression and a vocabulary enriched by extensive reading, he had the ability to arrange his thoughts clearly and logically and to express them forcibly. The reports he prepared during the ten years of the firm's existence are examples of his logical reasoning and clarity of expression.

The firm of Black, McKenney, and Stewart handled many important assignments; among the first works undertaken was an investigation and report on some harbor work at Tampa, Fla.; then followed a report on the harbor at Baltimore. In 1921, the firm was engaged to make a report on the canalization of the Magdalena River, in Colombia, across the bar at the Bocas de Ceniza. The field work on this project, including extensive surveys and an investigation of all available data, was undertaken by Colonel Stewart, but the report was prepared by Colonel McKenney in consultation with General Black. The work was done for, and the report was submitted to, the Compañia Colombiana de las Bocas de Ceniza, but the project recommended, which included the construction of two rubble mound jetties, was accepted subsequently by the Colombian Government. When, in 1925, that Government was ready to proceed with the work, the firm of Black, McKenney, and Stewart was engaged as Consulting Engineers to supervise and direct the construction,

and continued as such until work was discontinued, in 1929, with the jetties only partly completed. Enough work had been done, however, to demonstrate the soundness of the project. Subsequently, Sir Alexander Gibb. M. Am. Soc. C. E., of London, England, was engaged by the Colombian Government to advise it with regard to matters relating to rivers and harbors, and in his report on the Bocas de Ceniza project, he insisted that the work be completed exactly in accord with the plans of Black, McKenney and Stewart. Although Colonel McKenney had never visited this project during its construction, he was always in touch with it in an advisory capacity and conducted all the negotiations with the Colombian Legation at Washington.

In 1924, the firm was engaged by the City of Guayaquil, Ecuador, to prepare plans for a light and power plant for that city, and Colonel McKenney went to Ecuador to make the necessary field investigations and to conduct the surveys. While there, he visited Quito and concluded an arrangement with the President of the Republic whereby the firm would act as Technical Adviser to the Government. However, tthe contract that was then signed, was never approved by the Congress of Ecuador.

During 1924 and 1925, Colonel McKenney handled all the negotiations connected with the firm's participation in the project for the construction of a gigantic rail and water terminal at Bayonne, N. J. Under his direction, and in consultation with General Black, preliminary study plans and estimates were prepared for this $150 000 000 project. At this time, too, the firm prepared a report on a vast rail and river terminal at St. Louis, Mo.; a project for the improvement of the Lower Brazos River, in Texas, for presentation to the U. S. Engineer Department; and designs for breakwaters at Milwaukee, Wis.; it managed many other projects in which Colonel McKenney had a leading part.

In 1927, the firm was engaged by the Brotherhood of Locomotive Engineers to prepare plans for an extensive development at Venice, Fla., and Colonel McKenney directed all phases of the firm's work on this project and personally wrote the reports.

The last important work he did for the firm of Black, McKenney, and Stewart, was the preparation of a report, after exhaustive investigations, on the improvement of the Chattahoochie River below Columbus, Ga. After the submission of this report and upon the dissolution of the firm, he was retained by the City of Columbus as Consulting Engineer to continue the work he had been doing on the project.

When the firm of Black, McKenney and Stewart was dissolved in 1930, Colonel McKenney again established an office in Washington as Consulting Engineer and spent the remaining years of his life in the leisurely practise of the profession to which he had devoted all his active years.

Colonel McKenney had always been an interested student of military matters. Through his long and intimate association, while in the service of the District of Columbia, with the officers of the Corps of Engineers, he had, in a way, absorbed the traditions of that Corps and had seemed actually to belong to the Army. With this background it was natural that, in 1916, when it appeared to be certain that the United States would ultimately become

involved in the World War, he would want to prepare himself to take part in the nation's military effort. Accordingly, he was one of that group of patriotic men who attended the 1916 Plattsburg Camp, and afterward applied for a commission in the Officers Reserve Corps. His application was favorably considered, and he accepted appointment as Major, Engineer Section, Officers Reserve Corps, on May 23, 1917, and was assigned to active duty in the office of the Chief of Engineers at Washington, on July 26, 1917, in charge of engineer supplies and as Engineer Liaison Officer in matters affecting the Engineer Corps and other branches of the War Department, as well as the civil agencies having to do with war materials. He was commissioned Lieutenant Colonel, Engineers, National Army, on March 18, 1918. He was assigned to duty in the Purchase, Storage, and Traffic Division, General Staff, on May 29, 1918, and detailed as War Department Representative with the Priorities Division, War Industries Board, charged with fixing the priority of production, distribution, and transportation of supplies for the Army. He was commissioned Colonel, United States Army, on November 4, 1918. After the signing of the Armistice, Colonel McKenney was assigned as Assistant to the Director of Purchase, U. S. Army, with duties involving the settlement of purchase contracts, and, in January, 1919, he was appointed a member of the War Department Claims Board. On October 25, 1919, he was honorably discharged from the Service.

After his discharge from active duty, Colonel McKenney was appointed Colonel, Engineer Officers Reserve Corps, on February 3, 1920, which appointment he accepted on April 1, 1920; he was re-appointed in the same grade on February 3, 1925, and was transferred as a Colonel to the Auxiliary Reserve on February 3, 1930, and re-appointed in the same grade and status on February 2, 1935.

His engineering ability is attested by the character of the works he planned and constructed. The reports he prepared, with their lucid statement of facts and sound and logical conclusions, show the brilliant quality of his mind. He was a gentleman in the finest sense of the word; of a distinguished family the influence of a long line of cultured forebears showed in all his actions. A gifted conversationalist and a delightful companion, he made friends wherever he went and retained them always. He was a considerate employer and a staunch and loyal friend. One who was closely associated with him for the last fifteen years of his life wrote:

> "Colonel McKenney was an engineer of exceptional ability. He had a keen and penetrating intelligence, possessed sound judgment and the ability clearly and forcibly to express his thoughts. Full of sympathy and understanding he appreciated all the problems of his subordinates and was always helpful in their solution. He was one of the finest gentlemen I have ever known."

Colonel McKenney was a member of the Metropolitan Club and the Chevy Chase Country Club, and took an active part in the social life of Washington.

He was married in 1901 to Frances Marion Miller, of Washington, who survives him. He is also survived by three children, James Hall McKenney 3d, Francesca McKenney, and Charles A. McKenney, Jr.

Colonel McKenney was elected a Junior of the American Society of Civil Engineers on December 4, 1894; an Associate Member, on December 1, 1897; and a Member on March 2, 1909.

FRANK PAPE McKIBBEN, M. Am. Soc. C. E.[1]

DIED NOVEMBER 27, 1936

Frank Pape McKibben was born on November 13, 1871, at Fort Smith, Ark., the son of Frank Read McKibben and Minnie Elizabeth (Pape) McKibben. He was a student at the University of Arkansas, at Fayetteville, Ark., from 1887 to 1890 and at Massachusetts Institute of Technology, at Boston, Mass., from which he graduated in 1894 with the degree of Bachelor of Science in Civil Engineering.

From 1894 to 1903, Mr. McKibben was engaged as Instructor in Civil Engineering at the Massachusetts Institute of Technology; from 1903 to 1906, he was Assistant Professor of Civil Engineering, and from 1906 to 1907, Associate Professor at the same institution. He was then appointed Professor of Civil Engineering at Lehigh University, at Bethlehem, Pa., where he remained until 1919, when he became Professor of Civil Engineering at Union College, at Schenectady, N. Y.

In 1897, he designed the New Bedford, Mass., Bridge; he also served as Engineer for the bridge at Oil City, Pa. From 1898 to 1901, he was employed as Assistant Engineer, with the Boston Elevated Railway Company, and from 1901 to 1907, he served as Assistant Engineer, with the Massachusetts Railroad Commission. In 1918, Professor McKibben was Supervisor of Technical Training for the Emergency Fleet Corporation, in which position he did wonderful work. He was held in the highest esteem by every one in Schenectady, N. Y., in which, as City Engineer, he developed many outstanding improvements. From 1913 to 1926, he was variously engaged as Consulting Engineer for Venango, Lehigh, Northampton, Berks, and Luzerne Counties, in Pennsylvania, the Lehigh Coke Company, the Bethlehem Steel Company, the American Locomotive Company, and, in later years, the General Electric Company.

During this time, Professor McKibben wrote the chapter on "Arches," in the book entitled "Concrete, Plain and Reinforced," by the late Frederick W. Taylor and Sanford E. Thompson, M. Am. Soc. C. E.; also, the chapter on "Steel," for the American Civil Engineers Pocket Book.

Professor McKibben had more than thirty-two years of teaching experience in Massachusetts Institute of Technology, Lehigh University, and Union College. He was a Bridge Engineer of national reputation, having been Designer, Engineer, or Constructor, of many outstanding bridges of

---

[1] Memoir prepared by T. B. Wood, Esq., Chambersburg, Pa.

masonry, steel, and concrete. He traveled extensively abroad and during these travels inspected many famous old and new bridges. He also was an authority on electric welding, having been for several years Consultant for the General Electric Company relative to structural steel welding in which capacity as a Lecturer before engineering societies in all parts of the United States, he contributed valuable information on this subject. In recognition of his knowledge in this field, he was elected President of the American Welding Society in April, 1932. Professor McKibben was in charge of the design, construction, and equipment of the John Fritz Engineering Laboratory, at Lehigh University, in 1910 and 1911. He was Consulting Engineer to the Attorney General of Pennsylvania in the investigation of the failure of the Austin Dam in 1911, as well as Consulting Engineer for the Pennsylvania Water Supply Commission in 1914 and 1915. In 1915, he helped to organize the People's Trust Company, of Bethlehem, Pa., and was its Vice-President from 1915 to 1919. It is amazing how he did all these things, and in such a quiet, modest manner. The statement of one of his co-workers that, "it is remarkable how one man could have accomplished all this in a single life time," is particularly significant.

Professor McKibben was a man of the highest type, as an engineer, citizen, and Christian. His knowledge of the animal and plant life of the forest and of its birds was amazing, and no less was his knowledge of stamps and oriental rugs, with which he loved to work in his spare time, when most busy men would be taking their rest or ease. He also was extremely fond of Astronomy, giving more time to it than any of his regular problems required; it might be said that this was his real hobby. In addition to all these works, he also was greatly interested in the growing of apples and in farming.

A most kindly man, a wonderful companion, at every turn on a trip around the country side something presented itself to cause a remark by him, filled with information, stated in an interesting and instructive manner, that added so much to the pleasure of the trip. His was an analytical mind; that is what made him a good engineer. He imparted his knowledge analytically, yes, but tempered it with kindness, common sense, and knowledge of the human equation; that is what made him a good teacher. His ideas of society were so broad that he gave to each person his own right to do as he saw fit. He was an Elder in the Falling Spring Presbyterian Church, of Chambersburg, Pa. Above all else, he was a high type Christian man, and the world is better for the place he held in it.

Professor McKibben was a member of many organizations and societies for the advancement of science and served in many positions of importance in education, scientific investigation, engineering, and construction. He held many positions, in important engineering projects, as the author of various engineering books, and as a teacher. His engineering ability and general good judgment relative to civic and other problems were so well known and thought of, that he was chosen Consulting Engineer for a number of cities, counties, and of large business interests.

He was married to Arabella Almy, of Tiverton, R. I., in January, 1899, to which union was born a son, Elliot S. McKibben. Mrs. McKibben died in May, 1921. On March 24, 1923, he was married to Ariana Kennedy Elder, of Chambersburg.

He died on November 27, 1936, and interment was in Falling Spring Church Cemetery, at Chambersburg. He is survived by his widow; his son, Elliot; a sister, Mrs. J. Raymond Williams, and a brother, Dr. William McKibben, both of Miami, Fla.

Professor McKibben was elected a Junior of the American Society of Civil Engineers on January 3, 1895; an Associate Member on March 6, 1901; and a Member on October 3, 1905.

FREDERIC OZANAM XAVIER McLOUGHLIN, M. Am. Soc. C. E.[1]

DIED JUNE 28, 1936

Frederic McLoughlin was beloved by his associates for his human qualities and admired for his ability as an engineer. Almost his entire professional life was devoted to the organization and development of the School of Technology, College of the City of New York. His memory will live on in the ideals of that school and in the spirit of its staff. Beloved by all for his friendly and generous spirit, he was, nevertheless, a man of fearless convictions and outspoken opinions. He never sacrificed principle to good nature; yet so frank and amiable was his attitude that he could win a colleague's affection even while opposing him on a matter of policy.

Frederic Ozanam Xavier McLoughlin was born in New York, N. Y., on March 12, 1888, and attended the public schools of that city. He earned his Bachelor of Science degree at The City College, New York City, in 1909, being honored by election to Gamma Chapter of Phi Beta Kappa and receiving the Ralph Weinberg Memorial Prize. He also became a member of Phi Gamma Delta Fraternity. In 1913, he took his Civil Engineering degree at Columbia University, New York City, and, in the following year, was awarded the degree of Master of Arts in Highway Engineering by the same institution. At Columbia, he was the recipient of the J. Pierpont Morgan Scholarship and was elected to the Columbia Chapter of Phi Beta Kappa. During the summer vacations from 1911 to 1913, he was employed as an Inspector of the New York Board of Water Supply on the Catskill Aqueduct.

Professor McLoughlin was a teacher at The College of the City of New York from 1910 until his death. He rose to the rank of Instructor in 1916, was made Assistant Professor in 1918, Associate Professor in 1925, and Professor in 1934. He was identified with courses in Civil Engineering from the beginning of his career and became one of the original members of the Faculty of The School of Technology at the time the latter was

[1] Memoir prepared by R. E. Goodwin, M. Am. Soc. C. E.

made a separate unit of the College in 1919. From 1917 to 1919, he served as Civilian Instructor attached to the 30th Service Company, United States Signal Corps, in charge of instruction in Military Surveying.

At The City College he was Secretary of the Faculty of The School of Technology from the time of its founding until his death, and served as a member of the City College Co-Operative Store Committee. He established and organized the Summer Surveying Camp, founded and developed the Evening Courses in Building Construction, organized post-graduate courses in Highway Engineering, and was Chairman of the Curriculum Committee. He was the author of a Field Manual in Elementary Surveying, which is used in the Elementary Surveying Course at the College.

Professor McLoughlin was a leader in furthering student activities and student welfare. For a long time he was Faculty Adviser to the City College Student Chapter of the American Society of Civil Engineers, which he organized in 1921. He was Faculty Adviser to the student publications, *Tech News* and *Tech Journal*, and founded the Tech Council, a committee for co-ordinating the activities of the Student Chapters of the several National Engineering Societies.

He was a member of the Engineering Council for Professional Development Delegatory Committee for Region No. 2, a committee charged with the responsibility for examining and accrediting Technical Schools in this district; a member of the Society for the Promotion of Engineering Education; and for six years he was Secretary of Gamma Chapter of Phi Beta Kappa. His services as a Consulting Engineer were frequently in demand. He was an active proponent of the plan for standardizing engineering degrees.

On August 8, 1917, Professor McLoughlin was married to E. Margaret Brown, of Cornwall-on-Hudson, N. Y., who survives him.

He died at his summer home in Big Indian, N. Y., on June 28, 1936. Memorial services were held for him at The City College on July 1, 1936, at which the Great Hall of the College was filled with his friends and associates who came to pay their respects and to do honor to his memory. In his remarks at these services, Dr. Frederick B. Robinson, President of The City College, said in part:

"Frederic McLoughlin had a clear and vigorous mind. This made him effective as a teacher and valuable as a counselor in all matters of academic policy. He was a moving force in the development of The School of Technology. He was a man of generous heart, given to warm friendships with students and colleagues. He was a big brother to many a boy who needed help. Many a graduate of the college owes his success to the timely help of the McLoughlins and also to the entrée into engineering practice arranged by the Professor.

"Professor McLoughlin was not given to preachment, but the purest and loftiest of human ideals were expressed in his deeds. He was honorable, and dependable in all the relations of life—personal, official and civic. He wished the noblest destiny for his country, his college, his students and friends, and those bound to him by the most intimate ties of affection. He was unsparing of himself in practical efforts to carry those wishes into effect. Professor McLoughlin was a patriot in his unselfish loyalty to his country, a scholar in his labors for more knowledge and more adequate expression of the truth,

a doer of good deeds for his fellow creatures, and a devoted husband. We grieve over his loss to us in the flesh, but we thank the source of all good for the companionship we had with Frederic McLoughlin, and we know that his spirit will live in this college as an institution and in the lives of those who love him."

Professor McLoughlin was elected a Junior of the American Society of Civil Engineers on April 1, 1914; an Associate Member on April 19, 1920; and a Member on October 24, 1932. He was also a member of the Metropolitan Section of the Society and served on its Committee on Vocational Guidance.

ELWOOD MEAD, M. Am. Soc. C. E.[1]

Died January 26, 1936

Elwood Mead was born near Patriot, Ind., on January 16, 1858, the son of a pioneer Switzerland County farmer, Daniel, and his wife, Lucinda (Davis) Mead. From these humble beginnings, an inquisitive and clear-thinking mind and hard labor carried him to the very top of his chosen specialty—irrigation and reclamation engineering.

The boy who experimented with a home-made transit on his father's farm, and worked his way through school as a rodman on a survey crew, later was to guide the United States Bureau of Reclamation in mapping, planning, and launching the greatest reclamation construction program in history.

The man who was to head the Bureau of Reclamation during its entire period of construction of the mighty Boulder Dam, began his career (after having been graduated from Purdue University, at La Fayette, Ind., with a degree of Bachelor of Science in 1882 and a degree of Master of Science in 1884) as an Assistant Engineer in the United States War Department on a survey of the Wabash River in his native Indiana.

As a teacher and administrator in the field of irrigation, Dr. Mead was renowned throughout the world. In his specialty, he was a pioneer, and the influence of his research, innovations, and ideas is reflected in laws governing irrigation practice in the arid States of Western United States and in many other parts of the world.

In bestowing upon Dr. Mead an honorary degree of Doctor of Laws, in 1925, the University of Michigan, issued this statement:

"Dr. Elwood Mead, Commissioner of the Bureau of Reclamation, engineer, law-giver and administrator, whose labors will endure through ages yet to come. By framing and putting into operation the irrigation laws of the State of Wyoming, he established a precedent followed not only by the newer States of the West, but also by Canada, Australia, South Africa, and New Zealand. He brought order out of confusion and opened a way where none had been."

[1] Memoir prepared by R. F. Walter and William H. Code, Members, Am. Soc. C. E., with valuable assistance from Professor Frank Adams, of the Univ. of California, Berkeley, Calif.

In addition to the degree of Doctor of Laws, Dr. Mead also held a Civil Engineering Degree bestowed by the Iowa State College of Agriculture in 1883, and an honorary degree of Doctor of Engineering received in 1904 from Purdue University (the first honorary degree given by that University). In June, 1934, Dr. Mead was also awarded the degree of Doctor of Laws by the University of Wyoming.

The endeavors of Dr. Mead for the rights of humanity to the orderly use of water for agriculture by irrigation can be divided roughly into five parts, as follows: (1) Territorial Engineer of Wyoming, 1888–1889, and State Engineer, 1889–1899; (2) Chief of the Division of Irrigation and Drainage Investigations, United States Department of Agriculture, 1899–1907; (3) Chairman of State Rivers and Water Supply Commission, Victoria, Australia, 1907–1914; (4) Professor of Rural Institutions, University of California, Berkeley, Calif., 1915–1923; Chairman of the State Land Settlement Board, of California, 1917–1923; and (5) Commissioner of Reclamation, United States Department of the Interior, 1924 until his death.

After two years as Instructor in Mathematics, he was appointed, in 1886, Professor of Irrigation Engineering at the Colorado State College of Agriculture, at Fort Collins, Colo., the first such chair held in an American college. In addition, he served Colorado as Assistant to the State Engineer. He went to Wyoming as Territorial Engineer, in 1888, and served that State as its first State Engineer from 1889 to 1899. It was during this period that he first gained prominence.

When the new State was being organized, Dr. Mead, as State Engineer, proposed an entirely new Water Law for inclusion in the State Constitution, one in which the people turned their backs upon the common law principle of riparian rights which had thrown into confusion the legal status of water in so many communities of the arid West. Under the Mead plan, the State claimed title to all water, surface and underground. Diversion from streams and all appropriations of water in Wyoming since that time have been under the control of State Officials.

The success of the fight for this reform made the young engineer known throughout the entire West. His biennial reports discussed the determination of, and limitations to, the rights to water, their adjudication, and approval of permits to appropriate water, and his later reports emphasized the importance of having the land and water under one control; and, just as cities owned water-works, so he believed that irrigation communities dependent on a single large canal should own that canal. With the spread of his reputation as an authority on irrigation and water laws, the young engineer was in demand as a speaker at civic and technical associations, and delivered a very comprehensive address on "The Arid Public Lands—Their Reclamation, Management, and Disposal", before the then recently organized American Society of Irrigation Engineers. His reputation reached the East, and he wrote for the Departments of Agriculture and the Interior a series of *Bulletins* on water rights.

Elwood Mead served as Chief of the Irrigation and Drainage Division of the Department of Agriculture for eight years ending in 1907, and served the University of California concurrently as Professor of Institutions and Practice of Irrigation. During this period, he visited Italy and studied the institutional and legal phases of irrigation in that country. He was detailed as an expert in the celebrated Kansas-Colorado case to aid in the broad policy to be laid down by the Courts, and wrote several papers on the influence of State boundaries on water-right controversies and water rights within the States. Early in 1901, he lost his right arm in a street car accident, in Washington.

In 1907, Dr. Mead went to Australia as Chairman of the State Rivers and Water Supply Commission of Victoria. He inaugurated a comprehensive plan for water conservation and reclamation in the State of Victoria during his eight years of service, that is considered one of the models of the British Empire to-day. On reaching Australia, he found conditions somewhat like those in Wyoming at the earlier date, except in this case it was the "land hog" instead of the "water hog" who was standing in the way of development. The large land-owners were using the water as a kind of insurance for stock water in dry seasons, paying a very small sum for the large expense incurred in bringing the water long distances to the land and preventing land settlement. Here, again, he encountered the same old fight of vested interests, but by appealing to decency, justice, and common sense, Dr. Mead won his victory as he had done in Wyoming years before.

Large estates were cut up, and as a result of the controversy the Closer Settlement Act was enacted and a policy of State aid in placing settlers on the land was inaugurated. Dr. Mead assisted in settling controversies over the waters of the River Murray between the States of Victoria and New South Wales, suggesting a form of compact between the two States and advocating that irrigation and not navigation should have first place. Several of his addresses were published in American journals, including articles entitled "What Australia Can Teach America", and "Irrigation in Victoria."[3]

In 1913, Dr. Mead, then one of the leading authorities on land settlement, resigned his position in Victoria, Australia, but remained there until 1915. He then returned to the United States to accept the position of Professor of Rural Institutions at the University of California, and, also in 1917, of Chairman of the State Land Settlement Board. Shortly after his return to the United States, in 1915, he was engaged as Chairman of the Central Board of Review to aid in deciding some of the settlement problems on Federal irrigation projects. In 1917, he acted as Consulting Engineer on a board in connection with the plans for the All-American Canal to Imperial Valley in California.

Later, he was called upon by Secretary Lane, of the Department of the Interior, for expert advice regarding settlement problems in connection with placing World War veterans on farms. A pamphlet by him on a "Summary of Soldier Settlements in English Speaking Countries", was widely distributed.

[3] *Engineering Record*, August 14, 1909.

In 1923, Dr. Mead was appointed by the Secretary of the Department of the Interior as a Special Adviser on Reclamation, to serve with four others on the Fact-Finding Commission set up to investigate Federal reclamation projects. The Commission's report was the basis for reforms put into effect by Congress by the omnibus Reclamation Act of 1924.

On April 3, 1924, his intimate knowledge of irrigation and land settlement was again recognized by his appointment by President Coolidge as Commissioner of Reclamation. Under his leadership Federal reclamation has been placed on a still firmer foundation of usefulness to the nation. He was appointed by the President, a Special Commissioner on the International Water Commission, on December 27, 1924.

Dr. Mead was loaned to foreign governments in need of expert advice on water and irrigation problems. He went to Palestine to advise the Zionists upon the problems involved in reclaiming the arid lands of the Holy Land; he served on commissions in Cuba and Haiti, and acted as Adviser to the Governments of New South Wales, Australia, Canada, Hawaii, Java, and Mexico.

Perhaps no man knew the terrain of Western United States better than Dr. Mead. With 'Buffalo Bill" Cody, he explored some of the more difficult rivers of Wyoming in 1888. Repeated trips in the years following gave him first-hand knowledge of virtually every creek and range of hills in the arid region. In recent years, as Commissioner of Reclamation, he had made a tour of the West each year, inspecting Federal irrigation projects, examining areas where new projects have been proposed, and renewing acquaintances which were to be found in every hamlet from Denver, Colo., to San Francisco, Calif., and from Spokane, Wash., to El Paso, Tex.

Dr. Mead's administration of the Bureau of Reclamation was business-like and humane. He introduced several reforms one of the most important of which was the establishment of a policy of selecting settlers for new Federal reclamation projects on the basis of their qualifications for irrigation farming. Irrigation farming, Dr. Mead believed, required a high degree of skill for success. He took great pride in the growth and development of the communities and cities on Federal projects in the West.

He was an Honorary Member of the American Society of Agricultural Engineers, and a member of the Institution of Civil Engineers of Great Britain. He was also a member of the Water Resources Committee of the National Resources Board, and served on many other governmental committees and commissions. He was the author of two books, that are used widely as texts, entitled, "Helping Men Own Farms" and "Irrigation Institutions."

Dr. Mead is survived by his widow, Mrs. Mary Lewis Mead, by three sons, Tom C. Mead, Arthur Mead, and Lt. John Mead, U. S. Army; by two daughters, Mrs. Lucy Marston, wife of Maj. Morrill Marston, U. S. Army, and Mrs. Sue Kaiser; and by seven grandchildren.

In a letter of condolence to Mrs. Mead, Franklin Delano Roosevelt, President of the United States, wrote "Dr. Mead was one of the country's outstanding engineers. He was a builder with vision whose loss will be keenly felt."

Secretary of the Interior Harold L. Ickes, stated,

"The death of Dr. Mead is a profound shock to me personally. His place in the official family of the Interior Department will be almost impossible to fill. He was an outstanding man, famed in his field throughout the world. All who knew him loved and respected him.

"As Commissioner of the Bureau of Reclamation, Dr. Mead has left for the Nation many monuments in work well done. Perhaps no man contributed more to the planning of Boulder Dam and certainly no one had a more important part in the actual construction of it than Dr. Mead. If his place in the memory of his Nation were to rest on that accomplishment alone, it would be secure. But there were many other accomplishments in his long and exceptional career as an engineer, law-giver, teacher, and administrator in the field of irrigation.

"He showed the way when he formulated the water provisions of the constitution of the State of Wyoming, which he served as its first State Engineer, where some of the knottiest problems in the arid regions of the world existed. Wyoming, at Dr. Mead's urging, discarded the riparian theory of water ownership and adopted a system under which the State retained all water rights. Development of this primary resource was retained under the jurisdiction of the State. Revolutionary in the field of water law at the time, the plan since has been adopted by other Western States and by many other nations.

"The death of Dr. Mead is a distinct loss to the country, which by his life he has so enriched through original thought, and devotion to duty and ideals."

Miss Mae A. Schnurr was closely associated with Commissioner Mead during the twelve years of his official connection with the Bureau of Reclamation, first as his Secretary, and, later, as his Assistant. In speaking for the employees of the Bureau, she stated:

"It is an honor to speak for those privileged to have been associates of Dr. Mead. In his death we have suffered the loss, not only of a very able Commissioner of Reclamation, but of a kindly friend and counselor who made of each associate a competent and loyal assistant. His ability inspired respect, his kindly thoughtfulness made us admiring friends. His memory will stay fresh and revered in the hearts of all of us."

His successor, John C. Page, M. Am. Soc. C. E., then Chief of the Engineering Division of the Commissioner's Office, writes:

"The death of Dr. Mead means not only a tremendous loss to the Bureau of Reclamation, but it also creates a vacancy among the most eminent engineers in the world.

"Through a long and useful life, Dr. Mead exemplified the highest professional ethics and was recognized as an engineer with wide conception of the human as well as the technical side of the profession.

"Engineers throughout the world looked toward Dr. Mead for leadership in the field of reclamation. He had won his place in their esteem through sound developments and outstanding construction."

E. K. Burlew, Administrative Assistant to the Secretary of the Interior, when notified of Dr. Mead's death, made the following statement:

"Through 12 years of close association with Dr. Mead, I have come to esteem him as a friend and official. His professional attainments gave him an eminence that few men attain in their chosen field and his human attributes endeared him to all who had occasion to seek his kindly wisdom and straight-

forward honesty in the solution of their problems. He spent his life in creating homes for many thousands of people and in developing the natural resources necessary to maintain them. His passing will be mourned by a great multitude in the West who have him to thank more than any other man for their hearth and their economic independence."

The Federal Board of Geographic Names paid Dr. Mead a signal and appropriate honor in bestowing his name upon the new lake formed by Boulder Dam, the largest artificial lake in the world, an important new geographical feature of the nation, and a vital influence on the lives of millions of people in the Southwest.

The official designation by the Board of Geographic Names is as follows:

"*Lake Mead.*—An artificial lake in Mojave County, Ariz., and Clark County, Nev., formed by damming the Colorado River in Upper Black Canyon. Named in honor of Dr. Elwood Mead (born Jan. 16, 1858, died Jan. 26, 1936), Commissioner, Bureau of Reclamation, 1924–1936, under whose supervision the dam that impounds the lake was built."

Lake Mead began forming February 1, 1936, when the gates at the diversion tunnels of Boulder Dam were closed.

Noteworthy tributes were paid to this gentle and modest man by fine editorials and articles in scores of leading newspapers and magazines throughout the nation. Space will permit only brief reference to them. The following comment is from *Engineering News-Record.*

"A well merited tribute was paid to the memory of Elwood Mead and to the value of his long labors in western development by the action of the Board of Geographic Names in designating the inland sea formed by Boulder Dam as Lake Mead."

The Washington, D. C., *Daily News* published an especially fine editorial from which is quoted the following:

"It is to his credit and to that of Presidents Coolidge, Hoover, and Roosevelt that no one knew or cared what his politics were. * * * Such administrators as Dr. Mead are all too rare in state and national affairs."

Quoting from the *Arizona Republic:*

"His task was not an easy one. Reclamation projects are similar in one respect, their purpose. Each particular project has its multitude of problems, peculiar to it only. The ability of Dr. Mead to cope with the individual reclamation problems of each section was remarkable."

Throughout the West memorial services were held for Dr. Mead. The week of February 16 was set aside in his memory by proclamation of Governor B. B. Moeur, of Arizona, who said: "The entire citizenship of Arizona mourns the loss of Dr. Elwood Mead. We have lost one of our most constructive friends." Governor Clarence D. Martin, of Washington, also by proclamation, declared that week, "Elwood Mead Memorial Week" in his State. Fine eulogies were delivered by statesmen and others who knew the man and his works intimately, and many resolutions were passed by important State bodies in California and elsewhere.

Dr. Mead was a man of many friends. Throughout the seventeen Western States comprising the arid and semi-arid region of the United States, there is scarcely a community where the results of his labors during the past fifty years have not left their mark of progress. Under his leadership the construction of the great Boulder Dam was initiated and completed. Under him the Bureau of Reclamation constructed monumental works which now stand in nearly every Western State as evidence of the breadth of his vision.

Although one of the kindest and most lovable characters, Dr. Mead was also a doughty and determined fighter when his plans for what he believed to be in the public interest, were attacked, either at home or in the foreign country where he was located for many years.

No tribute to Dr. Mead would be complete unless mention were made of his fondness for the game of "Five Hundred", in which he was never too tired to engage after a strenuous day in the field or office. Dr. Mead knew this game with all its ramifications and, given an equal chance, no one could best him in the final score.

Dr. Mead's early ambition was to attend the United States Military Academy, at West Point, N. Y., for which he qualified by taking the necessary examinations. Subsequent ill health compelled him to give up this plan. He was greatly pleased to have a son graduated from that fine school, and at the time of his death was looking forward to the possibility that his grandson also might enter the Academy. And thus Dr. Mead's early frustrated ambitions are being realized by his descendants.

Although his life work might be considered as the antithesis of one dealing with war and its strategies, the facts are that in the pioneer days of irrigation, shovels, shot-guns, and rifles were common implements on display in settling disputes over water rights. His subsequent wise water laws pointed the way of peace by arbitration.

He always had the courage of his convictions. In recent years, when even some of his best friends began to think that perhaps he was too optimistic in planning for additional irrigation projects in the West, the Middle West suffered a period of devastation occasioned by drought followed by ruinous winds and dust storms. This calamity demonstrated conclusively the wisdom of the reclamation policies of Dr. Mead and his predecessors in office to whom he would be one of the last to deny full credit.

Friends of Dr. Mead traveling in Europe have heard warm tributes paid him in many unexpected quarters, namely: From a high official of the Italian Emigration Service, in Rome, who stated that Dr. Mead had been a great friend of Italy in advising on its land and water investigations in Australia and elsewhere; from the highest salaried agronomist of the British Empire, encountered in the Blue Nile country, who was in full accord with Dr. Mead's land and water policies; and from an Australian met casually at the British Exposition, in Wembley, in 1925. He had formerly been a tenant farmer in England, but was induced to go to Australia and take up land upon Dr. Mead's recommendations. He paid Dr. Mead the warmest of tributes.

An excerpt quoted from a fine eulogy given in Spokane, Wash., by a close friend reveals that the eight years spent in Australia by Dr. Mead, were not all a bed of roses:

"He advised the Government that its primary need was not one of more stored water and canals to carry it to the land, but a supplanting of large wheat and sheep ranches with group settlements and the creation of a type of agriculture best suited to irrigation, thus laying the foundation for a program of planned rural development and aided and directed settlement that might well serve as a pattern for the rest of the world. It is interesting to note that upon the completion of this work, the town whose leading newspaper had denounced the 'foreign interloper' requested and obtained the privilege of giving the official banquet to the departing engineer.

"Upon returning to the United States in 1915, Doctor Mead resumed his teaching at the University of California, becoming Professor of Rural Institutions. He also served as Chairman of the California Land Settlement Board, created by the State for the purpose of giving deserving and qualified persons assistance in acquiring small and improved farms and to demonstrate the value of adequate capital and organized direction in preparing agricultural land for settlement."

The years succeeding the launching of these two State colonization projects were most unpropitious for land settlement of either State or private character, both classes failing to meet the expectation of their promoters. The blame for the disappointing aftermath of the State enterprises was laid entirely upon Dr. Mead, and was courageously assumed by him, although he was only one on a board of several prominent and "hard-headed" citizens of the State the other members of which also believed in his land-settlement policies.

In a conversation with a friend during 1935, Dr. Mead expressed the belief that, in regard to the unfortunate land-settlement projects in California, the future would demonstrate that it was a case of the "stone rejected by the masons."

Dr. Mead had firm friends among the Jewish philanthropists back of the Zionist movement in New York, N. Y., London, England, and Paris, France.

He was most unselfish, lived a life of service in the interests of his fellow men, and literally "died in harness." He was a man of the highest integrity, and although the Commission and the Bureau of which he was in charge for so many years at home and abroad were engaged in vast projects, involving the expenditure of scores of millions of dollars, during his incumbency of office, his own high sense of honor and that of his many loyal assistants have been such as to leave a spotless record.

All engineers are proud when outstanding men in their profession leave such records of integrity. The personnel of the Reclamation Service especially can take great pride in this record as from the inception of the Bureau it has been in charge of men of similar high character. Dr. Mead and his predecessors in office have left a wonderful heritage which will be an inspiration to future successors and to all employees of the U. S. Bureau of Reclamation.

Dr. Mead was elected a Member of the American Society of Civil Engineers on June 7, 1893. He served as a Director of the Society from 1903 to 1905.

FRANK HOWARD NEFF, M. Am. Soc. C. E.[1]

DIED OCTOBER 11, 1936

Frank Howard Neff was born in Cleveland, Ohio, on July 30, 1865. His parents were William A. and Eliza (Mong) Neff, well known and highly respected citizens of Cleveland, whose homestead at the corner of 105th Street and Carnegie Avenue, was long a landmark.

His early education was acquired at the Cleveland Public Schools; he then entered Case School of Applied Science in 1883, and was graduated therefrom with the degree of Bachelor of Science in 1887. The degree of Civil Engineer was conferred upon him in 1892. The Class of 1887 was the third to be graduated at Case and among Mr. Neff's ten classmates were Dr. A. W. Smith, for many years Professor of Chemistry at Case, and Dr. Herbert H. Dow, founder of the Dow Chemical Company. The Civil Engineering Department at Case, at that time was in charge of the late Cady Staley, M. Am. Soc. C. E., of beloved memory, and a close friend of Professor Neff in later years.

Following his graduation, Mr. Neff served for a year as Instructor in Mathematics and Civil Engineering at Case. He then went abroad and studied at the Ecole des Ponts et Chaussées and at the Sorbonne, in Paris, France. Returning to Case School in 1890, he was appointed Assistant Professor of Civil Engineering, under Dr. Staley, who served both as President of the Faculty and as Professor of Civil Engineering at that time. In 1897, he was made full professor, in which capacity he served Case School of Applied Science until his retirement in 1931, with the title of Professor Emeritus of Civil Engineering. At the 1931 Alumni Reunion, Professor Neff was presented with an impressive testimonial of appreciation from the Alumni, which reads as follows:

"Your former students and fellow members of the Alumni Association of Case School of Applied Science wish to present this resolution of appreciation to you, Prof. Frank H. Neff, '87. Your forty-four years of splendid service to this college is an achievement worthy of a lifetime of endeavor.

"The spirit of your teaching has gone into great bridges and towering skyscrapers through the deeds of your students whom you taught to be engineers and men.

"In some measure we hope you can feel that what we do today and tomorrow is made possible by your teaching yesterday.

"We want you to know that we sincerely appreciate the vision and the spirit of unselfishness you possessed in keeping diligently at this task and doing it well."

Desirous of supplementing his teaching with active engineering practice, Professor Neff spent his summers for some years in the field, in charge of a survey party engaged in location work for the Cincinnati Southern Railway

[1] Memoir prepared by Wilbur J. Watson, M. Am. Soc. C. E., largely from data supplied by the Alumni Office of Case School of Applied Science, Cleveland, Ohio.

Company, then as a Structural Designer for the King Bridge Company, of Cleveland, at that time one of the leading bridge companies, and one year as Assistant on sewer construction.

His colleagues long considered two features of his work as outstanding—his unexcelled supervision of design in the drafting-room and his meticulous devotion to detail. These substantial qualities were said to have developed many of the best known engineers in the United States.

Professor Neff was of a quiet and somewhat retiring disposition, the perfect gentleman and scholar, seldom showing anger, always endeavoring to help his students, in his quiet patient way. In addition to teaching, he had served for more than thirty years as Treasurer of the Athletic Association and for many years as Treasurer of *Case Tech*, the student paper.

He was an ardent, although apparently not always successful, hunter and fisherman. He liked to spend at least a part of each summer at the Case Faculty Camp on Tomahawk Island, in Georgian Bay, about twelve miles above Penetanguishene, Ont., Canada ("place of the shining sand"). Perhaps even now in the cold winds that are whistling across Penetanguishene the spirit of this great and faithful teacher, true friend of all Case men, hovers peacefully, awaiting a far-off dawn. Throughout his life, Professor Neff was a faithful member of the Euclid Avenue Congregational Church, in Cleveland.

Professor Neff was a member of the American Railway Engineering Association, the American Society for the Advancement of Science, the Society for the Promotion of Engineering Education, the Cleveland Engineering Society, Cleveland Chamber of Commerce, the University Club, and the Rowfant Club. He was one of the organizers of the Case Chapter of Zeta Psi.

In later years, he became President of the Electric Railway Improvement Company, of Cleveland, manufacturers of electric railway equipment, which office he held at the time of his death.

His wife, Ida (Brown) Neff, died in 1914. Two sons, Frank H., Jr., and Edward B., survive him. Also surviving him are a brother and sister, Mr. H. A. Neff, and Mrs. B. K. King.

Professor Neff was elected an Associate Member of the American Society of Civil Engineers on May 6, 1903, and a Member on March 16, 1925.

EDWARD SHERMAN NETTLETON, M. Am. Soc. C. E.[1]

DIED JULY 23, 1936

Edward Sherman Nettleton was born in New Haven, Conn., on October 24, 1868, the son of John F. Nettleton and Sarah (Peck) Nettleton. He

[1] Memoir prepared by a Committee of the Connecticut Section, consisting of Frederick L. Ford and W. Vincent Barry, Members, Am. Soc. C. E.

was a direct descendant in the eighth generation of Samuel Nettleton who settled in Totoket, later Branford, Conn., in 1644. He was educated in Dwight Public School, of New Haven, the Hillhouse High School, Class of 1890, and was graduated from Sheffield Scientific School of Yale University in 1892, with the degree of Bachelor of Philosophy.

At Yale he took the course in Civil Engineering under the late Augustus Jay DuBois, M. Am. Soc. C. E., and in Military Science and Tactics under Lieut. Charles Totten, U. S. A.

After his graduation from Yale, Mr. Nettleton traveled in Europe for three months and on his return was first employed at Fort Wadsworth, Staten Island, New York, on Government fortification work. His next job was in Waterbury, Conn., where, for a short time, he was connected with the construction of a pipe line for the new city water supply. From April, 1895, to April, 1896, he was engaged as a Draftsman for Purdy and Henderson, Structural Engineers, in New York, N. Y.

In 1896, Mr. Nettleton returned to New Haven, where he entered the employ of the Department of Public Works as a Transitman in the Bureau of Engineering. After many years of experience in municipal engineering, and upon the resignation of City Engineer Frederick L. Ford, M. Am. Soc. C. E., Mr. Nettleton became Acting City Engineer of New Haven in May, 1920. On October 27, 1921, he was appointed head of the Bureau of Engineering by the late John J. Lane, then Director of Public Works of New Haven.

During the fourteen years that Mr. Nettleton served as City Engineer of New Haven, a total of \$6 500 000 in bond issues for public improvements, was expended under his supervision, both in the design and in the execution of the various projects involved. To relieve the congestion in traffic at the intersection of Broadway and York Street, his plan for the widening of Grove Street and its extension to Broadway was completed during the administration of Mayor John B. Tower, and the name, Tower Parkway, was given to the new highway beginning at York Street. Mr. Nettleton also planned the relocation of the street railway tracks on Broadway and the present layout of Broadway Parks, resulting in a greatly improved traffic flow through that artery. A present-day comparison of the status of the vicinity of Broadway and York Square, previous to the present layout of Tower Parkway and Broadway, speaks well for the knowledge and foresight with which he conceived and completed this great improvement to the appearance and traffic facilities of the central section of the city.

With the exception of the expenditures for permanent pavements the two major projects during Mr. Nettleton's term of office as City Engineer were the Tomlinson Bridge contracts and the construction of the East Street Sewage Treatment Works. Tomlinson Bridge, opened to traffic in April, 1925, is situated on the Boston Post Road, U. S. Route No. 1, crossing New Haven Harbor, and is of the Strauss trunnion bascule type, with approach spans and causeway. The cost to the City in bond issues was \$1 150 000. The East Street Treatment Works is a gravity-flow plant.

consisting of mechanical screens, grit chamber, three sedimentation tanks, and sludge disposal by barging to deep water in Long Island Sound. Operation of this plant which has a maximum capacity of 30 000 000 mgd and cost about $725 000, was begun in January, 1931. The execution of these contracts and the economical expenditure of the funds appropriated were under Mr. Nettleton's supervision as head of the Bureau of Engineering.

By an Act of the Connecticut Legislature, in 1921, the Mayor of New Haven was authorized to appoint a commission to write a zoning ordinance for the city and, in the same year, such a commission was appointed. City Engineer Nettleton was made a member of the Commission and acted as Secretary. Through an entire summer, public meetings were held for the benefit of citizens in every ward of the City and the details of the zoning district boundaries were developed on section maps of the city furnished by the Bureau of Engineering. It was not, however, until December, 1926, that the present ordinance was finally adopted on petition to the Board of Aldermen, by the City Plan Commission.

On June 4, 1901, he was married, in West Haven, Conn., to Elizabeth Hyndman, the daughter of William Hyndman, of Ketchum, Idaho. Their children are John Edward, of Milford, Conn., and Elizabeth (Mrs. P. Starr Cressy), of Malden, Mass. Besides the members of his immediate family, a brother, George Nettleton, and three grandchildren survive him.

After his marriage, Mr. Nettleton established his home on Townsend Avenue, in the 32d Ward of New Haven, and soon became identified with the community life of that neighborhood. An organization, called the Fairmont Association, was formed by the taxpayers in the Ward to raise funds for police and fire protection, and Mr. Nettleton was elected the first Clerk and Treasurer of the organization and served until 1922. As a member of the Church of the Epiphany (Protestant Episcopal), on Forbes Avenue, he served as Vestryman, Treasurer of the Church, and teacher in the Sunday School. A local newspaper well summarized his character in these words;

> "Besides a (career man) civil engineer he was a Churchman. Long a Sunday School teacher and Vestryman, he demonstrated solid spiritual, as well as practical engineering, qualities. Rather reserved by nature, he was nevertheless gracious in his co-operation with all who sought it and he will be missed at City Hall where he worked so long and in the community with whose physical development he was so long associated."

At the time of his death Mr. Nettleton was Secretary of the City Plan Commission of New Haven, a member of the Chamber of Commerce, and a Director of the Elm City Building and Loan Association. He was a member of the Connecticut Society of Civil Engineers, the American Road Builders Association, the American City Planning Institute, and the Graduate Club of New Haven.

Mr. Nettleton was elected a Member of the American Society of Civil Engineers on April 12, 1926.

GEORGE ISRAEL OAKLEY, M. Am. Soc. C. E.[1]

Died November 6, 1936

With an abiding loyalty to his country, his family, his many friends, his profession, George Israel Oakley died as he had lived, beloved by all for his sterling character. His death came as a shock to every one; and, in his passing, the profession lost a skillful technician, one with a quiet genius for organizing the many details of large engineering projects, one with the true spirit of craftsmanship, in a word, an engineer of the highest type. That he had chosen Civil Engineering as his profession is clear evidence of the disposition of his mind and heart; but a great deal of his work had to do with the installation of intricate mechanical details as part of the project as a whole. He would have been equally successful in any engineering field because of his scientific approach combined with the practical viewpoint which, due to his wide experience, he was able to bring to bear on each task assigned to him. That he performed those tasks with a high degree of ability and conscientious application is testified to by his associates on each job.

When he died, Mr. Oakley was in his 59th year, having been born on August 14, 1878, in Roslyn, Long Island, N. Y. He was the son of Charles Oakley and Lydia Ann (Ludlam) Oakley. He attended the elementary school at East Williston, Long Island, and entered the Jamaica High School, at Jamaica, Long Island, from which he was graduated in 1898. He then entered Union College, at Schenectady, N. Y., graduating with the degree of Bachelor of Engineering in 1902. While at college, he received a stage appointment, was a member of the Union Engineers' Club, the track team, and played class football and baseball.

After graduating from Union College, from 1902 to 1903, Mr. Oakley was, successively, a Transitman on the Baltimore and Ohio Railroad on Maintenance of Way and New Construction; an Assistant Engineer, with the New York and Long Island Traction Company, in charge of a field party on location surveys of 20 miles, and 5 miles of construction of interurban electric railway; a Transitman on a topographic survey on the Sacandaga River, above Northville, N. Y.; and he made an assessor's map for Nassau County, Long Island, of farm and village property remaining in the Town of North Hempstead, after the changes in boundary line, due to the formation of the new County of Nassau.

From 1903 to 1904, Mr. Oakley worked as Rodman for the Rapid Transit Subway Construction Company of New York, N. Y., and was engaged in checking bids for extra work and making formal reports on them. He was also engaged in checking monthly estimates, and in charge of construction work in the Lenox Avenue car storage yard and repair shops, in New York City.

---

[1] Memoir prepared by Thomas K. A. Hendrick, Assoc. M. Am. Soc. C. E.

From 1904 to 1905, he was employed by the Borough of Queens, New York City, in charge of a field party on triangulation surveys in that Borough and the relocation of street-line monuments.

From August, 1905, to 1915, Mr. Oakley was with the Department of New York State Engineer and Surveyor, for 7 yr as Assistant Engineer, and for $2\frac{1}{2}$ yr as Resident Engineer, on the New York State Barge Canal System. As Assistant Engineer, he was in responsible charge of parties on base line, center line, topographical surveys, land appropriation surveys, rock borings, land and river drive-rod soundings, and general studies for the canal prism and structural location of 30 miles of the canal through the Mohawk River Valley. He also established a line of gages on the river for the measurement of stream flow and especially for ascertaining the heights and the duration of normal and extreme high waters in the river. Pipe wells were driven and water levels obtained along various sections to obtain information for studies on the ground-water movements, especially as affected by floods in the river. Later, he was in responsible charge of construction work on Contracts Nos. 10, 18 and 30 (value \$2 500 000) which consisted of canal locks, guard-gates, fixed and movable dams, six fixed bridges and seven lift bridges, culverts, retaining walls, earth and rock excavation, dredging, etc.

As Resident Engineer, Mr. Oakley had full and responsible charge of Residency No. 4; 25 miles of canal, at Little Falls, N. Y.; contracts to the value of \$5 000 000; general supervision of all construction work, reports, and recommendations on new work; estimates for monthly and final payments to contractors; and the preparation of plans for the canal prism and incidental structures. The force of men under him varied from 25 to 75. He made formal reports on all claims for land appropriation and damages from canal construction. On one particular claim for water damages in the Village of Herkimer (10 000 inhabitants), alleged to have been caused by the changes in the river channel, Mr. Oakley took an important part in the hydraulic and hydrological studies necessary for the preparation of the defense and in giving expert testimony before the State Court of Claims. The case was subsequently decided in favor of the State in that it was not liable for the alleged damages.

From January to April, 1915, he was Engineer for the Acme Engineering and Construction Company, at Herkimer, N. Y., in charge of special investigations; and from May, 1915, to October, 1917, he was City Engineer for Little Falls, N. Y. He was Executive Officer of the Board of Public Works and Chief Engineer of the Little Falls Water-Works, a \$500 000 plant, consisting of four reservoirs, slow sand filter, 20 miles of transmission and distribution mains, chlorine purification plant, distribution system, and meter system. He was in responsible charge of all design, construction, and maintenance of streets, pavements, bridges, sewers, parks, cemeteries, and the water-works system. During his term, he completed \$300 000 worth of work. His city force consisted of from 50 to 75 men of different grades. Aside from his duties with the Board of Public Works,

the City Engineer was the Consulting and Advisory Engineer for the Mayor and the Common Council.

As City Engineer, Mr. Oakley recommended to the Board of Public Works the following improvements which were made under his direction and supervision: Purchase of additional land for sanitary protection of the water-shed; a general yearly plan for the reforestation of the cleared land on the water-shed; the rebuilding of a $\frac{3}{4}$-acre sand filter; the installation of a liquid chlorine plant for sterilizing all the water used in the system; and a general plan for the conservation of the water supply by the installation of Venturi water meters; water waste surveys; and the general installation of domestic and industrial water meters throughout the city. He made topographical surveys, and had measurements taken of the quantity of water from various springs and streams; he had rainfall records tabulated and made into usable data in that two United States Government Weather Bureau stations were located on City property and read daily by men in the City Engineer's Office. Other general information was collected and studies were made for possible future extensions.

From November, 1917, to 1919, Mr. Oakley was with Henry A. Van Alstyne, M. Am. Soc. C. E., in responsible charge of the design and supervision of the reconstruction of a 20-in. hydraulic dredge and other general engineering work connected with dredging contracts in Boston, Mass., and New York, N. Y., harbors. He also worked for the late Patrick McGovern, Affiliate, Am. Soc. C. E., of New York, on the construction of a compressed air and open rock tunnel under the East River at 60th Street, in New York City. He then became Assistant Superintendent on the construction of the open caisson foundation piers for the Boston Army Supply Base, which building was 120 by 1 500 ft.

From February, 1919, to January, 1922, Mr. Oakley was with the Guarantee Construction Company, in responsible charge of various contracts in Virginia, New York State, and Massachusetts. From September, 1922, to September, 1930, he was with the J. G. White Engineering Corporation as a Designing Engineer in the Hydraulic Department. From September, 1931, to December, 1932, he served the Board of Water Supply, City of New York, as Assistant Engineer, Grade 4. From December, 1933, to February, 1935, he was with the Public Service Commission of the State of New York in valuation and appraisal work. From February to July, 1935, he was with the Corps of Engineers, United States Army, 1st District, New York City, as Assistant Engineer on special design work for the improvement of the Winooski River, in Vermont. From July, 1935, to the time of his death, Mr. Oakley was an Assistant Engineer with the Department of Sanitation, City of New York, and had charge of important design work in connection with the vast new sewage disposal system of that city.

During the last few years of his life, Mr. Oakley acquired the site for his new home at 49 Crescent Road, Beacon Hill, Port Washington, Long Island. He himself made the plans and supervised the actual building of this new house, a model home in every respect. It was like one of his

hobbies to him; and of these he had many, such as a woodwork bench, machine shop work, about a dozen experimental radios, collections of rocks and minerals and miscellaneous firearms, antique and modern, along with his zeal in spending many hours on auto-mechanics. He took a great interest in describing various intricate points on how and why "the wheels went round"; and the care with which he kept his extensive engineering library was known only to his intimates. In the recreation room of his new home, he took great delight in entertaining informally his valued friends.

Mr. Oakley is survived by his widow, the former Vera Forrest Chapman, daughter of the late B. E. Chapman, of Little Falls, N. Y., to whom he was married on February 10, 1910, their son, Alan C., and one sister, Mrs. U. G. Williams, of Newport, N. Y. He was buried on November 9, 1936, in the family plot at West Hills, near Huntington, Long Island, where his parents and grandparents are also buried.

He was a Licensed Professional Engineer and Land Surveyor of the State of New York. He was a Mason, a member of Morton Lodge, No. 63, F. and A. M., of Hempstead, Long Island, having been raised September, 23, 1901; Astorogan Chapter, Royal Arch Masons, and the Little Falls, N. Y. Commandery, Knights Templars, of which he was also a Past Commander in 1915–1916. In addition, he was a member of the Central City Syracuse Scottish Rite Bodies, having been created a Thirty-second Degree Mason, and a member of Ziyara Temple, A.A.O.N.M.S. Funeral services were conducted by the Knights Templars, Noble George Willcox of Little Falls, N. Y., officiating.

Mr. Oakley was elected a Junior of the American Society of Civil Engineers on October 6, 1903; an Associate Member on November 6, 1907; and a Member on June 20, 1922.

VINCENT PHILLIP ODONI, M. Am. Soc. C. E.[1]

Died August 9, 1936

Vincent Phillip Odoni was born of Swiss parentage in Lucerne, Switzerland, on May 28, 1879. He received his schooling in Lucerne, where he attended the primary and High Schools preparatory to his enrollment as a student in the Swiss Polytechnic University, at Zurich, from which he was graduated with the degree of Civil Engineer in 1904.

The first years of Mr. Odoni's engineering practice were spent in Switzerland, where he was associated first with Colonel F. von Schumacher, of Lucerne, in the design and estimates of cost for water supply systems, hydro-electric plants, and cable railroads, and, subsequently, as Construction Engineer with the Chemin de Fer Electric de la Gruyere, Bulle, Canton de Fribourg. His last engagement in Switzerland was as Construction Engineer with the Government Railroads at the depot in Basle.

[1] Memoir prepared by A. L. Sonderegger, M. Am. Soc. C. E.

In 1907, Mr. Odoni came to the United States and found employment in Los Angeles, Calif., with the writer, in the design and construction of works for water supplies and irrigation. He was also in charge of dredging and jetty construction in Long Beach, Calif., Harbor.

In 1909, Mr. Odoni moved to Denver, Colo., to take employment with the Central Colorado Power Company in the design and estimates of cost for structures for the Boulder and Shoshone Power Plants. He was in charge of construction of the Fall River Power Plant, near Idaho Springs, Colo. The year 1910 and part of 1911 found him associated with the Field, Fellows, and Hinderlider Engineering Company, of Denver, his work including the investigation, design, and estimates for irrigation systems, dams, hydro-electric power development, etc., and, in the latter part of 1911, the construction of the outlet system of the Lyman Dam, in Arizona.

A new chapter in Mr. Odoni's life opened with his removal to Tuscon, Ariz., where he remained as Chief Engineer of Tucson Farms Company from the inception of this project until its completion in 1917. The water development connected with this enterprise included extensive studies of the movement and yield of ground-water supplies and of the economic production thereof on a very large scale. The full development of the project saw more than eighty well-pumping plants in operation and a successful irrigation enterprise "in full swing" in a semi-arid region.

The gigantic project of the Miami Conservancy District lured Mr. Odoni to Dayton, Ohio, where he remained until 1918 when he joined the United States Navy. During the two years following, he served as a Lieutenant in the Civil Engineering Corps and Project Manager of the Marine Corps Base, at San Diego, Calif. With the completion of this work, he returned to Tucson as Chief Engineer and Vice-President of the Tucson Farms Company, in charge of its irrigation system.

A new episode in Mr. Odoni's experience began in 1923 when he accepted the position of Chief Civil Engineer with the Haytian-American Sugar Company, at Port au Prince, Haiti. This position allowed full sway for his engineering ability. The work included the drilling and equipping of irrigation wells, the development of water and of irrigation systems for new cane plantations, the operation of steam and electric irrigation pumping plants, the construction of bridges, residences, pipe lines, and wharves for molasses delivery to tankers. He was also charged with soil studies and drainage systems for a number of plantations which suffered from high alkali and from high-water plane.

Engineers who have found themselves in remote areas, thrown upon their own resources, responsible for the construction, maintenance, and operation of a multiplicity of plants and structures, and called upon to meet emergencies of widely differing character with unskilled labor, will appreciate the ability required to fill such a position.

During his residence in Tucson, Mr. Odoni met and married Olive Haugen, who accompanied him to Haiti, making it possible for him to enjoy the comforts of a home in an otherwise lonely existence. He left

the employ of the Sugar Company in 1931 because of ill health, and returned to California.

After his return to California, his health continued to fail and for five years his life was one of sickness and suffering. The supreme patience with which he bore his long illness was exceeded only by that of his loving wife who devoted her energies and efforts to the comfort and aid of her husband. Being exceedingly fond of music, Mr. Odoni found solace in the excellent programs which the radio offered. His interest in engineering science and his studies in art remained active during the years of his illness and served to alleviate his sufferings.

He was an engineer of ability, having the capacity for original research and yet being able to adapt himself to circumstances and conditions, and to master the innumerable problems that present themselves to an engineer in general practice.

Mr. Odoni was elected an Associate Member of the American Society of Civil Engineers on April 4, 1911, and a Member on January 18, 1916.

MILNOR PECK PARET, M. Am. Soc. C. E.[1]

DIED AUGUST 16, 1936

Milnor Peck Paret was born in Pierpont Manor, Jefferson County, N. Y., on June 17, 1857. He was the son of William Paret and Maria G. (Peck) Paret. His father, who was of French parentage originating in Servillac, France, was born in New York, N. Y., on September 23, 1826. He was educated in the graded schools of New York City, and in Hobart College, Geneva, N. Y. In 1884, he was elected and ordained a Bishop of the Protestant Episcopal Church in the Diocese of Maryland and lived at Baltimore until his death, on January 18, 1911. His mother was of English parents, who resided in Flushing, Long Island, N. Y.

Mr. Paret was educated in the public schools of Elmira, N. Y., and the High School, of Williamsport, Pa. He was graduated from Lehigh University, in Bethlehem, Pa., in 1878 with the degree of Civil Engineer. He was a member of the Sigma Phi Fraternity. While at Lehigh he took an active part in college athletics being a member of both the baseball and the track teams.

Following his graduation in 1878, Mr. Paret spent a year traveling in Europe inspecting engineering works, and particularly the docks and terminals at Liverpool, England, and the railroad, tunnel, and highway construction in Switzerland and Italy.

On his return to the United States, he was employed (1879–1882) as Assistant Engineer under the late General W. P. Craighill, Chief of Engineers, U. S. Army, Hon. M. Am. Soc. C. E., on James River channel

[1] Memoir prepared by R. A. Thompson, M. Am. Soc. C. E.

and harbor improvements and fortifications and also on the Chesapeake and Delaware Ship Canal. For some time he was detailed to make reports and hydrographic surveys relating to projected jetty and harbor work at principal points on the Georgia and Florida coasts.

Mr. Paret engaged in private practice under the firm name of Paret and Farquhar, in Baltimore, in 1882–1883, and built a number of water-works and sewerage systems. He also designed and erected, in Baltimore, the first bicycle track built in the United States along scientific lines for racing purposes.

From 1883 to 1887, he served as Assistant Engineer in charge of the location and the heavy construction of the Pennsylvania Lines both East and West of Pittsburgh, Pa. He designed and built several important bridges for this Company, among others, a number of large spiral stone arches.

In 1888, Mr. Paret joined the Engineering Forces of the Kansas City Southern Railway Company, which was then being promoted and built by Mr. Arthur E. Stillwell, as the "Kansas City, Pittsburgh and Gulf Railway", from Kansas City, Mo., to Port Arthur, Tex., on the Gulf of Mexico. As Resident Engineer and Assistant Chief Engineer under the late Robert Gillham, M. Am. Soc. C. E., he located and built several sections of this railway in Indian Territory and Arkansas, and, later, the lower section in Louisiana and the terminals at Lake Charles. He made a special investigation for Chief Engineer Gillham of the feasibility of constructing a ship canal from Sabine River to Port Arthur, and it was upon his favorable report presented to the Secretary of War by Mr. Gillham that this outstanding improvement was authorized and built.

In 1901, Mr. Paret became Chief Engineer of the Kansas City, Mexico, and Orient Railway, which was then being promoted by Mr. Stillwell and his associates, as the short route from Kansas City to tidewater at Topolobampo Bay, on the Pacific Coast, *via* Wichita, Kans., San Angelo, Tex., and Chihuahua, Mexico. He built several hundred miles of this railroad from Wichita to Alpine, Tex.; east and west out of Chihuahua; and from Topolobampo Bay east to the foot of the Sierra Madre.

He resigned in 1909 to form a partnership with Mr. E. J. Beard as Consulting Engineers (Paret and Beard) in Kansas City, specializing in railroad, and hydro-electric and general engineering practice in the West. During this time, Mr. Paret served as Chief Engineer of the Utah Railway Company, in Salt Lake City, Utah, and the Utah and Grand Valley Railway—an electric line.

In 1914, he was appointed District Engineer by the Interstate Commerce Commission on railroad valuation work in the Pacific District, with headquarters at San Francisco, Calif. The engineers of this District made an inventory and reported on the value of about 56 000 miles of main-line railroad west of the Mississippi River. In 1917, he returned to Lake Charles, La., to manage the estate of his deceased father-in-law, Captain George Lock, a wealthy lumberman and land-holder. In 1920, when this estate was liquidated, Mr. Paret again entered private practice at Lake Charles as a Consult-

ing Engineer, specializing in railroad, irrigation, and land practice. He remained at Lake Charles until his death.

In 1898, Mr. Paret was married to Letitia Lock, daughter of Captain Lock, of Lake Charles. His widow and sons, Milnor Peck, Jr., and George Lock, and his daughters, Irene and Helen, survive him.

Mr. Paret was a member of the Protestant Episcopal Church and served as a Vestryman of his Parish for many years. At the time of his death he was a Director in the First National Bank, Edgewood Land and Logging Company, and Swift Coal and Timber Company, all of Lake Charles. During the World War, he was Chairman of the Council of Defense for Calcasieu Parish, Louisiana.

During his life, he wrote extensively on engineering subjects for many technical journals. He was the author of a number of articles on railroad location, track, tunnel construction, and similar subjects, among which was a series of highly technical papers written by him for *Engineering News,* from 1883 to 1887, while he was Engineer for the Pennsylvania Lines, describing the design and construction of a number of oblique stone arches which he built for this Company. These papers have since been accepted as the authority on this subject.

Through his long years of active service in his profession, Mr. Paret was regarded as an outstanding member of the Society, a man of high technical attainments, and an engineer of broad and successful experience. He was an able executive and a sound counselor. These qualifications in 1913 under the Civil Service tests given by the Interstate Commerce Commission for Senior Railroad Valuation Engineer for the United States at large, gave to him the highest rating among approximately 7 000 engineer competitors who also took the examination.

He was beloved and respected in the highest degree by his numerous friends and by his associates in professional as well as in public life. He was a kind husband and father, a patriotic citizen, and always gave freely of his time and energy to the welfare and civic organizations of the communities in which he lived.

Mr. Paret was elected a Member of the American Society of Civil Engineers on September 2, 1885. He was also member of the American Railway Engineering Association.

JAMES EDWIN PARKER, M. Am. Soc. C. E.[1]

DIED FEBRUARY 24, 1934

James Edwin Parker was born in Birmingham, Ala., on December 22, 1884. He was the son of Thomas F. and Nannie (Barker) Parker, pioneer residents of Birmingham. He received his education in the public schools of his home

[1] Memoir prepared by O. G. Thurlow, M. Am. Soc. C. E.

town before entering Howard College from which he was graduated in June, 1903, with the degree of Bachelor of Civil Engineering.

Mr. Parker began his practical experience in 1901 as Rodman with the Tennessee Coal, Iron, and Railroad Company. He worked with this Company as Draftsman and Instrumentman until January, 1904, when he became connected with the Southern Railway Company. From 1904 until 1907, he held positions with that Company and with the Seaboard Air Line Railway Company as Resident Engineer in charge of the construction of various spurs and other railroad work.

He spent the years, 1911 and 1912, with the late James Nisbet Hazlehurst, M. Am. Soc. C. E., as Resident Engineer in charge of the design and construction of a water-works and sewerage system for Kirkwood, Ga.—a $100 000 job—and at Key West, Fla., in charge of street paving, where 250 000 sq yd of vitrified brick and asphalt block pavement was built.

From 1912 to 1919, Mr. Parker was Principal Assistant Engineer of the River and Canal Commission, of Augusta, Ga., under the late Nisbet Wingfield, M. Am. Soc. C. E., Chief Engineer. As such, he designed a large part, and was in full charge of the entire construction, of a $2 000 000 flood-protection project at Augusta. The work consisted chiefly of: 11 miles of earth levee: 25 000 cu yd of reinforced concrete in flood-control bulkheads, gates, and retaining walls; raising two highway bridges over the river and building a new 110-ft span, combined street railway and highway; moving and rebuilding warehouses, factories, residences, railway yards, and terminals; the complete re-arrangement and construction of the entire sewerage system of the city, with numerous street changes, etc.; the construction of a modern steamboat terminal and warehouse; bank protection, paving, etc. During and after its construction this work was inspected by prominent consulting engineers, including the United States Board of Engineers for Rivers and Harbors, and was pronounced by all to be the equal of any similar work with which they were familiar.

This project was designed and built to protect the City of Augusta, and the adjacent territory from floods of the Savannah River. Since its completion it has successfully withstood several severe floods and has proved beyond question its value, having saved the community from damage considerably more than its cost.

Mr. Parker became Assistant Engineer, United States Civil Service, at Birmingham, in 1919, and worked with the writer who was Consulting Engineer for the Government, on the design of the Wilson Dam and Power House, at Muscle Shoals, Ala. After the completion of this project he was retained by several different municipalities in the design of waterways and sewerage systems and in flood-protection projects.

In September, 1920, Mr. Parker became associated with the Alabama Power Company as Assistant Engineer to the Chief Engineer, at Birmingham, and from that time until his death, in 1934, he was actively engaged in the work carried on by that Company. He designed and supervised the construction of a coal-handling and washing plant, at Gorgas, Ala., with a capacity of 120

tons per hr, and spent many years on the design of dams and hydro-electric power-plant developments.

Mr. Parker was a man of unusual ability and character. He stood high in his profession, taking a keen interest in every task and giving meticulous care in preparing and carrying out any work in which he was engaged. He was well liked by all who knew him and left a host of friends who sincerely regretted his death.

He was a member of the Alabama Technical Association, Sigma Nu Fraternity, and of the Masonic Fraternity.

He is survived by his widow, Mrs. Mary (Jones) Parker, and several brothers and sisters.

Mr. Parker was elected an Associate Member of the American Society of Civil Engineers on October 1, 1913, and a Member on August 28, 1922.

WALTER CAMP PARMLEY, M. Am. Soc. C. E.[1]

Died February 19, 1934

Walter Camp Parmley was born about twenty-five miles south of Madison, in Rock County, Wisconsin, on December 8, 1862. He was the son of Russel and Lucy E. Parmley, of New England Colonial ancestry. After his preparatory education, he entered the University of Wisconsin in 1883 and was graduated from its Civil Engineering Course in 1887.

Immediately after his graduation from college, Mr. Parmley went to California and opened an office in San Bernardino to practice as a Civil Engineer in a partnership, under the firm name of Parmley and Finkle. The firm was immediately successful. The work included surveys of important projects and the construction of the Jurupa Canal and the Vivienda Pipe Line, together with other irrigation systems. In 1889, Mr. Parmley accepted the position of Assistant Engineer on the Bear River Canal Project, in Utah, and the construction of a part of the Ogden City Water-Works, involving an expenditure of about \$300 000. In February, 1891, he became City Engineer of Ogden. It was here that he first became directly interested in water supply and sewer construction.

In 1893, it became necessary for him to relinquish this work and return to his home in Wisconsin. While there, he designed and laid out a system of sewers for the Village of Elkhorn. Later, he went to Peoria, Ill., and, as an Assistant in the Engineering Department of that city, designed and directed the construction of sewers costing more than \$800 000. He opened an office for private practice in 1895 and, in that connection, designed a sewerage system and chemical precipitation disposal plant for Kewanee, Ill.

In May, 1896, Mr. Parmley became Assistant City Engineer in the Department of Special Sanitation, in Cleveland, Ohio, and had an important part in

[1] Memoir prepared by C. T. Purdy, M. Am. Soc. C. E.

devising the sewer plans covering a large part of that city. He also assisted in the design of the Walworth Run Sewer with its intercepting sewers, and had charge of its construction.

The work in Cleveland, with its many responsibilities, continued until 1903. In connection with this work, he made an extensive study of the flow of water over weirs. The results of this study were embodied in a discussion[3] of the paper presented to the Society, in 1900, by the late George W. Rafter, M. Am. Soc. C. E., relating to the flow of water over dams. He also discussed other papers presented to the Society on similar subjects.

During this period, Mr. Parmley also began a study of the reinforcement of concrete used in sewers, sewer pipes, and tunnel construction. It involved an examination of the different kinds of soils and other loads to which they are subjected, the amount and character of the pressure produced, the stresses that are caused thereby, and exactly where and how such underground structures should be reinforced to secure the best results and, at the same time, an economical construction. He probably made the most thorough analysis of this subject that had been undertaken up to that time. The investigation also involved the derivation of various formulas for the determination of the stresses and the reinforcement required.

In this connection Mr. Parmley designed concrete blocks for use in the construction of large sewers, instead of brick or massive concrete material, the blocks forming segments of a circle, with special provisions for their reinforcement.

He also served in a consulting and designing capacity for the Water Supply Tunnel which was constructed in Cleveland during this period. It was 10 ft in inside diameter, about 3 miles long, and made of reinforced concrete block construction. Before leaving Cleveland he designed sewers in Columbus, and in Sandusky, Ohio, in which his improvements in reinforcement were used.

In 1904, Mr. Parmley opened an office in New York, N. Y., as a Consulting Engineer. This marked the end of a distinct period in his life and the beginning of another for which the first one had particularly fitted him.

Before he came to New York he was an employed engineer, working most of the time for some city or other interest. He was governed by their activities, he went where they required him to go, and he did what they called upon him to do. In a measure, they absorbed his life. For sixteen years it was substantially a continuous drive with an increasing responsibility with each new engagement. After he opened his office, these conditions gradually changed. It was the end of his moving about from one place to another. He established his home in Montclair, N. J., and it remained there. He was able to arrange his activities better.

His knowledge of sanitation, his ability to analyze unusual structural problems, his mathematical proficiency, and the breadth of his experience, eminently fitted him to serve as a counselor and designer for difficult and important projects.

For a considerable time Mr. Parmley's work called him to all parts of the Eastern, Middle, and Southern States, and concerned many undertakings

[3] *Transactions*, Am. Soc. C. E., Vol. XLIV (1900), p. 346.

in sewer construction. During these years, he continued his research work and the study of new and better forms of construction. He devised new methods of computations and new formulas relating to them.

He was greatly interested in the construction of the vehicular tunnel under the Hudson River, between New York City and New Jersey[3]. Of his own initiative he executed a design for the tunnel to be made entirely of a concrete segmental block construction instead of a cast-iron lining, which received much commendation.

Mr. Parmley's most valuable research work was done during the last years of his life. It pertained to the making of large concrete pipe conduits capable of carrying water satisfactorily under great pressure. Concrete pipes had been used mostly for drainage and sewer construction. For such uses they are not subject to outward pressure. When they have been used to carry water, the interior pressure has been relatively low. It was Mr. Parmley's purpose to design a concrete pipe that could be used for any requirement and thus give such construction a much greater range of usefulness.

The shrinkage of ordinary reinforced concrete pipe in the making causes a compression in the reinforcement and tension in the concrete, so that hair-cracks are likely to occur. When the pipe is put in place in the ground, the load of earth over it may add to the tension in the concrete, and when the pipe is filled with water under pressure the tension is materially augmented, hair-cracks are increased and enlarged, the pipe leaks, and the water is wasted. Ordinary reinforcement does not prevent it.

Mr. Parmley surmounted these difficulties by coating the reinforcement with a preparation that prevents the concrete from adhering to it. This alone overcomes the initial difficulty. The shrinkage occasions no stress in either material and the hair-cracks due to shrinkage are avoided. He provided nuts for the ends of the reinforcement rods, which were set in iron boxes buried in the concrete. The pipe is pre-stressed by tightening these nuts, putting tension into the rods and compression into the concrete. When the pipe is filled with water the outward pressure reduces the compression in the concrete as it increases the tension in the reinforcement rods.

To make this a practical development, Mr. Parmley studied every detail of the design, every possible reaction that could occur, and the machinery and methods that might be used in its manufacture. These factors were studied critically from the standpoint of cost, in order to keep the construction as economical as possible. To make sure that he had succeeded in his purpose, three sizes of large pipe, taken direct from the factory, were turned over to Purdue University, at Lafayette, Ind., to be thoroughly tested. The results were published by Purdue University[4] shortly after Mr. Parmley's death.

In all his investigations Mr. Parmley's developments followed mathematical analyses. In many cases his calculations went far afield, and resulted in new working formulas. Testimony from Purdue University, regarding the pre-stressed pipe, is to the effect that it is evident that Mr. Parmley's mathematical treatment of it was sound and that it betrayed his analytical

[3] *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–1920), p. 459.

[4] *Research Bulletin No. 46*, Purdue Univ., May, 1934.

ability and the correctness of his fundamental ideas. Pre-stressed pipe provides a new use for concrete, and a new method of designing long water conduits for the supply of cities and for penstock construction. Sometimes, it may be used to great advantage instead of iron or heavy masonry.

Mr. Parmley's acquaintance among engineers was extensive and his interest in the Society was maintained throughout his professional career. Many years ago, he was made a member of a commission in Essex County, New Jersey, his home county, for the extermination of mosquitos. He was particularly fitted for this undertaking, and his contribution to the work was noteworthy. In later years, he served as President of this Commission.

In 1889, two years after he was graduated from the University of Wisconsin, Mr. Parmley was married to Rose A. Webster. Mrs. Parmley and two daughters, Marjorie (Mrs. William Lentz, of Baltimore, Md.), and Florence (Mrs. Roy W. Chesnut, of New York City), survive him.

Mr. Parmley was a member of the Congregational Church and was prominent in its counsels and its activities. He was interested in most matters pertaining to his community. He was an amateur photographer of wide experience and artistic ability. He was very successful in taking color pictures.

He will be remembered longest for his pleasing personality and for his dependability, both in business matters and socially. He was a man of fine character, unassuming, always cheerful, and always kindly. By those who knew him well, he was beloved.

Mr. Parmley was elected an Associate Member of the American Society of Civil Engineers on April 1, 1896, and a Member on June 1, 1898.

HUGH PATTISON, M. Am. Soc. C. E.[1]

Died August 20, 1936

Hugh Pattison was born on August 3, 1872, near Cambridge, Md., the son of John Richard Pattison and Emily (DeValin) Pattison and a descendant from three of the earliest Colonial Maryland families—all early settlers in Dorchester County, namely, the Pattisons, the LeCompts, and the Skinners. Of these, Thomas Pattison first settled in Calvert County, but moved to Dorchester County in 1671. He was Clerk of the Court of Dorchester County and, in 1688, was appointed his Lordship's Attorney for that County. The home farm, about four miles from Cambridge, where Hugh Pattison and his brothers and sisters were born, has been left as part of his estate.

Mr. Pattison attended the McDonogh School for boys near Baltimore, Md., from June, 1883, to December, 1889, with a record as one of the outstanding students in ability and character, very much interested in machine shop work, and excelling as a draftsman. In January, 1890, he entered Johns Hopkins University, at Baltimore for the course in Electrical Engineering

[1] Memoir prepared by Alex McIver, Esq., New York, N. Y.

which he completed in June, 1892, receiving a Certificate of Proficiency in Applied Electricity (P. A. E.) such as all graduates in the Electrical Engineering Course received at Johns Hopkins in those days. In 1927 he was awarded a diploma as Bachelor of Science *Extraordinem*, by the same institution.

During his college vacations, Mr. Pattison worked for the Baxter Motor Company, of Baltimore, as Armature Winder and as Draftsman. After his graduation, he obtained employment in the Equipment Department, at the United States Navy Yard, at Norfolk, Va., and remained there several months in charge of the installation of wiring on three cruisers—some of the earliest, if not the earliest, electrical installation work on American war vessels. Then, with Sprague, Duncan, and Hutchinson, Limited, Consulting Engineers, he was Assistant Engineer in the Baltimore Office of the firm, engaged on the work of preparing plans and specifications and supervising electrical installations in office buildings and on the vessels of the Merchants and Miners Transportation Company. In 1894, he was placed in charge of the construction of the electric plant and all wiring work in the Congressional Library, at Washington, D. C., and after completing this work, stayed on in charge of operation of the plant until 1898.

Mr. Pattison then accepted a position with the Sprague Electric Company as Secretary to the Vice-President and Technical Director, in which capacity, for some time, he followed office work in connection with the first multiple-unit electric-train equipment on the South Side Elevated Railway, in Chicago, Ill., the Brooklyn (N. Y.) Elevated Railway, the elevator equipments on the Central London (underground) Railway, and, later, in charge of installing and testing multiple-unit railway equipments in Brooklyn and in Boston, Mass.

In 1901, he left the Sprague Electric Company to accept a position as Resident Engineer (representing the Consulting Engineer) in charge of the design and erection of a new power plant for the Pennsylvania Steel Company (later, Bethlehem Steel Company), at Steelton, Pa., including sub-stations, high-tension transmission lines, and the lighting and motor equipment in the new shops.

After the completion of the work at Steelton in 1903, Mr. Pattison went with Westinghouse, Church, Kerr and Company, New York, N. Y., as Engineer, and, with that Company, was engaged on the foundation work of the Long Island City Power House and later on the design and installation of electric car equipment and the erection of car inspection shops for the Long Island Railroad Company. After the completion of this work, he was made Assistant Engineer of Electric Traction with the Pennsylvania Tunnel and Terminal Railroad Company and the Long Island Railroad Company, and was placed in charge of the electrification of the West Jersey and Seashore Railroad, from Camden to Atlantic City, N. J. Later, he had charge of the construction and operation of an experimental single-phase, alternating-current, electric railway on Long Island for the purpose of obtaining information about alternating-current equipment to help in deciding the question as to whether direct current or alternating current should be used for the Pennsylvania Railroad tunnel electrification. During 1907, he served as Field Engi-

neer in charge of a series of tests on the West Jersey and Seashore Railroad made by the Pennsylvania Railroad Company to determine whether there were any features in the known designs of electric locomotives which might introduce strains on the track in excess of those exerted by steam locomotives, and to obtain information which eventually would lead to a mechanically satisfactory design of electric locomotive. Side pressures on rails were measured by the impressions made on steel plates by hardened steel balls, with ties of special construction having roller-bearings under the rail supports. High-speed tests were made with different types of steam and electric locomotives.

Mr. Pattison was next appointed Superintendent of Construction (under the Chief Engineer of Electric Traction) in charge of the construction work in connection with the electrification of the Pennsylvania Railroad in the New York Area, including the foundations and the erection of steel transmission-line towers across the New Jersey meadows from Manhattan Transfer through the New York Terminal to Sunnyside Yard, making and erecting reinforced concrete telegraph and telephone lines, all equipment in sub-stations, various electric circuits in the tunnels, station, etc.

After the completion of the Pennsylvania Railroad Terminal in 1911, Mr. Pattison was appointed Electrical Engineer for the Chicago Association of Commerce Committee of Investigation on Smoke Abatement and Electrification of Railway Terminals, in Chicago. He remained in this position in exhaustive studies until the completion of the work in 1915. Then, from 1915 to 1919, he was Electrical Engineer, Superintendent of Inspection (during the World War), and Assistant to the General Manager of the Eddystone Rifle Plant, at Eddystone, Pa.

For the next two years Mr. Pattison was engaged in making studies and analyses of existing steam railroad electrification, including the Chicago, Milwaukee and St. Paul Railway, the Norfolk and Western, the New York, New Haven and Hartford, and the Pennsylvania Railroads and making reports on comparative operating and maintenance costs for the Westinghouse Electric and Manufacturing Company.

During 1921 and 1922, Mr. Pattison served as Electrical Engineer of the Electrification Commission for the Illinois Central Railroad, Chicago, to decide upon plans for and the system of electrification to be used. He was a delegate to the International Railway Congress which met in Rome, Italy, in April, 1922. After the completion of the work of the Illinois Central Railroad Commission, Mr. Pattison spent several months preparing a proposal for the electrification of the Virginian Railway, and, then, from 1923 to 1933, he was Engineer of Electric Traction of the Virginian Railway Company, having general engineering supervision over the electrification work between Mullens, W. Va. and Roanoke, Va., covering power plant, transmission and over-head lines, sub-stations, and locomotives during the construction period, and, subsequently, over the electrical operation.

In 1933, Mr. Pattison accepted the position as Engineer of Car Equipment with the Third Avenue Railway Company, New York City, at the time when this Company was embarking upon a new, extensive program of rehabilitation of cars and equipment. He had charge of the Drafting-Room work

and was responsible for all revisions in car and equipment designs and for new designs. Due to his wide experience, Mr. Pattison was also consulted on the technical side of almost all engineering projects involved in the Mechanical and Building Departments of the Third Avenue Railway Company. His last important work was the supervision of the designs of entirely new light-weight intermediate side-door cars of aluminum alloy and steel alloy, respectively, which may prove to be the ultimate standards to be adopted. He was busily engaged in this work until he went to the New York Hospital, less than a week before his death, for an operation from which he did not recover.

As a man and as an Engineer, Mr. Pattison always commanded the respect and admiration of his associates and of men under him. He was eminently fair and just in all his dealings, always thoughtful and considerate, and always ready with encouragement or help. He became deeply interested in any task or engineering problem which his duties imposed, went about his work in a quiet and unassuming manner, doing what he believed was right, and his example was always a source of inspiration to his co-workers He had a remarkable memory for incidents and details, the gift of expressing his ideas clearly, a keen sense of humor, and, as a conversationalist, was always entertaining.

One of Mr. Pattison's associates in the Third Avenue Railway Company has written about him as follows:

"Hugh Pattison accepted the position of Engineer of Equipment in the Mechanical Department of the Third Avenue Railway Company in June, 1933, just when this particular department greatly needed attention. He brought to the position technical ability of the highest order and a rich background of experience, but, above all, he brought a fine influence in the spirit in which he did his work and in the steadily splendid example which he set. His loss is one that you and I and the world at large can ill afford. There are entirely too few men like Hugh Pattison."

Dr. Cary T. Hutchinson, of the early firm of Sprague, Duncan, and Hutchinson, Limited, with whom, later, Mr. Pattison was associated at different times, has written as follows:

"Long association with Hugh Pattison beginning in 1893 and continuing well through his life saw the development of a man of the highest integrity both personal and intellectual. He never deviated from what he thought was right, no matter how great the pressure upon him might be. His loyalty to friends was unfailing and his modesty was extreme. His engineering knowledge and ability were of the highest order. It will be hard to find his equal. His friends will long remember him."

Mr. Pattison was never married. He is survived by two brothers, Judge John R. Pattison, of Cambridge, Md., for many years a Judge of the Court of Appeals of Maryland, and Mr. James B. Pattison, of Philadelphia, Pa., and by several nieces. Former Governor Robert E. Pattison of Pennsylvania was a first cousin.

He was a member of the American Institute of Electrical Engineers and of the American Society of Mechanical Engineers.

Mr. Pattison was elected a Member of the American Society of Civil Engineers on March 4, 1913.

DWIGHT PORTER, M. Am. Soc. C. E.[1]

DIED FEBRUARY 26, 1935

Dwight Porter was born in Hartford, Conn., on August 28, 1855, the son of James Timothy and Elizabeth Ann (King) Porter. His early education was received in the public schools of Hartford, but before entering college, he was employed in a bank for several years. Entering the Sheffield Scientific School of Yale University, at New Haven, Conn., he was graduated with the degree of Bachelor of Philosophy, the form of degree at that time granted to graduates in Engineering. While a student at Yale, Mr. Porter received a number of prizes, both for excellence in special subjects and for general excellence. He was President of his Class in his Junior year as well as a member of the Class Cup Committee. He served as Vice-President of the Young Men's Christian Association of the Sheffield School. He was also a member of the Colony and the Berzelius Societies.

Following his graduation in 1880, he became a Special Expert Agent of the Tenth United States Census. His work consisted of investigations and reports on water powers of the United States, as follows: (1) The water power of the region tributary to Long Island Sound; (2) the water power of the Hudson River and of Lake George Outlet; (3) the water powers tributary to Lake Ontario and the New York State Canal; and (4) the water powers of the Eastern Gulf Slope.

The reports were very thoroughly prepared, contained much valuable information, and served a very useful purpose for many years. They were, in fact, for at least twenty years after their publication, the outstanding source of information on the water powers of these districts and even to-day are very often consulted for information of value. Mr. Porter was engaged in this work until 1883.

He then became Instructor in Mathematics and Drawing at the Massachusetts Institute of Technology, at Boston, Mass., under Gen. Francis A. Walker, who had recently been appointed President of the Institute after having served as Superintendent of the Tenth Census of the United States. Thereafter Mr. Porter became, successively, Assistant Professor and Associate Professor of Civil Engineering, until 1896, when his title was changed to Professor of Hydraulic Engineering and, in 1914, to Professor of Hydraulic and Sanitary Engineering. He was Head of the course in Sanitary Engineering, one of the established courses in engineering, known as Course XI, from 1909 until his retirement in 1921, when he was given the title of Professor Emeritus. The Faculty elected him Chairman of the Faculty for two successive terms as was then the custom.

[1] Memoir prepared by C. Frank Allen, M. Am. Soc. C. E.

To aid in his teaching, he wrote two textbooks for the use of his students, one on "Hydraulic Measurements," and the other on "Stereotomy," a subject which he taught to the Civil Engineering students for several years.

Professor Porter, however, was more than a teacher in the classroom sense. Students and others closely associated with him thought of him quite as much as a counselor and friend.

His profession was that of Engineering Teaching. This was his main interest. In it, he was painstaking, thorough, and precise. To this work he gave unstintingly of his time and energy and this tended to restrict, in some degree, opportunity for the exercise of engineering practice. Nevertheless, as a Consulting Engineer, he made examinations and studies, followed by reports, depositions, and testimony, for various clients over a considerable range of subjects, including storm damage, tide damage, back-water damage, stream diversion, power diversion, fire protection, Venturi and other meter tests, as well as certain patent cases.

Somewhat more specifically there were reports in connection with the Charles River Dam, at Boston, and particularly as to the effect upon the sewers entering the river from Beacon Street houses bordering on the river and the proposed basin. His report on certain tenement districts in Boston was rated as more complete than any similar report for any other city which had been made before this time.

Previous to the construction of the Cape Cod Canal, Professor Porter was asked to make a study of the probable conditions to be met in cutting the proposed channel. When the Canal was finally built, engineers expressed surprise at the remarkable degree to which his predeterminations proved true.

Furthermore, in 1896 and 1897, he made a series of reports on runoff, rainfall, and available water power. These reports included the various rivers of the State of Maine.[2] He also made similar reports between 1898 and 1905, concerning the Merrimac River, Blackstone River, Taunton River, and other streams in their vicinity, which, however, have never been published by the U. S. Geological Survey. Nevertheless, they have been of material use to the District Engineers of the Survey in their work.

He was for a considerable time, a member of the Examining Board of the Massachusetts Civil Service Commission for the examination of State and City Civil Engineers.

For many years Professor Porter had his residence in Malden, Mass. He was President of the University Club of Malden, a member of the Malden Historical Society, a Trustee of the Public Library, and had served the usual term as Deacon of the First (Congregational) Church, of Malden, where his counsel and advice were most welcome and appreciated. The pastor of this Church at the funeral services referred to Professor Porter as the most courteous man he had ever known, and this appealed to

[2] These repts. were published in the Annual Repts. of the U. S. Geological Survey.

his friends as a very apt characterization. It may be further said of him that he was a competent engineer, a successful teacher, a useful citizen, a good neighbor, a man of fine character throughout.

Professor Porter was a member of the Boston Society of Civil Engineers, the New England Water Works Association, the Yale Club of Boston, the Technology Club, the Faculty Club of Technology, and was one of the Founder Members of the Society for the Promotion of Engineering Education.

He was married on September 21, 1881, in Hartford, to Alice Case Marsh, who died on April 11, 1908. He is survived by two daughters, Katherine Elizabeth (Mrs. Charles B. Waterman), and Anne Alice; and a son, James Marsh.

Professor Porter was elected a Member of the American Society of Civil Engineers on October 4, 1893.

ANDREW JACKSON POST, 2D, M. Am. Soc. C. E.[1]

Died February 25, 1936

Andrew Jackson Post, the second of that name, was born in Jersey City, N. J., on November 17, 1871, the son of Andrew Jackson Post, 1st, and Margaret (Combe) Post.

Mr. Post was born and reared in an engineering atmosphere. His grandfather, Simeon S. Post, was one of the founders of the American Society of Civil Engineers, his membership dating from November 5, 1852. Simeon S. Post had been Chief Engineer of the New York and Erie Railroad and of the Bergen Tunnel and the Long Dock Company and, at the time of his death in 1872, he was Principal Assistant to Edwin F. Johnson, Chief Engineer, of the Northern Pacific Railroad Company. Simeon S. Post gave special attention to the application of iron to bridge construction and, in 1863, obtained letters patent for his improvements in iron truss bridges which resulted in the well-known "Post truss." He is also credited with the invention of the parabolic head-light reflector used upon locomotives, and with originating the system of railroad baggage checks and the first diagram for making railroad time-tables.

His father, Andrew Jackson Post, 1st, was also a member of the American Society of Civil Engineers, having studied Civil Engineering under his father and having specialized in bridge building. In 1877, he turned his attention to the construction of the iron work of buildings and with the late William H. McCord formed the firm of Post and McCord. It was about this time that the evolution of what was to become the structural frame of the modern

[1] Memoir prepared by Aubrey Weymouth, M. Am. Soc. C. E.

skyscraper began, and the history of the firm is coincident with the development of the steel industry as applied to building construction in New York, N. Y. The train-shed of the old Grand Central Station and the roof of the amphitheatre of the original Madison Square Garden were among the important works of the firm in those early days. Two of the early apartment houses, the Dakota, at 72d Street and Central Park West, and the Chelsea, on West 23d Street, were also constructed by the firm.

Under the inspiration of this family background it was natural that an engineering career should appeal to Andrew Jackson Post, 2d, as a profession. He was educated at Stevens Institute of Technology, at Hoboken, N. J., from which he was graduated in 1892 with the degree of Mechanical Engineer. While in college Mr. Post was a member of the lacrosse team and also a member of the Chi Phi Fraternity, of which he was, successively, National Treasurer and National President after graduation.

In 1892 he entered the employ of Post and McCord and from that time until his death he was continuously engaged in the structural steel industry. One of his earliest responsibilities with the firm placed him in charge of the construction of the steel frame work of the Empire Building, at 71 Broadway, New York City, the present home of the United States Steel Corporation.

Mr. Post's father died in 1896 and, in 1900, Mr. McCord disposed of his fabricating plant in the Greenpoint Section of Brooklyn, N. Y., to the newly formed American Bridge Company, and it was operated by that Company for a number of years as its Brooklyn Plant. From 1900 to 1903, Mr. Post was Engineer in Charge of this plant.

In 1903 with Mr. W. H. McCord as President, the firm of Post and McCord was re-established as a Corporation to engage in the work of furnishing and erecting steel construction. Mr. Post was appointed Chief Engineer and afterward, successively, Secretary, and Vice-President. Upon Mr. McCord's death in 1912, he became President of the Company.

Notable among the long list of steel frames of New York's monumental structures built under Mr. Post's direction are the following: The Metropolitan Tower, Hotel Pennsylvania, Standard Oil Building, New York Telephone Company's Barclay-Vesey Building, American Telephone and Telegraph Building, the large power houses of the Consolidated Edison Company and the New York Steam Corporation, the Chrysler Building and the famous Empire State Building, the tallest building in the world. When Post and McCord obtained the contract in 1931 for the steelwork of the group of buildings for Rockefeller Center amounting to 125 000 tons, it was the largest single order for structural steel in building history.

In 1918, during the World War, the firm of Post and McCord, under Mr. Post's direction, executed the general contract as well as the steel work for all the buildings of the Federal Shipbuilding Company, at Kearny, N. J., for the U. S. Steel Corporation.

Mr. Post's reputation for clear judgment and wise counsel caused him to be drafted for many activities outside his immediate business. He was one of the founders of the New York Building Congress and was always much interested in its work. He was formerly a Vice-President of the Congress and a member of the Executive Committee from its organization. As a member of the Committee of the Merchants Association, he assisted in the writing of the proposed new Building Code of the City of New York. He was Treasurer of the Architects' Building, at 101 Park Avenue, and Treasurer of the 115 East 61st Street Building Corporation. He was also Treasurer of the American Institute of Steel Construction and a member of its Board of Directors and of the Board of Directors of the National Erectors Association. For many years he was President of the Iron League of New York, the local association of steel contractors.

Mr. Post was an enthusiastic golfer and was one of the organizers and President of the Woodway Country Club, at Stamford, Conn. He was also a member of the Union League Club of New York and the Architectural League of New York.

His home was at Old Greenwich, Conn. He was married in 1894 to Mary Abbett, a daughter of *ex*-Governor Leon Abbett, of New Jersey. He is survived by Mrs. Post and two sons, Andrew J. Post, Jr., and Leon Abbett Post; a brother, Robert C. Post; and a sister, Mrs. Edgar L. Bradley, of Keene, Va.

Mr. Post's relations with his clients, his business associates, and his employees were characterized by the finest quality of consideration and fairness. The vexatious problems of a busy contractor's life were met with admirable serenity and able resourcefulness. No better evidence could be submitted of the deep impression which his clean personality and fine character had made on the members of the Building Industry than is found in the following action of the New York Building Congress:

"When a member of a group is an acknowledged leader, when he is known for his probity, when he is respected by his business associates and employees, then his passing is a great loss to the community.

"Such an one was Andrew Jackson Post, for twenty-three years President of Post and McCord, Inc., Engineers and Erectors of the frames for many of the country's finest buildings, a Founder and a Member of the Executive Committee of the New York Building Congress; President of the Iron League of New York; Treasurer and Director of the American Institute of Steel Construction.

"It was with deepest sorrow that the Executive Committee of the New York Building Congress learned of the passing of a valued friend and adviser. In session this Eleventh Day of March, Nineteen Hundred Thirty Six, the members of the Executive Committee express their sincere sympathy to the family and business associates of our former member now departed this life."

Mr. Post was elected a Member of the American Society of Civil Engineers on April 30, 1912.

WILLIAM FULLERTON REEVES, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 18, 1936

William Fullerton Reeves was born on Van Dam Street, in New York, N. Y., on December 13, 1859. He died on September 18, 1936, of a heart attack after a few days' confinement at the apartment which he owned and which for several years had been his home, 1 West 67th Street, New York City. He was buried in the family plot at Woodlawn Cemetery. He was of a robust physique, and although his friends had noticed a slowing up of his movements for a year, none realized his serious condition as he cheerfully carried on the fight to the end.

He was the son of Abraham M. and Julia (Jenkins) Reeves. His mother's sister married a brother of Judge William Fullerton, for whom he was named. His father was a Contractor and was connected with the early construction of the New York Elevated Railroads. The boy was taken out of school and put to work, but with characteristic determination, he arranged to be coached in his studies after working hours and received a diploma of graduation from high school, on July 3, 1877. He continued his studies while still at work, and, from 1900 to 1908, took private courses in civil, hydraulic, mechanical, and electrical engineering, and under Professor Collins P. Bliss, of New York University, made tests of boilers and the strength of materials, in the University laboratories.

From February, 1879, to 1880, Mr. Reeves was employed as Checker, Rodman, and Levelman with the New York Land and Improvement Company and for contractors on the construction of the Elevated Railroads. In August, 1880, he entered the employ of the Manhattan Railway Company and remained in continuous service with that Company and its lessor, the Interborough Rapid Transit Company, to the time of his death, a service of fifty-six years. His positions were, successively, Rodman, Levelman, Transitman, Draftsman, and Assistant Engineer, in which latter capacity he was the Engineering Representative of the Law Department.

It is difficult to do justice to Mr. Reeves in a memoir because his always calm and friendly personality and desire to extend fellowship added so greatly to his services to society and the Engineering Profession. His very social nature inspired sociability among engineers with whom he was in contact, thus leading to an understanding and appreciation of one another and often facilitating business dealings.

Having been born and having always resided in New York City, he experienced its many transformations and enjoyed its many and distinctive successive phases of living. He was the pitcher of the first baseball club formed in the City. As a member of the Salmagundi Club, he associated

[1] Memoir prepared by a Committee comprising George H. Pegram, Past-President and Hon. M. Am. Soc. C. E., *Chairman*, Robert Ridgway, Past-President and Hon. M. Am. Soc. C. E., and Arthur S. Tuttle, Past-President, Am. Soc. C. E.

with artists, and was himself an artist of modest pretentions in painting, with much skill in wood carving, producing several ambitious creations as an amateur. His hobby was cabinet work in which he excelled.

He took much interest in the development of the City and throughout his life collected photographs and records which might have led to his writing an interesting history of New York. In 1915, Mr. Reeves contributed a paper on "Transit Problems in American Cities" to the International Engineering Congress, held in San Francisco, Calif. In this paper he presented a general review of the development of transit facilities in a number of large cities.

He was induced to write the history of the Elevated Railroads which was published later by the New York Historical Society in 1935. It is interspersed with photographs which, incidentally, depict the character of street conditions at various periods.

Beginning work with the Elevated Railroads with their inception, Mr. Reeves became the Engineering Expert for the lawyers who had the difficult task of overcoming the obstructions and restrictions imposed by such radical changes in the use of the streets traversed by these railroads. This naturally drew him somewhat away from the usual duties of strictly engineering work, as his capability in this line was so great that he was induced to continue as the Engineering Representative in the Law Department throughout his fifty-six years of service. The Transportation System which he served included the elevated roads, the subways, and, for twelve years, the street-car lines.

Mr. Osgood Nichols, of the Law Department of the Interborough Rapid Transit Company, thus describes his services:

"It is difficult to respond to a request for a brief statement of the connection of Mr. William F. Reeves with our legal work, so extensive and diverse has it been over a period of half a century. Throughout the course of the litigation and settlements through which the Manhattan and Interborough Companies have acquired the rights to street easements of abutting property owners, Mr. Reeves, beginning in 1890, testified practically in every trial. Of this litigation the Court of Appeals said: 'It is unprecedented in the records of this Court.' For many years so great was its volume, that a term of the Supreme Court was devoted solely to the trial of these cases, in practically all of which Mr. Reeves testified as to the elevated railroad structure and the operation of the system in its relation to the abutting properties. So accurate and satisfactory was his testimony that he was called in a great proportion of the 1975 cases tried in Court as a witness for the claimants, receiving often the commendation of the Court, and always the respect and confidence of the litigants.

"Following the third-tracking and extension of the elevated lines under the Certificates of 1913, twenty-three commissions were appointed to try these cases. More than two thousand parcels were thrown into these proceedings in which, during their continuance, several hearings were often held daily. A policy of settlement resulted in disposing of nearly all claims of this character during the past twenty-five years, and in the thousands of settlements involved, Mr. Reeves afforded the Legal Department the necessary engineering details.

"In large measure, his engaging personality, candor, and fairness were instrumental in securing amicable adjustments in avoidance of litigation costs. His memory as to engineering details, particularly of the Manhattan System,

was extraordinary, reinforced as it was, by research into the history of the Manhattan Railway and a unique collection of photographs and data relating thereto.

"Mr. Reeves' work in connection with cinder and smoke conditions in relation to the owners of property adjoining our power stations was of great importance. It was largely due to his efforts and contact with owners that complaints have been minimized and litigation arising from these conditions avoided.

"In the preparation of maps involving a great variety of conditions and in collecting data relative to the valuation of Interborough and Manhattan properties, Mr. Reeves' work was most valuable and extensive. In proceedings before the Transit and Public Service Commissions, Mr. Reeves' work has been important and extensive. He was also called upon to assist the Legal Department in negligence cases.

"It has been a great privilege and pleasure throughout more than forty years to have been associated with Mr. Reeves in a service and friendship which can never be replaced."

His friends were many and they will long miss his companionship and their association with him. He took a keen interest in the affairs of the Society and served helpfully on many of its Committees and on those of the Metropolitan Section, of which he was a Vice-President, from 1930 to 1932.

In 1882, Mr. Reeves was married to Mary L. Crocker, a lady of prominent family and much social charm, who died in 1928. They had no children, and he is survived only by a married sister.

He was a member of the Engineers Club, the Salmagundi Club, the Pleiades Club, and the New York Historical Society.

Mr. Reeves was elected a Member of the American Society of Civil Engineers on October 1, 1912.

DOUGLAS WILLIAM ROSS, M. Am. Soc. C. E.[1]

DIED JUNE 22, 1935

Douglas William Ross was best known as a pioneer in the field of Irrigation Engineering. Although his professional record of forty-two years includes several years in mining and railroad work, his greatest accomplishments were in his chosen field. Due to his brilliance of mind and the high quality of his leadership, all his engagements after the first few years carried a high degree of responsibility. Geographically, he left his record of engineering accomplishments in Canada, Colorado, Kansas, Wyoming, Utah, Nevada, Idaho, Oregon, California, Arkansas, Tennessee, the Gulf States, and in Mexico. His last assignment was in Washington, D. C., as Chief Examining Engineer on Reclamation, Flood Control, and Power Projects, for the Federal Emergency Administration of Public Works.

Douglas William Ross was born on May 7, 1865, in Dunwich Township, Elgin County, Ontario, Canada, the son of John and Mary (Griffin) Ross.

[1] Memoir prepared by J. L. Savage, M. Am. Soc. C. E.

He was graduated from the Collegiate Institute, at St. Thomas, Ont., Canada, at the age of 17 years, and, later, attended the University of Toronto, at Toronto, Ont., Canada.

Mr. Ross' first work was as an Instrumentman during 1883 and 1884 on public land surveys in the Northwest Territories of Canada. He left Canada, and, for three years beginning in 1886, he was engaged on location and construction surveys for the Atchison, Topeka and Santa Fé Railway Company, in Kansas; for the Union Pacific Railway Company, in Colorado and Nevada; and, finally, for the Sioux City and Pacific Railway Company. This completed his railroad experience. In 1890, he obtained the position of Topographer and Assistant to the late Arthur De Wint Foote, M. Am. Soc. C. E., on surveys and investigations for the reclamation of desert lands in Idaho. This work was being done under the direction of the United States Geological Survey. It was on this assignment that Mr. Ross became intensely interested in irrigation work. During this same year of 1890 he was employed by the Idaho Mining and Irrigation Company, and, under the direction of C. H. Tompkins, M. Am. Soc. C. E., Chief Engineer, and the late Mr. Foote, Consulting Engineer, was placed in charge of the location of the New York Canal in the Boise Valley, Idaho. This canal, with a base width of 40 ft, a length of nearly 100 miles, and a designed capacity sufficient to irrigate more than 200 000 acres of desert land, was the initial development of the Boise Irrigation Project later to be taken over and completed by the United States Reclamation Service.

In 1891, Mr. Ross was appointed Superintendent of the Phyllis Canal of the Idaho Mining and Irrigation Company, which was 55 miles long and provided for the irrigation of 25 000 acres of fertile valley land. In this engagement he gained experience in the operation of irrigation works that was of inestimable value to him later in the location, construction, and planning of many major projects. In 1892, he left Idaho to accept a position, under the late William Hammond Hall, M. Am. Soc. C. E., Chief Engineer in charge of the construction of the Sunnyside Canal, in Yakima County, Washington. Returning to Idaho a year later Mr. Ross organized a company and built the Riverside Canal for the irrigation of about 15 000 acres in Canyon County, Idaho. From 1893 to 1896, he was Superintendent of an irrigation system in Payette Valley, Idaho, and from 1896 to 1899, he was Manager for the Pioneerville Gravel Gold Company, Limited, in Boise County, Idaho. During both these latter connections, he also acted in a consulting capacity for various irrigation enterprises in the State.

In 1899, Mr. Ross was made State Engineer of Idaho, which position he held for four years. During the latter part of his term of office he drafted an Irrigation Code which was enacted into law by the Idaho State Legislature in 1903. Following this service with the State, he was appointed Supervising Engineer for the U. S. Reclamation Service in charge of its work in Idaho and part of the time in Oregon and Utah. He retained this important executive position until 1908. It was during this period that the main features of the great Minidoka and Boise Irrigation Projects were planned and partly constructed, including four important dams, two power plants, and the irriga-

tion systems for nearly 300 000 acres of land. In the summer of 1908, Mr. Ross resigned his position with the Reclamation Service to accept an engagement as Consulting Engineer for the irrigation and land interests of the American Water Works and Guaranty Company, of Pittsburgh, Pa. The development work of this Company was located in Idaho and California. He was Manager and Chief Engineer of its land and irrigation project in the Sacramento Valley, California, upon which more than \$8 000 000 was expended. Governor Hiram Johnson appointed him a member of the Irrigation Board of California for a period of four years.

During the World War, Mr. Ross was in immediate charge of the examination of cut-over and other waste lands in the Gulf States, and in Arkansas and Tennessee, in connection with the plans of the Secretary of the Interior, the Hon. Franklin K. Lane, for the rehabilitation of returned soldiers. For nearly two years after the war, he was located in Washington, D. C., in the interests of national legislation for the reclamation of lands, representing reclamation and land interests chiefly of Louisiana, working through the New Orleans Association of Commerce and with the co-operation of an association representing the Public Land States, the National Reclamation Association, the United States Chamber of Commerce, the Legislative Committee of the American Legion, and other civic organizations. Afterward, for nearly four years, from 1922 to 1926, he was engaged in reporting on land colonization and irrigation projects in Mexico.

From 1927 until 1932, Mr. Ross was first Consulting Engineer and then Chief Engineer for the Brown County Water Improvement District No. 1, with offices in Brownwood, Tex. In the latter capacity he had direct charge of the construction of the Brownwood Dam, an earth-fill structure, impounding 125 000 acre-ft of water for flood control, irrigation, and municipal supply. This dam was completed in May, 1933. In July of that year, Mr. Ross was appointed a member of a Board of Engineers to examine and pass on projects proposed for building with Public Works Administration Funds. He held this responsible position with the PWA in Washington, D. C., until his death about two years later.

A few excerpts from letters received from many of Mr. Ross' associates and other friends, are quoted, as follows:

"Mr. Ross had the spirit of a true promoter and an insight into the future possibilities of this western country. As State Engineer in 1903 Mr. Ross wrote the first comprehensive reclamation law that was ever passed in the State of Idaho. As a member of the Legislature I was associated with him in this work and can testify to his patient and persevering study of irrigation problems that were finally embodied in a bill passed by the Legislature, and which, as I have said, was the foundation of the future irrigation developments of the State.

"Upon the passage of the National Reclamation Act Mr. Ross immediately visioned the development which later transformed the Boise Valley through the building of Government works. All through the preliminary stages of work Mr. Ross was the guiding mind. I was in Washington with him in company with Governor Steunenberg and Judge Richards when Secretary Hitchcock gave his first approval of the Payette-Boise Project and allocated the first money for the commencement of work. I consider that Mr. Ross had high

attainments as an engineer, but his ability reached beyond the technical part of his profession, and he had the ability to see the economic and social results which followed the irrigation development of this Western Country." (J. H. Lowell, Secretary, The College of Idaho, Caldwell, Idaho.)

* * * * * * * * * * * * *

"I first met Mr. Ross when he came to Idaho in the early history of the Reclamation Service. He came there in connection with the Boise-Payette Project. His life was lived in the service of reclamation and conservation. He was a true friend of the West. He knew its problems and shared with others in a desire to correct the present evils and make it a better place for future generations. He was devoted to his work. He was honest, painstaking, and considerate of the feelings and aspirations of others. In his passing, reclamation lost one of its greatest advocates." (The Hon. Theodore A. Walters, First Assistant Secretary of the Interior, Washington, D. C.)

* * * * * * * * * * * * *

"I consider the most important phase of Mr. Ross' engineering career began with his appointment as District Engineer of the U. S. Geological Survey. In this position he had supervision of the investigations and construction of projects covering the reclamation of arid lands in the States of Idaho, Oregon, and Utah. This work was undertaken by the Federal Government under the recently enacted Reclamation Act.

"As soon as the Reclamation law became effective, there was a demand for immediate construction. To select the first projects to be undertaken and to prepare plans and specifications for their construction required organization of forces on a large scale and in a short space of time. In this work, Mr. Ross showed his ability both as an engineer and as an executive.

"Mr. Ross was thoroughly human; he seemed to see the best there was in a person and was always ready to defend those he knew against attacks reflecting upon their integrity or ability." (J. B. Bond, M. Am. Soc. C. E.)

* * * * * * * * * * * * *

"About 1915 I was assigned the task of compiling the history of the Boise Reclamation Project from its inception to the end of 1911. With complete access to all files and records the writer had ample opportunity to determine the persons responsible for the planning and setting in motion the forces necessary to secure the approval and construction of the first unit of the project. It is certainly true that the will power and drive of D. W. Ross was the beginning of all. Seldom is energy and fire coupled with education and technical training as in this man. Without the prompt and effective action of Mr. Ross, Idaho's two very successful irrigation projects, the Boise and Minidoka, might never have been built." (Gilbert Hogue, Engineer, U. S. Bureau of Reclamation, Friant, Calif.)

* * * * * * * * * * * * *

"I knew Mr. Ross in the capacity of Supervising Engineer for the U. S. Reclamation Service, in charge of irrigation investigations and construction in the State of Idaho during the period of 1903 to 1908. It was my privilege to work under him during this period, on the surveys and construction of, first, the Minidoka Project and, later, the Boise Project. Mr. Ross was an able engineer and a man of unusual executive ability for his young age; also he had a splendid and aggressive personality." (C. C. Fisher, M. Am. Soc. C. E.)

* * * * * * * * * * * * *

"Mr. Ross was an able engineer of scholarly and well trained mind. He had an unusually broad experience with the building of works of this class [referring to the construction of the Brownwood Dam] in Utah, Wyoming, and California * * *." (R. A. Thompson, M. Am. Soc. C. E.)

"It was not my privilege to have met Mr. Ross until late in his long and notable career although I had previously known considerable of him and his work for many years and had acquired a high regard for his ability and leadership as an engineer and executive especially in the reclamation development of the West.

"When I did have close association with him, his qualities as a man and engineer that undoubtedly had made him such a leader and builder were clearly manifested He worked with great energy, enthusiasm and thoroughness. He analyzed the problems at hand by clear thinking, sound judgment, and honesty of purpose and seemed to possess remarkable ability in discerning the economic and human factors involved. He commanded and was freely given the respect and loyalty of his associates and he extended to all a fine friendliness and consideration. I wish I might have known him earlier and longer." (W. H. Nalder, M. Am. Soc. C. E.)

* * * * * * * * * * * * * * *

"I first met Mr. Ross when I was a young assistant engineer, in charge of a comparatively important engineering investigation, on which I needed advice from some one with experience and mature judgment. I appealed to Mr. Ross who was considerably older and held the important position of Supervising Engineer in the Reclamation Service at the time. I will always remember the patience and careful consideration he gave to my problems although not in his assigned line of duty.

"I later came in contact with him from time to time and on one occasion, a short time before his death, when he visited the Denver Office of the Bureau of Reclamation seeking data and advice in connection with a difficult investigation he was making under his important assignment in the Public Works organization at Washington, D. C.

"I have always been greatly impressed by Mr. Ross' sterling character and his innate sense of fairness and responsibility. He was sensitive to a fault but his high qualities as a gentleman were recognized by all who knew him. He was a great inspiration to the younger engineers and his splendid influence is still discernible in many engineers throughout the Western States who started their professional careers under him in 1903 on the Minidoka and Boise projects of the U. S. Reclamation Service.

"The death of Mr. Ross removes from the Engineering Fraternity one of its outstanding and most distinguished members." (R. F. Walter, M. Am. Soc. C. E.)

* * * * * * * * * * * * * * *

"It was my good fortune and pleasure to have Mr. Ross closely associated with me from July, 1933 to May, 1935, when illness necessitated his return to his home in California. During this period Mr. Ross acted as my Examining Engineer on Reclamation, Flood Control, and Power Projects.

"The selection of projects to be included in the reclamation program for which the Public Works Administration allotted funds in excess of \$100 000 000 was based largely on the studies and recommendations made by Mr. Ross. His extensive knowledge of reclamation, gained through intimate contact with this work in many sections of the West over a long period of years, his keen appraisal of the engineering and economic factors involved, and his sound judgment and honesty of purpose, made his services invaluable.

"He was a man of the highest character, considerate, sincere, and respected by every one who knew him." (Fred E. Schnepfe, Assoc. M. Am. Soc. C. E.)

On May 10, 1892, Mr. Ross was married to Edith E. Spofford, at Boise, Idaho, to which union two daughters, Katherine and Mary Kenneth, were born. Mrs. Edith E. Ross died in 1904, and, later, Mr. Ross was married to Inez V. Spofford, by which marriage three sons were born, Douglas

William, Jr., Donald Spofford, and David Goodall Ross. Mr. Ross was stricken with his fatal illness while engaged with the PWA, in Washington, but returned to his home in Berkeley, Calif., where he passed away on June 22, 1935. His widow and all five children survive him.

Mr. Ross was elected a Member of the American Society of Civil Engineers on March 1, 1899.

DONALD BENJAMIN RUSH, M. Am. Soc. C. E.[1]

Died February 15, 1937

Donald Benjamin Rush was born on May 8, 1886, at Dana, Ind., the son of Fred and Annie (Hinkle) Rush. After completing his Grammar and High School work, he entered Rose Polytechnic Institute, at Terre Haute, Ind., in 1906, and was graduated with the degree of Bachelor of Science in Civil Engineering in 1910. In 1921, he received the degree of Master of Science from the Institute.

Early in life, Mr. Rush evidenced a natural bent for engineering work. His father, Fred Rush, was a Mining and Municipal Engineer of the firm of Rush and Emerson, Terre Haute, Ind. During the vacations of his college course, Donald Benjamin Rush worked as an Assistant on mine surveys, railroad construction, and municipal engineering, so that at the time of his graduation he had already acquired a considerable amount of practical experience.

From 1911 to 1912, he was in the Engineering Department of the Chicago and Alton Railroad Company, as Assistant Bridge Engineer. From 1913 to 1914 he was connected with the Chicago Electrification of Railroads Commission, and assisted materially in the development of the modern types of catenary construction.

From 1914 to 1918, his work was in connection with analysis of railroad construction, operation, and economics, as Assistant to the late John Findley Wallace, Past-President, Am. Soc. C. E., and to Bion J. Arnold, M. Am. Soc. C. E.

In 1918 Mr. Rush joined the staff of Robert W. Hunt Company, in Chicago, Ill., remaining with that Company until 1935. From 1923 to 1935, he was Manager of the Cement and Concrete Department of the Company. In 1936, he organized and became President of the Rush-Roberts Engineering Company, specializing in consultation, inspection, and testing of building materials and construction. Mr. Rush was particularly interested in the subject of concrete mixtures and strengths, foundations, and soil pressures, and had done some very able work along these lines. His work on the testing of soils to determine safe allowable pressures, contributed materially to the proper engineering methods of

[1] Memoir prepared by I. F. Stern, M. Am. Soc. C. E.

handling this difficult problem, and he developed some very efficient data on this subject.

He was also deeply interested in mining, and at various times was called upon to make analyses and reports on various mining projects, in which his early training was adequately put to use.

Mr. Rush was always deeply considerate of the rights of others. He had a keen sense of humor and was noted among his associates for his dry wit. His home was in Glen Ellyn, Ill.

In 1912, he was married to Rose E. Duenweg, of Terre Haute, Ind., and is survived by his widow, his two sons, Richard, and James A., his mother, and one brother.

Mr. Rush was elected a Member of the American Society of Civil Engineers on May 12, 1930.

FREDERICK EDWARD SCHALL, M. Am. Soc. C. E.[1]

Died August 6, 1936

Frederick Edward Schall was born in Kuchen, Geislingen, Württemberg, Germany, on December 19, 1857, the son of John and Mary Schall. He received his elementary education in the public schools, attended the Royal Building Academy Trade School, at Stuttgart, and worked as an Apprentice to learn stone-cutting. In 1876, he entered the Government Railway Service, and was engaged in railroad construction for the Provinces of Hesse, Nassau, and Baden, Germany; and, from 1877 to 1878, he was Assistant Engineer to a contractor on railroad construction. From the late fall of 1878 to the spring of 1880, he was in the German Army, from which he was honorably discharged on November 7, 1880, and relieved of any further military duties.

From 1880 to 1881, he assisted his eldest brother, a Registered Land Surveyor of Württemberg. He sailed for the United States in July, 1881. Upon his arrival in this country, Mr. Schall worked at stone and marble cutting until he could in some measure master the English language. In order to accomplish this as quickly as possible, he attended night school at the Business College of Easton, Pa.

On July 15, 1883, he entered the service of the Lehigh Valley Railroad Company as a Draftsman in the Engineering Department, which position he held until 1887 when he transferred to the Bridge Department as Draftsman and Bridge Designer. From 1888 to 1897, he served as Chief Draftsman in the Chief Engineer's Office, at Bethlehem, Pa. During this time Mr. Schall also designed and built all the bridges on the new line of the Lehigh Valley from Geneva to Buffalo, N. Y., co-operating with the late Paul S. King, M. Am. Soc. C. E., Chief Engineer of Construction. In 1897, he was made Assis-

[1] Memoir prepared by George T. Hand, M. Am. Soc. C. E., and H. T. Rights, Assoc. M. Am. Soc. C. E.

tant Engineer in charge of the Chief Engineer's Office, and, in 1899, was promoted to the position of Bridge Engineer, which he held until April 1, 1929, when he was appointed Consulting Bridge Engineer; this latter position he held until his death.

During Mr. Schall's fifty-three years with the Lehigh Valley Railroad Company, he saw practically all the bridges on the line between New York, N. Y., and Buffalo rebuilt twice on account of the fast changing conditions and the increase in the weight of locomotives. He also saw the construction of the Vosburg and Rockport Tunnels, and prepared plans and specifications for the construction of the new Musconetcong Tunnel in 1927.

Mr. Schall was always a very active supporter of engineering societies and activities. He had been a member of the American Railway Bridge and Building Association since 1899, and had served as Vice-President for five years. He was elected President of the Association for the year from 1911 to 1912. He had also been a member of the American Railway Engineering Association since 1905 and had served on its Masonry Committee since 1908. He was elected President of the Lehigh Valley Section of the Society for the year 1931.

In addition to the societies previously noted, Mr. Schall was a member of the American Society for Testing Materials, The Engineers' Club of Philadelphia, Pa., The New York Railroad Club, and the Engineers' Club of the Lehigh Valley.

He was a man of sterling character, a staunch friend, a strict disciplinarian of himself and his employees and had the highest ideals of duty to his employer. He never spared himself when there was work to be done. He was a man of strong conviction and believed in stating his opinions so that there could be no doubt as to his position on the question under consideration.

He was married on January 18, 1883, to Mary K. Kurtz, of Belvidere, N. J., who died on February 15, 1921. He is survived by his two daughters, Emma and Fanny Schall, and a son, Walter Schall.

Mr. Schall was elected a Member of the American Society of Civil Engineers on October 1, 1902.

LEIDY RUDY SHELLENBERGER, M. Am. Soc. C. E.[1]

Died July 25, 1936

Leidy Rudy Shellenberger was born on a farm near Perkasie, Bucks County, Pa., on April 5, 1865. His parents were of German descent, and he received his early education in the rural school of the district in which they lived. Later, he taught in a country school for three years and while thus engaged he studied at the Millersville (Pa.) State Normal School from which he was graduated in 1886.

[1] Memoir prepared by S. J. Harwi, M. Am. Soc. C. E.

He entered the College of Engineering, Lehigh University at Bethlehem, Pa., in 1887, where he studied under the late Mansfield Merriman, M. Am. Soc. C. E., and was graduated with the degree of Civil Engineer in 1891. Mr. Shellenberger gained his early professional experience, from 1891 to 1895, in the drafting-rooms of several small structural iron works.

From 1895 to 1903, he was Assistant Engineer with the Pencoyd Iron Works, at Pencoyd, Pa., and had charge of the design and detailing of the Richmond Viaduct, at Richmond, Va.; the Rondout Viaduct, in New York State, for the New York Central Railroad Company; several highway bridges; and a number of mill and other buildings.

From September, 1903, to November, 1904, Mr. Shellenberger was associated with the late Charles C. Schneider, Past-President, Am. Soc. C. E., and made preliminary surveys and designs for a new Union Station at Cincinnati, Ohio, the estimated cost of which was $10 000 000. From 1904 to 1908, he made many preliminary and final studies and designs for the Architects of the Grand Central Station, in New York City. He also supervised the erection of the steel for this work.

He was with the Public Service Commission of New York City from 1908 to 1912, and was engaged principally in making preliminary and final designs for subways.

In 1912, he organized the Bayonne (N. J.) Launch Company, of which he was Secretary and Treasurer. In 1913, Mr. Shellenberger returned to the Public Service Commission of New York City, as Designer, and had charge of the design of subway work valued at approximately $10 000 000. He resigned in 1916, and went with the Chile Exploration Company as Designer and Squad Engineer for a period of two years, after which he was with the Dwight P. Robinson Company in a similar capacity until 1921, when he became connected, as Designer, with the Engineering Force for the Holland Tunnel, with which he remained until 1924.

He then became Chief Designer of Bridges and Structures for the New Jersey State Highway Department, at Jersey City, N. J. As such, he had charge of the design of the Route 25 Connecting Link, commonly known as the Pulaski Skyway, which is one of the largest viaducts of its kind. Upon the completion of this work, in 1933, he retired from active engineering. He died after a short illness on July 25, 1936, and was buried at Perkasie, Pa.

Mr. Shellenberger was a tireless, energetic, and thorough worker, and possessed sound engineering judgment. He was a man of sturdy character, simple habits, and had a genial personality. He was a member of the First Reformed Church, at Bayonne, N. J., and, at the time of his death, was an Elder of that Church. He was a Thirty-second Degree Mason and also a member of the Shrine, Salaam Temple, of Newark, N. J.

On March 29, 1902, he was married to Mary Lavinia Stump, of Stouchsburg, Pa., and is survived by his widow and two sons, John and William Howard Shellenberger.

Mr. Shellenberger was elected an Associate Member of the American Society of Civil Engineers on May 2, 1900, and a Member on December 15, 1924.

ZENAS HARRISON SIKES, M. Am. Soc. C. E.[1]

Died August 1, 1936

Zenas Harrison Sikes, the son of Zenas L. and Emma (Harrison) Sikes, was born at Suffield, Conn., on March 5, 1874. His preliminary education was obtained at the Suffield School and at the Williston Academy, at Easthampton, Mass. He was graduated with the degree of Bachelor of Philosophy from the Sheffield Scientific School of Yale University, at New Haven, Conn., in 1898.

After his graduation in 1898, Mr. Sikes became connected with the Pennsylvania Lines West of Pittsburgh, first as Assistant Engineer in the Maintenance-of-Way Department and then as Designer and Draftsman in the office of the Bridge Engineer.

In 1901, he took a position with the Riter-Conley Manufacturing Company as Detailer on various types of steel structures and, later, as Designer in the Bridge Department. In 1906, Mr. Sikes started his career with the New York Central Railroad Company with which he was connected until his death. He spent three years as Designer and Estimator on various railroad structures. In 1910, he was promoted to the position of Assistant Engineer of Structures, in which capacity he was engaged in the preparation of designs and general detail plans for various types of railroad and highway bridges. In this position he had an important part in several undertakings of considerable magnitude, such as tthe bridge carrying the Hudson River Connecting Railroad over the Hudson River, at Castleton, N. Y.; several Strauss trunnion bascule railroad bridges; the bridges of the track elevation and the elimination of grade crossings through the City of Syracuse, N. Y., and the bridges for the extensive West Side Improvements, in New York, N. Y.

In 1900, Mr. Sikes was married to Jennie Fuller, of Suffield, Conn. Mrs. Sikes, together with a son, Dr. Ralph F. Sikes, and a daughter, Mrs. Ernest Warner, survives him.

Mr. Sikes was a member of the American Railway Engineering Association, the American Association of Engineers, the New York State Society of Professional Engineers, and the Yale Engineering Association. He was a Mason and a member of the Yale Club of New York City. He was active in religious work, having been Trustee of the Young Men's Christian Association, at Yonkers, N. Y., the Railroad Young Men's Christian Association, in New York City, and the Baptist Church of the Redeemer, of Yonkers.

He will be remembered by all those with whom he came in contact for his exceptional Christian character which was exemplified particularly through a marked degree of unselfishness and devotion. Mr. Sikes' able and conscientious efforts made him recognized as a worthy member of the Engineering

[1] Memoir prepared by B. S. Voorhees, M. Am. Soc. C. E.

Profession, and his generous contributions toward welfare and religious work won him admiration in the community in which he lived.

Mr. Sikes was elected an Associate Member of the American Society of Civil Engineers on June 30, 1910, and a Member on March 14, 1916.

JAMES CUMMIN STEVENSON, M. Am. Soc. C. E.[1]

Died December 29, 1936

James Cummin Stevenson, the son of James Oliver and Emilie Blanche (Rattiseau) Stevenson, was born in Galveston, Tex., on December 16, 1885. He attended the public schools of Galveston, and, in 1904, he entered the University of Texas, at Austin, Tex., from which he was graduated with the degree of Civil Engineer in 1908. The excellency of Mr. Stevenson's work as a student was recognized by the Faculty of the University by his appointment as a Student Assistant in the Engineering Department. During his last year in college his classmates paid a tribute to his popularity by electing him President of the Senior Class.

Mr. Stevenson's first engineering experience was acquired during the vacation periods of his college years, when he worked for the Gulf, Colorado and Santa Fé Railway Company as Chainman, Rodman, and Instrumentman. From June, 1908, to December, 1910, he served, successively, as Inspecting Engineer, Draftsman, Assistant Engineer, and Assistant City Engineer of the City of Galveston, in connection with the raising of the grade of the city as a flood preventive. From December, 1910, to May, 1911, he was Assistant Engineer for the United States Boundary Commission in connection with the delineation of the boundary between the United States and Mexico along the Rio Grande. From 1911 until 1932, except for a period of four months during 1918, when he was Executive Assistant to the Construction Quartermaster at the Army Base, at Brooklyn, N. Y., Mr. Stevenson was connected with H. L. Stevens and Company of Chicago, Ill., on the design and construction of fireproof buildings, successively, as Designing Engineer, Assistant Superintendent of Construction, General Superintendent, Assistant Chief Engineer, Chief Engineer, and Vice-President and Managing Partner.

Mr. Stevenson's building experience, embracing a period of twenty-five years, covered a large number of structures. The last twenty-three years of his life were spent exclusively in hotel construction and operation. Among the buildings which he supervised from their inception to their completion, including the securing and execution of the contracts with the owners, the design and construction, and, frequently, the financing and operation, are the following: Kirkwood Hotel, Des Moines, Iowa; Both-

[1] Memoir prepared by W. F. Krahl, Assoc. M. Am. Soc. C. E.

well Hotel, Sedalia, Mo.; Bankhead Hotel, Birmingham, Ala.; St. Nicholas Hotel, Springfield, Ill.; Hotel Chieftain, Council Bluffs, Iowa; Hotel Tall Corn, Marshalltown, Iowa; Hotel President, Waterloo, Iowa; Hotel Wenonah, Bay City, Mich.; Hotel Northland, Marquette, Mich.; Hotel Vicksburg, Vicksburg, Miss.; Capitol Hotel, Lincoln, Nebr.; Onesto Hotel, Canton, Ohio; and the Metropole Hotel, Cincinnati, Ohio.

In 1932, after the depression had put an end to new hotel construction, Mr. Stevenson opened his own office, in Chicago, as a Consulting Engineer and specialized in the re-habilitation and financial re-organization of hotel properties. In this work, too, he was successful. His buildings were economically designed, admirably planned, and soundly constructed. His intimate knowledge of construction costs influenced advantageously the planning and construction of his projects, and his experience in hotel management helped his clients to avoid errors involving unnecessary operating expenses.

He was a reader and a profound student of economics. He had the ideal engineering mind—keen, analytical, and well balanced. He was experienced in at least three branches of engineering, successful as a salesman, a financier, and a business executive, a builder of note, exceedingly versatile, modest, and unassuming, but the master of any situation which presented itself. Mr. Stevenson's memory will live not only in the stone and mortar of the many fine permanent structures which he visualized and built, but in the affections of those whom he served so well, and in the hearts of the many who called him "friend."

In his home life he was very fortunate and supremely happy. On June 18, 1913, he was married to Mary Pearl Melton, of San Antonio, Tex. His widow, two daughters, Mary Jane and Catherine Melton, and one son, James Cummin, III, survive him. For them it may be said, "Love hath a tie which Time nor Death can sever."

Mr. Stevenson was elected an Associate Member of the American Society of Civil Engineers on March 4, 1913, and a Member on September 9, 1919.

EARL STIMSON, M. Am. Soc. C. E.[1]

Died May 27, 1936

Earl Stimson was born at Cincinnati, Ohio, on September 2, 1873, the son of Earl W. and Florence Pritchard (Cummins) Stimson. His ancestry of Scotch-Irish origin, settled in New England, his father and mother moving later to the Middle West. His early education included the usual course in the public schools of his native city, with one year (1892), at the University of Cincinnati, and two years (1893–1894), at Cornell University, at Ithaca, N. Y.

[1] Memoir prepared by the following Committee: J. E. Greiner, Hon. M. Am. Soc. C. E., and H. A. Lane, and P. G. Lang, Jr., Members Am. Soc. C. E.

The entire period of Mr. Stimson's long and useful professional career was spent in the service of The Baltimore and Ohio Railroad Company and its affiliated lines, which he entered in June, 1895, in the capacity of Rodman in the Maintenance-of-Way Department, at Cincinnati. In 1896, he was advanced to the position of Assistant Engineer, at Cincinnati, and, in 1898, he was transferred to Chillicothe, Ohio. Between February, 1899, and May, 1901, he occupied the position of Resident Engineer at Osgood, Ind., in charge of revision of grades and alignment between Milan and North Vernon, Ind. In May, 1901, he was appointed Assistant Division Engineer at Chillicothe, and in April, 1902, became Division Engineer of the Springfield Division, with headquarters at Flora, Ill., being subsequently transferred to the Illinois Division at Washington, Ind.

In May, 1905, Mr. Stimson was made Engineer, Maintenance of Way, of The Baltimore and Ohio Southwestern System, at Cincinnati. In September, 1907, he was made Chief Engineer, Maintenance of Way, of the same System, continuing in that position until April, 1910. During that month, and shortly after the operations of the Southwestern were merged with those of The Baltimore and Ohio Railroad, he was promoted to the position of Chief Engineer, Maintenance of Way, of the latter System, with offices at Baltimore, Md. Mr. Stimson remained in that position until August, 1918, when, due to the re-organization of the operations of the System incident to Federal Control, his jurisdiction was extended over the Western Maryland Railroad and other neighboring lines which at that time were allied with The Baltimore and Ohio Railroad Company in the Allegheny Region under the direction of Mr. C. W. Galloway as Federal Manager, Mr. Stimson's title being General Superintendent, Maintenance of Way and Structures. At the termination of Federal Control, on March 1, 1920, he became Chief Engineer, Maintenance, of The Baltimore and Ohio System, in which position he spent the remainder of his life. Mr. Stimson's rapid rise in the short period of fifteen years from the position of Rodman to the head of a large and important Department extending over the entire System, is an eloquent tribute to his ability as an Engineer and Administrator.

Between Mr. Stimson's entrance into railroad service, in 1895, and his death in 1936, there occurred a period of profound change and re-adjustment in all important phases of the railroad and construction industries. The major technical problems of his life were concerned, primarily, with the co-ordination of railroad maintenance procedure with the advancing tide of knowledge and improvement. For many years he was actively associated with important national organizations devoted to the furtherance of engineering and maintenance interests. Although his direct professional activities for a period of more than forty-one years were spent on The Baltimore and Ohio System, his influence upon the development of maintenance technique, exerted through his participation in the work of such organizations, was subject to no limitations of extent or importance. To the problems which he was called upon to meet and solve, he applied a combination of an analytical mind and resourcefulness and ability for laborious and thorough research with systematic classification.

For many years Mr. Stimson was active in the affairs of the American Railway Engineering Association, serving as Director in 1914; Vice-President, in 1917 and 1918; and as its President for the term, 1919–1920. He held memberships in the American Railway Engineering Association's Standing Committees on Standardization, Economics of Railway Labor, and Wood Preservation, and between 1927 and his death, he was Chairman of its Committee on Rail. He was also a member of the Special Committee on Stresses in Railroad Track.

As Chairman of the Rail Committee of the American Railway Engineering Association, his constructive activities were especially marked. These activities comprised the conclusion of an arrangement with Dr. Elmer A. Sperry which resulted in the perfection of the transverse fissure detector car, the development of standard design for 112-lb and 131-lb rail and fastenings, revision of rail specifications, and the conclusion of arrangements with rail manufacturers and the University of Illinois for an exhaustive study of transverse fissures by Professor H. F. Moore.

The list of professional societies with the work of which Mr. Stimson was associated, also includes the American Wood Preservers' Association, in which he served as a member of the Committee on Fireproofing. He also was appointed a representative of America to the International Railway Congress Association and prepared and presented a report on "Maintenance Organization and Economic Methods," read at the Ninth Congress, held in Rome, Italy, in April, 1922.

His association and work in the National Societies did not make him lose sight of the value of such activity in his own community, and for fifteen years, Mr. Stimson was a member of the Engineers' Club of Baltimore, serving as a Director for a number of years and being elected its President for the term, 1923–1924. A further evidence of the progressive character of his professional work is furnished by his numerous contributions to the columns of technical periodicals, and his addresses at association meetings and before college students.

Mr. Stimson will always occupy a high place among those who have faithfully and efficiently discharged their duties in the walk of life to which they were called, and the respect and esteem which his achievements have won for him in the field of professional activities, are surpassed only by the tribute and regard voluntarily accorded him by those whose good fortune it was to enjoy the privilege of a close association with him.

Beneath his close adherence to strict discipline, he displayed a real humanitarianism toward the members of the organization under his direction. His social instincts found expression through membership in the Merchants Club of Baltimore, the Maryland Country Club, and the Ohio Society in Maryland.

On November 30, 1899, Mr. Stimson was married to Katherine S. Hopper, of Cincinnati. Mrs. Stimson and their children, Earl, Jr., Elizabeth, Alfred, Katherine, and Emma, survive him.

It is a tribute to Earl Stimson's character and devotion to duty that his death at Massillon, Ohio, on May 27, 1936, occurred during an inspection

trip. His long tenure of office, the wide variety of his railroad and engineering activities, his outside associations, had all brought an increasing circle of friends, to whom his passing leaves a sense of deep personal loss.

To his survivors, Mr. Stimson has bequeathed an example of a life of untiring activity and notable achievements, a genial and natural personality, and if his memory proves an inspiration to those of his own generation and those of the rising generation who have come under his leadership and have been associated with him, he will not have lived in vain.

Mr. Stimson was elected a Member of the American Society of Civil Engineers on January 19, 1920.

CHARLES EUGENE SUDLER, M. Am. Soc. C. E.[1]

Died May 3, 1936

Charles Eugene Sudler was born in Baltimore, Md., on October 3, 1876, the son of Colonel and Mrs. John Emory Sudler. His father was a practicing civil engineer, and, for two years after graduating from High School, young Charles received practical education in engineering from him.

In 1896, he secured employment as a Mechanical Draftsman in the machine shop of the Murrill and Keizer Company, of Baltimore. In the latter part of 1897, Mr. Sudler and several other young engineers formed a partnership which operated a small yacht-building yard in Baltimore; as Manager and Engineer of the firm he designed and built a number of boats ranging from small tenders and gasoline launches to a schooner yacht of 65-ft length. Due to lack of capital and inexperience in business, the undertaking was not profitable, and was abandoned in 1900. However, this experience left a lasting impression on Mr. Sudler and even in later years he was happiest when he was engaged on maritime work and on subjects related to shipping.

From 1901 to 1903, he was employed as a Draftsman in the office of A. M. Kinsman, Engineer of Construction and, later, Chief Engineer, of the Baltimore and Ohio Railroad during the rebuilding and double-tracking of this line west of the Ohio River. In addition to much diversified work on plans, estimates, calculations, etc., Mr. Sudler, during this period, had been given considerable opportunity to observe actual construction work; he often said that he was indebted to Mr. Kinsman for the real foundation of his career.

In 1903, he became Superintendent and Engineer for the Hoover and Kinnear Company, Contractors, of Columbus, Ohio, which firm specialized in railroad construction, including tunnels, earthwork, and bridges. Mr. Sudler had charge of the design of coffer-dams, arch centering, and the construction plant for the Company's various contracts, for which he prepared estimates and organized the field and office forces. Contracts for the reconstruction and track elevation of the Baltimore and Ohio Railroad, at Wheeling, W. Va.,

[1] Memoir prepared by Eugene E. Halmos, M. Am. Soc. C. E.

and at Bellaire, Ohio, and other contracts of similar character for the Pennsylvania Railroad Company, were under his supervision. He also had charge of the construction of the Big Walnut Bridge for the Baltimore and Ohio and the Pennsylvania Railroad Companies near Columbus, Ohio. Other contracts under his charge included bridges, culverts, and tunnels on the Buffalo and Susquehanna and Wabash Railroads.

In 1906, he became Chief Engineer of the Hamilton Manufacturing Company, of Columbus, Ohio, in the development of the first successful mine-loading machine under the Hamilton patents. A new design of coal-storage and reclaiming machinery was developed and built for the Illinois Steel Company; this machine stocked and reclaimed coke at a rate of 3 tons per min; it was accepted and paid for on the strength of its first day's trial run.

In 1908, Mr. Sudler returned to Baltimore, having been appointed Principal Assistant Engineer under the late Oscar Francis Lackey, Assoc. M. Am. Soc. C. E., Harbor Engineer. At this time, following the disastrous fire of 1904, the City of Baltimore had purchased a large part of its water-front and was carrying forward an ambitious program of municipal maritime construction. Mr. Sudler had active charge of the design and construction of wharves, piers, bridges, buildings, floating equipment, dredging, etc. The steel and concrete arch bridge over Jones Falls, at Pratt Street, Baltimore, included in the foregoing, received considerable notice in engineering literature.

In 1911, Mr. Sudler became Engineer and Manager of the Furst Concrete Scow Construction Company. This was a new plant, consisting of a 1 000-ton railway dry dock, machine and wood-working shops, concrete barge plant, and office building, all of which were constructed under his plans and direction. In addition to the first large concrete barge built in the East, his Company produced composite and wooden scows, and made general repairs on vessels and machinery.

Between 1913 and 1915, Mr. Sudler acted as Superintendent of Construction for the million-dollar Perry Memorial, at Put-In-Bay, Ohio. This very beautiful but little advertised structure is located on a small island in Lake Erie. From 1916 to 1918, he was engaged in the development of mineral and timber property in Eastern Tennessee, as part owner.

In 1919, Mr. Sudler became associated with Parsons, Klapp, Brinckerhoff & Douglas, Consulting Engineers, New York, N. Y., and for two years worked in collaboration with the writer on the design of graving and floating dry docks and ship-repair plants. For the succeeding two years he was in charge of the Hydrology Division of the New York Water Power Investigation, conducted by the firm, under the direction of John P. Hogan, M. Am. Soc. C. E. This work embraced the analysis of the flow and the power possibilities of all New York State streams, and included the study of rainfall and run-off relations, flood flows, etc. Some of the results of the study were presented to the Society under the title, "Storage Required for the Regulation of Stream Flow."[3] For this paper, Mr. Sudler was awarded the Norman Medal in 1928.

[3] *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 622.

In 1924, he took a position with the New York Times Company on research work and the construction of a new rotogravure plant. In 1927, Mr. Sudler became connected with the Port of New York Authority in the preparation of studies for the Suburban Transit Engineering Board on the suburban passenger problem for the entire Metropolitan District, and on an analysis of construction cost estimates. From the time of the consolidation of the Port of New York Authority and the New York-New Jersey Tunnel Commission, in 1930, to his death, Mr. Sudler was assigned to the Chief Consulting Engineer, Ole Singstad, M. Am. Soc. C. E., to assist in investigations, preliminary studies, lay-outs, and other work contemplated in connection with improvement of traffic in and around New York City. Mr. Sudler did particularly fine work in connection with the studies and preliminary planning of the Manhattan approach for the Midtown Hudson Tunnel. He also assisted Mr. Singstad in the preparation of a detailed history of the design, construction, and operation, of the Holland Tunnel. His last work consisted in the preliminary planning and estimation of the cost of the proposed Queens-Midtown Tunnel under the East River.

Mr. Sudler was greatly admired by his associates for his remarkably able, versatile, and analytical mind; he was as much at home in the field of Mechanical Engineering as in matters of Civil Engineering. He had a most likable personality, and all who came in contact with him remember him with the kindest thoughts.

Mrs. Sudler, the former Helen Hamilton, a son, Hamilton G., two daughters, Mrs. Sarah S. Westerman and Mrs. Josephine C. Buell, two brothers, Ralph Sudler, and Emory Sudler, M. Am. Soc. C. E., and two sisters, Annette and Elsa Sudler, and his mother, Mrs. John E. Sudler, of Washington, D. C., survive him.

Mr. Sudler was elected a Member of the American Society of Civil Engineers on October 1, 1913.

WILLIAM STANTON TWINING, M. Am. Soc. C. E.[1]

DIED FEBRUARY 8, 1937

William Stanton Twining was born near Titusville, Pa., on February 20, 1865, the son of Charles and Mary (Stanton) Twining. His parents removed to Union City, Pa., in 1870, where he entered the public schools, from which he was graduated in 1881. He then entered the employ of the Industrial Iron Works, at Union City, as a Machinist's Apprentice and remained there three years. In September, 1884, he entered Cornell University, at Ithaca, N. Y. A year later, he entered Allegheny College, at Meadville, Pa., from which he was graduated in 1887 as a Civil Engineer with the degree of Bachelor of Science. He remained at Allegheny College as an Instructor

[1] Memoir prepared by Charles H. Stevens, M. Am. Soc. C. E., and Joseph W. Silliman, Assoc. M. Am. Soc. C. E.

in Civil Engineering and Chemistry until 1890, having been granted the degree of Bachelor of Arts in 1889.

Mr. Twining's long connection with the development of the electric street-railway industry began when he entered the Electric Railway Department of the Thompson-Houston Electric Company, in Boston, Mass., as Assistant Engineer, and was associated with the design and erection of steam-driven electric power plants at Indianapolis, Ind., Allentown, Pa., and Toledo, Ohio. In 1891, he entered the employ of the Harlem Bridge, Fordham and Morrisania Railway Company (later, a part of the Union Railway Company of New York City) as Principal Assistant Engineer in charge of the electrification of the street railway system, and, in the following year, he was engaged on similar work with the Atlantic Avenue Railway Company (later, a part of the Brooklyn-Manhattan Rapid Transit System).

In 1893, Mr. Twining entered the employ of the Peoples Traction Company, of Philadelphia, Pa., as Assistant to the Chief Engineer, and was made Chief Engineer in 1895. In that year, the principal street railway lines of Philadelphia were consolidated as the Union Traction Company and Mr. Twining was made Chief Engineer of the Consolidated System.

During this period, the street car lines passed from the horse-drawn type to electric operation, and the successful reconstruction of the roadbed, with its overhead trolley system, new cars, large generating plants, with their far-flung distribution system, is an enduring monument to the genius, resourcefulness, and skill of Mr. Twining as an Engineer.

In 1902, the Philadelphia Rapid Transit Company was formed, and this Company leased the electrified street railway system, controlled and operated by the Union Traction Company. This Company also secured public franchises authorizing it to construct and operate a number of high-speed subway and elevated passenger railway lines.

With the transfer of the Union Traction System to the Philadelphia Rapid Transit Company, Mr. Twining continued as Chief Engineer, in which position he directed and supervised the construction and equipment of the Market Street Subway and Elevated Passenger Railway; and a two-track subway in Market Street, extending from the Delaware River to the Schuylkill River, at which point it became a two-track elevated railway structure of steel and concrete, to the western boundary of the City near Sixty-ninth Street. This system is six miles in length, and its construction embraced some outstanding improvements over the existing structures of this period.

In 1910, he became associated with the firm of Ford, Bacon and Davis, of New York, N. Y., as an Engineering Executive and, in this capacity, on behalf of the firm, studied the operating structure of many of the prominent public utility systems of the United States, submitting reports and recommendations covering operation, valuation, and improvement of the properties.

In 1912, Mr. Twining returned to Philadelphia as a representative of Ford, Bacon, and Davis, which firm had been retained to advise the City of Philadelphia in the formulation of a comprehensive plan for the improve-

ment of the passenger transportation system and to develop and recommend a program for the construction of a system of high-speed transportation lines by the City of Philadelphia. These studies continued until 1916, at which time, Mr. Twining severed his connections with the firm of Ford, Bacon, and Davis, to become the Director of the Department of City Transit of the City of Philadelphia, a position that he filled for a period of eight years.

During this time the Frankford Elevated Railway, a two-track elevated structure of steel and concrete, six miles in length, was constructed and equipped for operation. This line connected with the eastern terminus of the Market Street Subway, and extended to the northeast section of the City, locally known as Frankford. Also, a beginning was made on the construction of the Broad Street Subway on that part of the subway under City Hall.

In 1924, Mr. Twining retired from the public service and devoted his time to consulting practice, and to the study and development of matters of a lifetime interest.

He possessed, to a rare degree, the ability to conceive, envision, and plan comprehensive engineering systems and structures; he was a master worker in his chosen field of endeavor; his warm personal charm drew his associates into a close relationship and encouraged them to give to their work the best that was in them.

Throughout his professional career, Mr. Twining was steadfast in his convictions and adhered to his conceptions as to what constituted the right and proper course of procedure. He was loved and esteemed by those who were privileged to be associated with him as co-workers and also by those who were admitted to the closer and more intimate tie of friendship.

Mr. Twining was a member of the Union League, the Franklin Institute, and the Engineers Club of Philadelphia. His membership in technical societies included the American Society of Mechanical Engineers, the American Institute of Electric Engineers, the American Academy of Political and Social Science, and the Phi Kappa Psi Fraternity.

In 1916, he was married to Mrs. Harriett P. Rundell, of Toledo, Ohio, who survives him.

Mr. Twining was elected a Member of the American Society of Civil Engineers on September 3, 1913.

RAY BENEDICT WEST, M. Am. Soc. C. E.[1]

DIED JUNE 3, 1936

Ray Benedict West was born at Ogden, Utah, on October 21, 1882. His grandparents were pioneers of the West. He was the son of Joseph Alva and

[1] Memoir prepared by a Committee of the Utah Section, consisting of O. W. Israelsen, *Chairman*, R. B. Ketchum, Richard R. Lyman, and R. K. Brown, Members, Am. Soc. C. E., and George D. Clyde, Assoc. M. Am. Soc. C. E.

Josephine (Richards) West. His father, with whom he worked as a youth, was a very successful civil engineer.

Ray Benedict West was graduated from the Utah State Agricultural College, at Logan, Utah, with the degree of Bachelor of Science in Civil Engineering, in 1904. He went to Cornell University, at Ithaca, N. Y., from which he received the degree of Civil Engineer, in 1906. In 1928 and 1929, he did graduate work at the University of California, at Berkeley, Calif.

Following his graduation from Cornell University, Mr. West practised his profession in the field of railroad location and construction, working at various times with the Eureka Railroad, the Sumter Valley Railroad, and the Oregon Short Line Railroad Companies. Later, he and his brother, Mr Joseph W. West, engaged in the private practice of engineering at Portland, Ore.

In 1913, he was made Professor of Agricultural Engineering at the Utah State Agricultural College, at Logan, and, in 1916, Dean of the Schools of Agricultural Engineering and Mechanic Arts. In 1927, he was made Dean of the newly created School of Engineering, which position he held at the time of his death.

While at the Utah State Agricultural College, Dean West had charge of the operation and maintenance of the State Power Plant, which produced and distributed electric power for some of the public institutions of the State; he designed and supervised the construction of the Athletic Stadium and also the Amphitheatre, two remarkably beautiful and well-built structures. He also designed and supervised the construction of a new water system for the College. He was active and influential in all phases of the College building program, including the making of plans and selection of locations for major campus buildings. He had general supervision of the design and construction of the Livestock Building, which was completed in 1917; the Engineering Building, and the Plant Industry Building, in 1919; the Library, in 1930; and, finally, the Home Economics-Commons Building completed in 1935.

Dean West consecrated his time, his energies, his vision, and his judgment to the educational advancement, the development, and the building of the Utah State Agricultural College continuously for twenty-one years. During the World War he had charge of the soldier training work at the College and after the war, he directed the training of disabled soldiers. In the administrative councils of the College, his sound judgment and knowledge of practical affairs were in frequent demand. For many years, he was Chairman of the College Athletic Council.

He was a Fellow of the American Society for the Advancement of Science and a member of the following societies: The American Society of Agricultural Engineers; American Association of Engineers; Society for the Promotion of Engineering Education; and Phi Kappa Phi Scholastic Fraternity.

During 1934 and 1935 Dean West was a member of the State Planning Board of Utah, and, in 1936, he was appointed by the Governor of the State as the Director of this important Board. It was while thus engaged, and on

leave of absence from the College, that he was stricken with pneumonia and passed away within a week.

The School of Engineering at the Utah State Agricultural College grew at a rapid rate under his direction. The course of study was strengthened, and the Faculty enlarged. The graduates of the School, who were trained under his direction, have made remarkably fine records, particularly in the fields of irrigation and highway construction. Dean West was not only an excellent teacher and a fine school administrator, but a generous, public-spirited citizen. He was active in the Kiwanis Club of Logan, was Chairman of important committees of the Chamber of Commerce, and, for four years, acted as Bishop in one of the leading Logda wards of the Latter Day Saints Church.

Many of the leaders of the State in religious, educational, and civic matters, including the Governor, paid high tribute to his great worth. He was probably best known, however, for his kindly, pleasing, and genuine personal qualities, which endeared him to his fellow workers and to the many students who came within his influence and to whom he was always a great inspiration.

A fitting tribute and appreciation of his character and accomplishments was prepared by the Faculty and the Board of Trustees of the Utah State Agricultural College. Quoting from this splendid tribute:

"He created, with the help of a faculty whose ideals coincided lovingly with his, an Engineering School * * * which today has no superior in the West. From it have gone, as graduates bearing the stamp of their association with Dean West, approximately one hundred and fifty engineers who, as leaders in this western commonwealth, are a significant monument to his name not only as a competent administrator, but also as a great teacher.

"Nor was his influence as a builder of men limited to members of the Engineering School. As chairman of the Athletic Council for a number of years, he ushered in a new era for competitive sports at the College. As a worker on the Attendance and Scholarship Committee, on the Social Affairs Committee, as a willing and wise adviser to all who sought his help, he became a veritable shaper and saver of youth.

"Through his multitudinous activities, Dean West came into closer contact with all departments of the College than did any of his colleagues. He was a useful man who won the esteem of all. All shared the fruits of his productive career. For this we offer our gratitude. In his passing we shall experience an irreparable loss.

"The Nation was quick to see his worth during the World War, during which he bore a large part of the responsibility of managing the soldiers assigned to the College for training, a duty meritoriously performed. * * *

"His wisdom, his willingness, his practical grasp and understanding of the problems of the hour made him a public servant of such value to the State and Nation that the vacancy caused by his death will be difficult to fill."

He was married on September 20, 1905, to Mary S. Morrell, of Logan, Utah, who with five sons, Ray B., Jr., Allen M., Philip L., Willard J., and Robert E., and one daughter, Mary A., survives him.

Dean West was elected a Member of the American Society of Civil Engineers on August 27, 1928.

ARTHUR CHAMBERS WHEELER, M. Am. Soc. C. E.[1]

DIED JUNE 3, 1935

Arthur Chambers Wheeler was born at Detroit, Mich., on November 17, 1880, the son of the late Levi Lockwood Wheeler, M. Am. Soc. C. E., and Isabel (Chambers) Wheeler. He was graduated from the University of Michigan, at Ann Arbor, Mich., in 1903, with the degree of Bachelor of Science in Civil Engineering.

Most of his life was spent in an engineering atmosphere as his father, "Captain" Wheeler, until his death in 1927, was employed on river and harbor improvement work by the United States Corps of Engineers, on the Great Lakes, the Mississippi River, and the Hennepin Canal in Illinois.

After his graduation from the University of Michigan, Mr. Wheeler was employed on Hennepin Canal and Illinois River surveys and improvement work for three years, when he accepted a position with the Philippine Commission and completed various engineering projects in the Philippine Islands, including the sub-division of the City of Baguio, until 1907 when he returned to the Territory of Hawaii.

In Hawaii, Mr. Wheeler served as Assistant Engineer, United States War Department; Assistant Superintendent of the Territorial Department of Public Works; County Engineer for the County of Hawaii; and the Hawaiian Contracting Company. For several years prior to his death he practiced privately as a Consulting Engineer and Surveyor.

He was married on June 23, 1914, at Honolulu, to Harriet E. Grant. Mrs. Wheeler died in 1922 Surviving him is one son, Lee Grant, Jr.; a brother, Frank D. Wheeler; and two sisters, Mrs. William W. Clingan and Mabel Wheeler.

Mr. Wheeler was a member of the Masonic Fraternity, of the Benevolent and Protective Order of Elks, and of the Hawaiian Engineering Association.

He was a man of quiet and pleasing personality, slow to anger, and with a tendency to make few but loyal and lasting friendships. His engineering work was always marked with a fine degree of accurate detail and completeness.

Mr. Wheeler was elected an Associate Member of the American Society of Civil Engineers on October 7, 1908, and a Member on April 12, 1926.

FRANK ORMOND WHITNEY, M. Am. Soc. C. E.[2]

DIED MAY 13, 1936

Frank Ormond Whitney, the only child of Jonas and Elizabeth Corey (Rice) Whitney, was born at Fitchburg, Mass., on July 21, 1851. He was a

[1] Memoir prepared by G. K. Larrison, M. Am. Soc. C. E.
[2] Memoir prepared by Frank E. Winsor, M. Am. Soc. C. E.

direct descendant of John and Eleanor Whitney who settled in Watertown, Mass., in 1635, and seven of his direct ancestors served with the Colonial forces in the Revolutionary War. He was educated in the public schools of Fitchburg, being graduated from the High School in 1868, following which he entered the Worcester Polytechnic Institute, at Worcester, Mass., which was established in that year, and was then known as the Worcester Technical School. He was graduated from the Institute in 1871, in the first class of seventeen members, with the degree of Bachelor of Science.

Mr. Whitney was employed in the City Engineer's Office in Fitchburg during the summers of 1869 and 1870, and was with the Fitchburg Water Department in 1871. He entered the employ of the City of Boston, Mass., in the Surveying and Engineering Departments on December 4, 1871, and remained in that service until February 1, 1924, when he retired. He was Chief Engineer of the Street Laying Out Department for twenty-five years, during which period he had charge of many important projects by which the street system of old Boston was transformed from that of the "horse and buggy" age to meet the demands of present-day traffic. City improvements aggregating more than $50 000 000 were constructed under his direction. After his retirement at the age of seventy-three, Mr. Whitney continued to be active, established a consulting practice, and devoted his time to a great variety of other interests.

He became a member of the Boston Society of Civil Engineers in 1879, was a valued contributor to its publications, and served as a Director in 1894 and 1895 and as Treasurer from March, 1915 to March 1931, when he refused a renomination.

For thirty-five years, he was a Director of the Merchants Cooperative Bank, of Boston, served as Second Vice-President in 1919 and 1920, as First Vice-President from 1921 to 1933, and as President from 1933 to the time of his death. He was also a Trustee of the Eliot Savings Bank, of Boston. He was a member of the Walnut Avenue Congregational Church, of Roxbury, Mass., and served as Superintendent of the Sunday School, as a Deacon, and as Chairman of its Prudential Committee. Among other affiliations, Mr. Whitney was a member of Aberdour Lodge, A. F. and A. M., and of the Sons of the American Revolution. He was a devoted alumnus of his Alma Mater, rarely missing an Alumni Meeting in Boston or Worcester, and left a substantial bequest to the Institute. A week before his death, he was informed that the Board of Trustees had voted to confer upon him the honorary degree of Doctor of Engineering.

On October 26, 1881, he was married to Anna Myrick Snow, of Boston, who died on September 6, 1917. His only child, Franklin Snow Whitney, was born on June 4, 1883, was graduated from Harvard University in 1906, and died on February 23, 1924.

Although Mr. Whitney outlived most of his contemporaries, he retained his youthful vision, keeping in contact with new developments and with younger associates, and carrying on his varied interests with characteristic energy even to the end. He leaves many warm friends who will miss his genial presence and wise counsel.

Mr. Whitney was elected a Junior of the American Society of Civil Engineers on May 3, 1876, and a Member on January 5, 1887.

CHARLES VICTOR WITT, M. Am. Soc. C. E.[1]

Died December 6, 1936

Charles Victor Witt was born on September 25, 1877, in Gleiwitz, Germany, where he attended the public schools and, later, the High School. In 1897, he entered the Royal Technical Institute, in Dresden, from which he was graduated in 1900.

From 1900 to 1901, he was employed by Rietschel and Henneberg, specialists on large central heating systems. In 1901, Mr. Witt came to the United States and found immediate employment with the Carnegie Steel Company, at Pittsburgh, Pa., as Special Engineer for the development of machinery and processes. In 1902, he entered the employ of the Westinghouse Electric and Manufacturing Company, at East Pittsburgh, Pa., under the Engineer of Works who had charge of the arrangement of machinery, the development and maintenance of the power plant, as well as the buildings and grounds. Mr. Witt became Assistant Engineer of Works and, eventually, had full charge of this Office until 1906.

In 1906, he took the position of Manager with James McNeill and Brother Company, steel plate construction fabricators, at Pittsburgh, and shortly was made General Manager, Vice-President, and Director. Mr. Witt had full charge of the office, works, and Construction Department; became an expert in steel-plate construction; and directed the production of large steel pipe lines for municipal water supplies for many of the largest cities in the United States. He was with this firm for a period of twenty years, until 1926, and during this time had become acquainted with—and was friend of—a large circle of water-works engineers and city officials throughout the United States.

In 1926, Mr. Witt founded the Witt Steel Company, later the Witt-Humphrey Steel Company, of Greensburg, Pa. He was President of this Company and continued in the same line of steel-plate work, including a large water supply line for the City of Philadelphia, Pa. He resigned, however, from this Company in 1931, when a position as General Manager and Chief Engineer in the Steel Watermains Association, also of Greensburg, Pa., was offered to him. With a number of the largest steel pipe manufacturers of the East as members of this Association, it was organized with a view to collecting all available information and data on municipal water supply lines for ready reference, not only to the individual members of the Association but also to the water-works engineers, city officials, and the general public. Because of his expert knowledge in this line and his large circle of acquain-

[1] Memoir prepared by C. F. W. Rys, Esq., Pittsburgh, Pa.

tances among water-works engineers, Mr. Witt was chosen to head this Association. He undertook this work with his usual energy, organized the office, and made necessary and desirable contacts. In 1935, however, the new concern fell a victim to the effects of the depression and was closed. Mr. Witt's health having become seriously impaired, he finally decided in 1935 to take a trip abroad. He stayed at one of the German health resorts and returned considerably improved, but planned a complete rest. However, a heart trouble from which he had suffered, unfortunately returned, and caused his death at the comparatively early age of 59 years.

Mr. Witt was a member of the Engineers Society of Western Pennsylvania and of the German-American Technological Society.

For those who knew him, it is easy to understand why he made friends wherever he went, because in addition to a clear constructive brain, he possessed a good humor and a warm heart ready to help those who needed help.

Mr. Witt was elected a Member of the American Society of Civil Engineers on April 18, 1927.

HANS HERMANN WOLFF, M. Am. Soc. C. E.[1]

DIED OCTOBER 1, 1935

Hans Hermann Wolff, the son of Norbert and Clementine Wolff, was born in New York, N. Y., on August 12, 1877. His early education was secured in private schools, after which he entered the Engineering School of Columbia University, from which he was graduated in 1898 with the degree of Civil Engineer.

Mr. Wolff's first employment after graduation was as a Rodman for the Third Avenue Railroad Company, of New York City. He then went to Ecuador where he spent two years as Leveler, Transitman, and Topographer on the Guayaquil and Quito Railroad. On his return to the United States, he spent a short period in the Engineering Office of the Kansas City Southern Railroad Company and then went to Cape Girardeau, Mo., where he was in charge of construction on the St. Louis and San Francisco Railroad, which was then being built from St. Louis, Mo., to Memphis, Tenn. He was afterward employed for several years in railroad, bridge, and masonry construction in Pennsylvania and New York State for the New York Central, Buffalo and Susquehanna, and the New York, Pennsylvania, and Southern Railroad Companies.

As a member of the contracting firms of Allen and Wolff and Allen, Connolly, and Wolff, Mr. Wolff had charge of sewer construction in Newton, N. Y., and the building of five miles of the Delaware and Eastern Railroad, near East Branch, N. Y.

[1] Memoir prepared by Gustavus Sessinghaus, Esq., Denver, Colo.

He served as District Engineer in the State of Washington during the construction of the Chicago, Milwaukee, and Puget Sound Railroad. After the completion of this work, he established an office in Seattle, Wash., and was a member of the firm of Cross and Wolff. He was also Northwestern Representative of Hildreth and Company.

After the United States entered the World War, Mr. Wolff joined the Engineer Officers Training School and was promoted to the rank of Captain in the Engineer Reserve. He was assigned as Commanding Officer of the 556th Engineers Service Battalion, at Camp Humphreys, Virginia. This battalion was soon disbanded, and Captain Wolff was attached to the 353d Engineers Service Battalion. He was discharged from service on December 12, 1918. In 1932, he was given a certificate of capacity for promotion to the rank of Major, Engineer Reserves. He had also served as Regimental Adjutant of the 328th Engineers.

Following the war, he spent some time in New York City, giving attention to the business which his father had established. He then took up his residence at Denver, Colo., became interested in oil and mining, and spent a year at the Colorado School of Mines, at Golden, taking courses in Geology. For several years Mr. Wolff was engaged in handling oil leases, but returned to New York City in February, 1932, expecting to remain there but a short time; business matters, however, prolonged his stay until 1935.

In the spring of 1935 he had to undergo an operation for appendicitis from which he never fully recovered. His death occurred on October 1, 1935, from angina pectoris. He was buried on October 5, 1935, with military honors, in Arlington National Cemetery, at Fort Myer, Virginia. He is survived by his widow, the former Frances A. Babcock, of Kansas City, Mo., to whom he was married on October 25, 1915.

He was a member of the Colorado Scientific Society, of Denver; the Army and Navy Club, of Washington, D. C.; Arcade Lodge, F. & A. M., of Arcade, N. Y.; Denver Chapter No. 2, R. A. M., Denver; Colorado Commandery No. 1, Knights Templars; Columbia University Alumni Association; and the Reserve Officers Association of the United States.

Mr. Wolff was a capable engineer and a fine type of citizen. As a youth he had instruction in the violin, became an accomplished performer, and displayed a taste for artistic and cultural things. As a student of history, he understood well the causes of the rise and fall of the different peoples. He argued zealously for the preservation of the rights, liberties, and prerogatives of the American citizen. He protested against any manifestation of intolerance. He kept up his military training and preserved his interest in military matters. With a wide circle of friends and acquaintances, his association with them was of a most wholesome nature. Modest and unassuming, life meant much to him; he enjoyed living; his passing was untimely, and he will be missed by those who knew him.

Mr. Wolff was elected an Associate Member of the American Society of Civil Engineers on January 8, 1908, and a Member on September 5, 1911.

BRUCE CLINTON YATES, M. Am. Soc. C. E.[1]

DIED AUGUST 10, 1936

Bruce Clinton Yates was born on a farm near Grafton, Taylor County, W. Va., on September 10, 1869. His parents came to Grafton (then in Virginia) soon after the first settlers arrived there in 1852, and engaged in farming near the Tygart River. When the boy was twelve years old, his parents moved with their family of four boys and one girl to Lancaster County, Nebraska, settling on a farm near Emerald, seven miles from Lincoln, at that time the new Capital of the State.

He attended a country school, and studied two years in preparation for entrance to the University of Nebraska, at Lincoln, successfully passing the entrance examinations in 1888. Pursuing the course in Civil Engineering, he was graduated in 1892, with the degree of Bachelor of Civil Engineering.

The Engineering Department of the Burlington and Missouri River Railroad Company, in Nebraska (later, the "lines west of the Missouri River," of the Chicago, Burlington and Quincy Railroad Company) was located in Lincoln, and was busy with the construction of the line to Billings, Mont. Like many another engineering student of the State University at Lincoln, Mr. Yates found service during three summer vacations on this railroad construction in Wyoming and Montana. From June, 1892, he continued in such work until October, 1894, when the line was completed to Billings, and the forces were reduced, due to the general depression in business. As Instrumentman and Computer on grading construction, Assistant on track-laying, Inspector on pile-driving, and Division Engineer on construction, his experience was varied and extensive.

From October, 1894, to February, 1895, Mr. Yates (with others released by the Burlington and Missouri River Railroad Company) was with the Butte, Anaconda and Pacific Railroad Company on location in the Rocky Mountain region in Montana. From April to November, 1895, he was again on construction work with the Burlington and Missouri River Railroad Company, this time on the Spearfish Line in the Northern Black Hills, in South Dakota, where he came in contact with conditions surrounding the Homestake Mine and with mining in the gold fields of the Black Hills.

From November 1895, to October, 1897, Mr. Yates was in general engineering practice at Deadwood, S. Dak., in partnership with Mr. Frank S. Peck, largely on Government survey contracts and mine surveys.

On October 1, 1897, he began his life work with the Homestake Mine, as a member of its Engineering Staff. Thereafter, he was promoted through the positions of Assistant Engineer, Chief Engineer, Assistant Manager, and General Manager. As Chief Engineer, he devised the sys-

[1] Memoir prepared by F. T. Darrow, M. Am. Soc. C. E.

tem of mining by shrinkage stopes which displaced the square sets of earlier days; as General Manager, during the period of Homestake's great growth and modernization, he directed and co-ordinated these plans. Increasingly, as the years passed, his merits were appreciated throughout the State, and during these recent years of depression, he was frequently called to the State's service.

In addition to his duties as General Manager of the Homestake Mining Company, Mr. Yates also had charge of the Wyodak Coal Mine, at Gillette, Wyo.—a strip mine operating a 90-ft vein of lignite coal.

The Homestake Mine is an old mine. As a producer of gold from low-grade ores, it has been worked profitably for sixty years. It is the leading industry of the Black Hills in mines and lumbering, and is one of the largest gold mines in the world. It owns most of the Town of Lead, S. Dak. Three generations of many families have grown up about it and found work with it.

Since January 1, 1918, Mr. Yates, as General Manager with headquarters at Lead, had been its operating head. As such he had carried on the Homestake policy of friendly co-operation with all interests of the community and a helpful and liberal policy with the employees.

A quality of humanness endeared Mr. Yates to every one with whom he came in contact. At heart, he had an abiding interest in the welfare, not only of Company employees, but of all townspeople, and the industrial peace of Lead as well as the staunch loyalty of Homestake employees to Mr. Yates were substantial evidences of his greatness.

He never regarded another man's difficulties as too trivial to concern him. Employees had implicit faith in his sense of fairness. Those who came in contact with him along lines of charitable enterprises, always were surprised at his knowledge of unfortunate townsfolk.

It is recalled that during the influenza scourge of 1918, which turned the Homestake Recreational Building into a community hospital, Mr. Yates made a personal inspection every day. That incident was characteristic of his kindly interest in the townspeople. Countless incidents of small personal charities and kindlinesses not generally known to the public could be cited.

Mr. Yates was a member of many societies, among which were the American Institute of Mining and Metallurgical Engineers, the American Mining Congress, and the National Safety Council, of which he had served as Chairman of the Mining Section. He introduced safety measures in mine work as well as methods which have been fully proved and adopted generally in such work. He also held the Honorary Degree of Engineer of Mines from the South Dakota School of Mines, at Rapid City.

He was married on November 21, 1896, to Ada Myers, of Beatrice, Nebr., who died in Lead, on May 26, 1928. He was married, in 1929, to Carmen Martin, of Iron Mountain, Mich. He is survived by his widow, Mrs. Carmen Yates; a sister, Gertrude Yates; and five children, Arthur, George C., Mrs. Mary Cadwallader; and Mrs. A. D. Bell. Another son, Bruce C., Jr., died in Berkeley, Calif., on November 17, 1936.

His death was due to an attack of coronary thrombosis. Over-exertion and loss of rest on preceding days, when a forest fire was threatening the lumber camp at Moskee, Wyo., may have contributed to his death.

Mr. Allan J. Clark, Chief Metallurgist of the Homestake Mining Company, writes[2] of Mr. Yates as follows:

"But it was not alone his friendliness that made Yates so readily accessible to all, of whatever station in life. It was his humanness, his ready sympathy with the need of others. Some months ago, he was lightly told he might expect an early visit from one of the chronically aggrieved, and the suggestion was made that he should spare himself from many such visits. His reply, to the effect that even if he gave no help, the visitor felt better for having told his troubles, was so typical of his consideration that it merits setting down here."

Mr. Yates was elected an Associate Member of the American Society of Civil Engineers on June 7, 1905, and a Member on October 15, 1923.

AARON STANTON ZINN, M. Am. Soc. C. E.[1]

DIED MAY 7, 1936

On Saturday afternoon, May 9, 1936, in a little cemetery adjacent to a country churchyard, a few miles south of Deer Creek, Ind., there was laid to rest an Engineer who had participated in an important capacity on one of the nation's greatest engineering projects—the Panama Canal.

As the writer stood under the shade of a big cedar tree and looked over the fence at a farmer furrowing, there came to his mind the first verse of Gray's "Elegy Written in a Country Churchyard":

"The curfew tolls the knell of parting day,
The lowing herd winds slowly o'er the lea,
The ploughman homeward plods his weary way,
And leaves the world to darkness and to me."

And that other verse, which Wolfe quoted the night before he took Quebec,

"The boast of heraldry, the pomp of pow'r,
And all that beauty, all that wealth e'er gave,
Await alike the inevitable hour.
The paths of glory lead but to the grave."

There was a striking contrast to the quiet of the eternal home of Aaron Stanton Zinn with the surroundings of his home for many years at Empire, Canal Zone, just on the edge of the Culebra or Gaillard Cut, where one could look down on myriads of steam shovels, steaming construction trains, and hear the thunder of the dynamite roaring the removal of that rock cut.

[2] *Mining and Metallurgy*, October, 1936.

[1] Memoir prepared by Alonzo J. Hammond, Past-President, Am. Soc. C. E.

Aaron Stanton Zinn, the son of George and Eliza (Nutt) Zinn, was born near Deer Creek, Ind., on August 26, 1862. His great-grandparent on his father's side came from Germany in 1749 and settled in Pennsylvania; and on the mother's side from Switzerland, also settling in Pennsylvania. Each side had a son, Jacob, in the Revolutionary War.

Jacob Zinn, the grandfather, moved to Carroll County, Indiana, in 1851, locating on a 480-acre farm near Deer Creek, later giving the land needed for the cemetery and the United Brethren Church. In this little cemetery, there lie thirty-two Zinn relatives, and now Aaron Stanton Zinn is with them.

George Zinn, the father of Stanton, in 1856, settled on a 160-acre farm near that of Jacob, the grandfather, and in 1865 the family moved to Logansport, Ind. Stanton Zinn was a twin in a family of eight children, four boys and four girls.

Mr. Zinn was educated in the public schools of Logansport, was graduated from the High School in 1884, and, later, took a 3-yr course in Civil Engineering at Rose Polytechnic Institute, at Terre Haute, Ind.

Leaving college in June, 1887, he entered the employ, as Draftsman, of the Atchison, Topeka and Santa Fé Railway Company, following which he was connected, successively, with the Illinois Central Railway Company; the Harney Peak Tin Mining Company; the Pennsylvania Railroad Company; and the Elgin, Joliet and Eastern Railway Company (Chicago Outer Belt Line), designing shops at Joliet, Ill., for the last-named line.

Mr. Zinn then entered politics and was elected County Surveyor of Will County, at Joliet, and from 1892 to 1895 he also carried on a general engineering business in partnership with Mr. O. R. Rauchfuss, a former classmate.

From 1895 to 1900, he was with the Vandalia Railway Company as Assistant Engineer, Maintenance of Way, at Terre Haute, in charge of construction surveys, spiraling curves, and the location and construction of more than 100 miles of track to coal mines, etc.

An important event occurred in June, 1897, when he was married to Mabel Gray Cooper, of Marquette, Mich., a charming, vivacious girl whose restless energy was actuating in the life partnership which resulted. From this union there was one child, a son, Kenyon Cooper Zinn.

From 1900 to 1904, Mr. Zinn was Assistant Engineer on track elevation for the Chicago and Western Indiana Railway Company, at Chicago, Ill. During 1904 and 1905 he was with the Rock Island Railway Company, first as Division Engineer of the Oklahoma Division, and, later, as Principal Assistant Engineer, at Oklahoma City, Okla., in charge of the maintenance and construction of about 1 800 miles of road.

After another engagement with the Chicago and Western Indiana Railway Company, for which he designed a 52-stall elliptical engine-house, he took charge, as Construction Engineer, for the Michigan Central Railway Company, at St. Thomas, Ont., Canada, of the design and construction of 95 miles of second main track. While on this work in October, 1906, he was called to the Panama Canal by John F. Stevens, Past-President and Hon. M. Am. Soc. C. E., Chief Engineer, and appointed Resident Engineer on the

Culebra, or Central, Division (32 miles) where he remained for seven and one-half years.

As is well known, the work on the Culebra Cut was a transportation problem, so that the railway experience of Mr. Zinn, which had attracted the attention of Mr. Stevens when he also was with the Rock Island Railway Company as Vice-President, was of vital importance in the handling of the railway problems involved, and Mr. Zinn's services, during the latter part of Mr. Steven's term, no doubt assisted materially in the placing into operation of that effective railroad system which produced the economies of operation for the Culebra Cut.

When the late Col. (afterward Maj. Gen.) George Washington Goethals, U. S. Army, M. Am. Soc. C. E., became Chief Engineer and Col. David St. Pierre Gaillard, U. S. Army, Division Engineer of the Central Division, Mr. Zinn acted as Division Engineer during the illness of Colonel Gaillard. When he decided in 1914 to leave the Canal, he was recommended by Colonel Goethals to the President of Panama for the position of Consulting Engineer and took charge of the building of the railway from Pedregal to Boquette, or from the coast to the coffee ranches. He spent two and one-half years on engineering work for the Republic of Panama, the opening of the railroad being attended by much pomp and ceremony, with President Belisaro Porras of Panama attending.

During 1917 and 1918, Mr. Zinn was engaged in war work, first as Assistant General Superintendent of Construction for Camp Sherman (Chillicothe, Ohio, Cantonment) and, later, with the New York Nitrates Corporation, in New York, N. Y. From 1919 to 1923 he was with the Missouri Pacific Railroad Company at St. Louis, Mo., most of the time, in the Valuation Department.

In April, 1923, Mr. Zinn removed to Los Angeles, Calif., and took a position as Chief Draftsman on the Harbor Plans for Los Angeles, for the Chamber of Commerce, continuing in this work until 1925.

From 1925 until his death, with the exception of a leave of absence on account of ill health, he was connected with Los Angeles County, engaged principally in the designing of sewers. His illness became serious when on a visit to his sister, at South Bend, Ind.; perhaps the All-Wise Providence arranged it so he could be laid in his last resting place, as provided by his forefathers. He is survived by his widow and his son.

Mr. Zinn held memberships in the Western Society of Engineers and the American Railway Engineering Association, and had contributed articles to the technical press, as well as to the publications of the Western Society of Engineers, covering the construction of the Central Division, Panama Canal, and the Chiriqui Railway for the Republic of Panama, the latter a most interesting presentation of engineering work in a tropical country with native labor.

He was a man of sterling character; his friendship was genuine and complete; his praise for those he admired was without stint, and he had the confidence and regard of all his associates, as instanced decidedly by his contacts on the Panama Canal.

Mr. Zinn was elected a Member of the American Society of Civil Engineers on October 5, 1909.

ALBERT READ BAKER, Assoc. M. Am. Soc. C. E.[1]

DIED SEPTEMBER 7, 1936

Albert Read Baker was born at Norwalk, Ohio, on May 28, 1882, the son of Daniel Albert and Arabella (Benson) Baker. His family moved to California in 1894, and he received his early education in the public and High Schools of San Diego, and his technical education at the University of California, at Berkeley, Calif.

After leaving college in 1905, Mr. Baker's first work was in connection with the construction of the Stanislaus River hydro-electric power development on which he spent four years. This engagement was followed by two years as an Assistant Engineer on the reconstruction of the sewerage system and the high-pressure fire-protection system of San Francisco, Calif., which was undertaken as an aftermath of the 1906 earthquake and fire. Following this work, he spent a few months with the Snow Mountain Water and Power Company as Assistant Engineer on penstock construction, and nearly a year in British Columbia as Office Engineer in connection with the Sooke Water Supply for the City of Victoria.

In November, 1912, Mr. Baker returned to California to become Chief Engineer of the Marin Municipal District organized to provide a water supply for about ten or twelve towns and adjacent territory in Marin County, across the Golden Gate from San Francisco—a task which was to absorb his best efforts for more than six years, and the successful consummation of which blazed the way for a number of similar developments throughout the State. The principal physical features of the project were the Alpine Dam, a gravity concrete structure, 100 ft in height; the Pine Mountain Tunnel, 8 ft in diameter and 8 700 ft long; and seven miles of pipe line, with the necessary roads and appurtenant structures. The construction of these works, however, was preceded by a task of even greater magnitude, namely, the development, in the face of strenuous opposition, of the finally approved plan for the project, the overcoming of legal and political obstacles, and the final campaign resulting in the approval by the electorate of a $3 000 000 bond issue for construction purposes. All this work was carried on under the inspiring leadership of the late M. M. O'Shaughnessy, M. Am. Soc. C. E., Consulting Engineer for the project, and a member of its Board of Directors, but its success may be ascribed, in no small measure, to Mr. Baker's firm persistency of purpose and

[1] Memoir prepared by Charles A. Bissell, M. Am. Soc. C. E.

undeviating courage in the face of seemingly insurmountable obstacles, as well as to Mr. O'Shaughnessy's engineering vision, unfailing optimism, and fighting spirit.

On the completion of this work late in 1919, Mr. Baker was for a year with the Southern California Edison Company, in charge of the diamond drill exploration of the foundations of the Shaver Lake Dam, followed by work with the Pacific Gas and Electric Company on the construction of the Spring Gap Power House on the Stanislaus River. During 1922 and 1923, he was in charge of all construction work at Early Intake, on the Hetch Hetchy water supply project for the City of San Francisco, including the intake section of the Hetch Hetchy Tunnel and the Early Intake diversion dam.

After a year spent in valuation work for the East Bay Municipal Utilities District, Mr. Baker, in June, 1925, became connected with the construction of the Oakland-Alameda Estuary tube, a vehicular under-pass connecting the East Bay cities of Oakland and Alameda, Calif. His first work in this connection was as Engineer for Robinson, Roberts, and Rohl, the Sub-Contractor for the Approach and Tunnel Section at the Oakland end. Later, he served as Engineer and Assistant Superintendent for the General Contractor, the California Bridge and Tunnel Company, on the construction of the twelve pre-cast reinforced concrete sections, each 203 ft in length, and having an interior diameter of 32 ft, which were constructed in the dry dock at Hunters Point, in San Francisco, and one after another floated across the Bay and sunk to line and grade to form the subaqueous section of the tube. An interesting and comprehensive paper by Mr. Baker on the construction of this tube was published in the technical press.[3]

In September, 1929, Mr. Baker joined the Engineering Staff of The Metropolitan Water District of Southern California, an organization of municipalities formed for the purpose of bringing Colorado River water across the State of California, over 250 miles of desert and mountain, to provide a supplemental domestic water supply for the population of the Southern California coastal plain. At this time preliminary surveys had largely been completed, the selection of the route for the 1 500 sec-ft aqueduct had been practically determined, and one of the immediate tasks was the development of the details of plans on a self-liquidating basis for financing the project and the repayment of its cost, which was estimated to be in excess of $200 000 000. Into these financial studies for which his earlier experience with the Marin Municipal District had given him valuable training, Mr. Baker plunged with characteristic energy and enthusiasm. During the two-year period preceding the bond election of September 29, 1931, at which the issue was carried by a 5 to 1 majority, and subsequent thereto, he was responsible for the production of a large volume of financial studies of great importance in establishing the feasibility and sound financial basis of the enterprise.

[3] *Engineering* (London, England), September 26 and October 10, 1930.

As construction on this project got under way (the work was begun almost simultaneously at numerous points in the effort to relieve the prevalent unemployment crisis), Mr. Baker was given the responsibility as Materials Co-Ordinator for planning and expediting the inspection and delivery of construction materials for the entire aqueduct and distribution system work, both contract and force account. It was in the midst of this work, in the prime of his life, that after a brief illness he passed away on September 7, 1936.

Mr. Baker possessed a pleasing personality and high character. He was thoroughly reliable and possessed a fine balanced judgment. He was unusually co-operative in working with others. Mr. Baker lived simply with his family to whom he was exceptionally devoted.

On March 12, 1913, he was married to Ivy Hayward, who, with one son, John Raymond, and two daughters, Marjorie Hayward and Katharine Read, survives him.

Mr. Baker was elected an Associate Member of the American Society of Civil Engineers on October 1, 1913.

LeROY WRIGHT BARBOUR, Assoc. M. Am. Soc. C. E.[1]

Died September 14, 1936

LeRoy Wright Barbour was born in Greenwich, N. Y., on October 22, 1882, the son of Sidney Matthew and Elizabeth Remington (Wright) Barbour, whose ancestors came to America in the Seventeenth Century.

In 1888, Mr. Barbour's parents moved to California, taking up their residence at La Manda Park, near Los Angeles. Shortly thereafter the family settled at Corona in Riverside County, California. Here, Mr. Barbour attended the grade school, and finished his college preparatory work at the Palo Alto High School. In the fall of 1903, he enrolled at Stanford University, taking up the course in Mining and Metallurgy. This line of study did not exactly appeal to him and he finally decided upon a Civil Engineering course, receiving his degree in 1909.

Immediately after his graduation, Mr. Barbour obtained employment with the Banco Del Oro Mining Company, at Magdalena, Sonora, Mexico. This work was in charge of Horace Pomeroy, an experienced Mining Engineer and a former graduate of Stanford University. Here, Mr. Barbour acted as Assistant Engineer and Refiner and obtained much valuable experience.

The period from October, 1910, until July, 1913, he spent in making surveys on a water project for the City of Los Angeles, near Blyth, Calif., and acting as Resident Engineer for the Nevada, California Power Company, at Bishop, Calif.

---

[1] Memoir prepared by E. D. Cole, Esq., Culver City, Calif.

During the following three years Mr. Barbour was employed as Construction Superintendent for the firm of Mahoney Bros., Allinson, and Cole, of San Francisco, Calif. This firm was engaged in building large earthen reservoirs for the storage of heavy crude oil. The inside area of these reservoirs was completely lined with a 3-in. slab of concrete. As it was essential that these slabs should be oil-proof and free from checks and cracks, it was imperative that great care should be exercised in their construction. The fact that these reservoirs are still in use to-day and have proved satisfactory in every way is history, and a large share of the credit is due to the painstaking care and the thoroughness with which Mr. Barbour directed this work.

Early in 1917, Mr. Barbour entered the employ of the Empire Gas and Fuel Company, at Bartlesville, Okla., where he acted as Resident Engineer of the Company's Gainesville Refinery. He remained with this Company until 1920, under Mr. J. J. Allinson, then Chief Engineer. During this time, he acted as Resident Engineer at the refinery at Cushing, Okla., and, later, at the Ponca City, Okla., plant.

About this time, Mr. Allinson resigned as Chief Engineer to take a similar position with the Pierce Oil Corporation, and he had become so favorably impressed with Mr. Barbour's work and ability that he decided to take him with him. Thus, it was that early in 1923, Mr. Barbour was established as Resident Engineer at the refinery at Tampico, Tamps, Mexico. From that time until 1927, he was, successively, Resident Engineer, Assistant Superintendent, and Superintendent of the plant.

In 1930, Mr. Barbour was made Manager of Production and Refineries for the Pierce Corporation, with headquarters at Tulsa, Okla. This position he held until the Pierce interests were acquired by the Sinclair Refining Company in 1931. He was then transferred to Fort Worth, Tex., as Superintendent of the Fort Worth and Gladewater Refineries. This position he held at the time of his death.

Mr. Barbour possessed a keen analytical mind and boundless energy. These qualities, in addition to an entirely likable nature, made him outstanding on any work that he undertook. "Roy," as he was familiarly known, was a natural leader of men and was highly respected by all and loved by those who knew him well. His zeal and intense interest in his work were unfortunately the contributing factors that led to his death. It was on one of his frequent tours of inspection around the refinery that he noticed that the workmen making an excavation were confused over some detail of the work. Mr. Barbour leaped down into the excavation and accidentally bruised his knee against an excavating tool. This bruise, although not considered serious at the time, eventually developed into sarcoma which, later, caused his death.

Mr. Barbour was married to Blanche Mankins, the daughter of Henry and Josephine Mankins, of San Luis Obispo, Calif., in 1915, and to this union four daughters, Josephine, Elizabeth, Mabel, and Billie, were born. Mrs. Barbour and his four daughters survive him. He is also survived by his father and mother and by one sister.

He was a Mason, a member of Delta Lodge No. 425 of Tulsa, Okla., and of the Cushing, Okla., Chapter No. 81, Royal Arch Masons.

He will perhaps be remembered best because of his infectious laugh that endeared him to many. He was essentially a man's man and a tried and true friend, and to those of us who knew him best he leaves a priceless heritage in that his life was an exemplification of the meaning of friendship in its truest sense.

Mr. Barbour was elected an Associate Member of the American Society of Civil Engineers on April 19, 1920.

ARTHUR TAYLOR BRAGONIER, Assoc. M. Am. Soc. C. E.[1]

DIED JUNE 29, 1936

Arthur Taylor Bragonier was born at Shepherdstown, W. Va., on August 20, 1890, the son of the late Joseph S. and Rosalie B. Bragonier. He was a descendant of an old Southern family, his grandfather having served as a Captain in Stonewall Jackson's Brigade during the Civil War.

He was graduated from Shepherd College and then studied at Washington and Lee University, at Lexington, Va., and at Lehigh University, at Bethlehem, Pa. He received the degree of Bachelor of Science in Civil Engineering from West Virginia University in 1916.

Mr. Bragonier began his professional career as Chainman for the Norfolk and Western Railway Company in 1912, and for nearly five years, from June, 1914, until December, 1919, he enjoyed a varied engineering career, as follows: Assistant to the County Road Engineer on road surveys in McDowell and Logan Counties, in West Virginia; this was followed by an engagement as Chainman, with some office work, with the Western Maryland Railway Company; Draftsman in the Valuation Department of the Norfolk and Western Railway Company; and in charge of a field party for the Baltimore and Ohio Railway Company. More than a year was spent as Transitman with The Koppers Company, of Pittsburgh, Pa., on the layout and checking of toluol recovery plants in Cleveland, Ohio, Washington, D. C., and New Orleans, La., and in charge of the construction of an 1 800-ton reinforced concrete coal bin at Norristown, Pa. In July and August, 1919, Mr. Bragonier served as County Road Engineer of Jackson County, West Virginia, on the preparation of Federal Aid maps and on the layout and construction of concrete roads; and from August to December, 1919, he was Assistant to the County Road Engineer of Doddridge County, West Virginia, on the layout and supervision of construction of a concrete road.

In January, 1920, he was appointed Instructor in Surveying in the College of Engineering at West Virginia University, which position he retained until

---

[1] Memoir prepared by Professor R. P. Hron, Huntington, W. Va., assisted by Howard A. Levering, M. Am. Soc. C. E.

July, 1922, his summer vacations having been spent with the State Road Commission. In July and August, 1922, he was employed as Designer in the Division Engineer's Office of the State Road Commission, with headquarters at Morgantown, W. Va.

In recognition of Mr. Bragonier's achievements in the field of Highway Engineering, he was given the Detroit-Edison Fellowship in Highway Engineering, in August, 1922. This Fellowship permitted him to study at the University of Michigan, Ann Arbor, Mich., from which he received the degree of Master in Civil Engineering in 1923.

From June, 1923, to October 22, 1925, he served as Assistant Engineer with the West Virginia State Road Commission, Division No. 2, Huntington, W. Va., in charge of the construction of concrete and bituminous macadam road surface and on road design.

In September, 1925, Mr. Bragonier was appointed first as Instructor and then as Assistant Professor of Applied Mathematics at Marshall College, at Huntington, W. Va.; and, later, on account of his excellent teaching ability, he was made Associate Professor, in which position he continued until his death. At the time he was taken ill, Professor Bragonier was engaged in a thorough study of traffic accidents with a view to their prevention. He was greatly instrumental in the development of the two-year course in Engineering at Marshall College and a number of young engineers, now eminent in the profession, gained their basic engineering knowledge from him. In 1935, he was again honored when West Virginia University conferred on him the degree of Civil Engineer.

Professor Bragonier was a member of the American Society for the Promotion of Engineering Education, and the West Virginia Society of Professional Engineers. He was also a member of the Masonic Fraternity (Mt. Nebo Lodge No. 91, A. F. and A. M.; Macklenberg Chapter No. 31, Royal Arch Masons; and Potomac Commandery No. 5, Knights Templars). He was also a member of Trinity Protestant Episcopal Church, at Huntington.

He died at his home, in Huntington, after a short illness of bacterial endocarditis, on June 29, 1936, and was buried in the family plot at Elmwood Cemetery, at Shepherdstown, where four generations of his family are interred.

He is survived by his widow, Mrs. Dorothy (Berry) Bragonier, whose native home was Martinsburg, W. Va., and to whom he was married on June 10, 1924, and a brother Dr. Richard Keene Bragonier, of Keystone, W. Va. Mrs. Bragonier is also a teacher in the Teacher's Training School of Marshall College, at Huntington.

Professor Bragonier was an excellent teacher, and was intensely interested in his work. He always stood for excellence in scholarship, and had little patience with students who did not put forth their best efforts. He was a scholar by nature, and will be greatly missed by both the Faculty and the students of Marshall College. He taught so many engineering subjects that it will be difficult to find a man who can successfully take his place.

Professor Bragonier was elected an Associate Member of the American Society of Civil Engineers on February 23, 1932.

CHARLES WILLIS CHASSAING, Assoc. M. Am. Soc. C. E.[1]

Died June 1, 1934

Charles Willis Chassaing, the son of Joseph Henry and Marie Louise (Gratiot) Chassaing, was born in Gratiot, Wis., on December 1, 1872. He received his technical education at Washington University, in St. Louis, Mo., from which he was graduated in 1896 with the degree of Bachelor of Science.

From July, 1896, to March, 1898, Mr. Chassaing was Assistant Engineer in the Chief Engineer's Office of the Union Pacific Railway Company, on computations and plans for railway bridges; he also acted as Field Inspector during the erection of several railway bridges.

He was with the St. Louis Water Company, in the Extension Office, from June, 1898, to April, 1899, and assisted in plate-girder design, railway bridge design, and structural steel work for buildings.

In April, 1899, Mr. Chassaing entered the employ of The Union Iron and Foundry Company, of St. Louis, serving as Draftsman until about June, 1902, when he became Chief Draftsman with supervision of all shop drawings and of listing and ordering material. He also designed the steel work for several buildings, consisting of roof trusses, plate girders, columns, etc.

He served as Engineer with Eames and Young, Architects, of St. Louis, from April, 1907, to August, 1909. In this position he designed the steel work for the Crunden Branch Library and The David Rankin, Jr., School of Mechanical Trades, at St. Louis, and for hospital buildings for the Federal Penitentiaries, at Atlanta, Ga., and Leavenworth, Kans., and other buildings.

From August, 1909, to September 1910, Mr. Chassaing was engaged with E. J. Eckel and Company, Architects, at St. Joseph, Mo., as Engineer and Superintendent of Construction. As such, he designed steel-frame and reinforced concrete structures, and also supervised construction work in the field.

From September, 1910, until his death, he was in the employ of Selden-Breck Construction Company, General Contractors, of St. Louis, in the capacity of Structural Engineer and Estimator. His activities with this Company were many, including designing, quantity surveys, purchasing, and the administration of construction work. During the World War, he had charge of the surveying and laying out of the work in connection with the construction of both Camp Doniphan, at Fort Sill, Oklahoma, and Fort Benning, at Columbus, Ga.

Modest, a man of few words, conscientious, and of integrity beyond reproach, Mr. Chassaing gained the respect and admiration of all with whom he came in contact, and gave willingly to any one needing assistance He took great delight in solving technical problems in engineering.

[1] Memoir prepared by Selden-Breck Construction Co., St. Louis, Mo., from information on file at the Headquarters of the Society.

Although he never married, he was fond of home life, where he spent the greater part of his leisure time in reading. His main recreation was hunting and trap-shooting.

Mr. Chassaing was elected an Associate Member of the American Society of Civil Engineers on September 6, 1910.

WILLIAM DRISCOLL, Assoc. M. Am. Soc. C. E.[1]

Died December 6, 1935

William Driscoll was born on May 23, 1870, at New Britain, Conn. He was the son of John and Mary (Halloran) Driscoll. His father and mother, natives of Ireland, came to the United States in early youth and were married in this country.

His early education started in the public schools of Greenfield, Mass., and was supplemented while a cadet-student by special courses in Civil Engineering at Norwich University, at Northfield, Vt. Although he was not graduated from the University, he often spoke with deep affection of his college days and of friends made at Norwich.

Mr. Driscoll's unusually broad and varied experience as a Locating and Construction Engineer carried him through many foreign countries. He blazed many trails through remote wilderness zones of Mexico, the West Indies, Central America, and Brazil, on railroad location and construction. He was also called to take responsible charge of hydro-electric power developments in Spain prior to the World War. On several assignments, after the projects were built, he was also retained as a Field Engineer on maintenance and operation.

Mr. Driscoll won an enviable reputation as an Engineer who could be trusted to undertake and carry on responsible assignments in the most difficult wilderness zones where the engineer must master all field problems, ranging from reconnaissance into location, and carry on through to the finish of construction. He could be depended upon to lay out his camps and to organize and direct the work of both skilled craftsmen and the primitive workers of the jungles and the mountains. He handled his field forces ably, with tact and discretion, and obtained results with minimum friction.

The best evidence of Mr. Driscoll's trustworthiness, constancy, and intelligent devotion to duty is shown by the fact that he was repeatedly recalled by his superiors. Often when completing one assignment in a foreign country, he received cabled offers simultaneously from previous associates inviting him to go to other countries where his former chiefs were inaugurating new projects. A list of the railroad, power, and general development

---

[1] Memoir prepared by J. A. Sargent, M. Am. Soc. C. E.

projects on which Mr. Driscoll was employed, reads much as if it were a compilation of the more difficult feats of railroad and hydro-electric power engineering through the mountainous wilderness zones of Mexico, Central America, and South America, not to mention many interesting and difficult tasks completed in various parts of the West Indies.

Soon after finishing an assignment for the Cuba Railroad Company, prior to the World War, he was called to Spain as Assistant Engineer, resident on the Lerida Weir Dam that was being built on the Segre River up stream from the ancient Town of Lerida. This was the location where, about 49 B. C., Julius Cæsar shortened and widened the river by cutting several parallel channels across the "short end of the horseshoe", following one of the notorious destructive floods of the Rio Segre. The whole story of this earlier engineering job is told in Caesar's Commentaries, covering the "Siege of Ilerda." During the construction of the present Lerida Dam on the identical site of Caesar's operations, William Driscoll obtained and read the leading works describing this job which had been started nearly twenty centuries before and which Mr. Driscoll helped to finish. It was a deep satisfaction to him that he was permitted to see the finish of such a project devoted to the beneficient use of water instead of strategic use in war.

A well-known General Manager of railroad construction and operation puts "in a nutshell" what many other friends and associates have stated in effect:

"His work was always satisfactory. He was very methodical and constant. The training that Bill Driscoll received at the Military Academy in his earlier days stayed with him through life. This was shown by his exceptional orderliness."

Another friend and admirer remarked casually that it was always a pleasure, after a hard ride, to reach one of "Bill" Driscoll's camps. No matter in which jungle, forest, or mountain wilderness the trails crossed, his camps would be well located, as nearly like "Spotless Town" as painstaking care could make them. They were sanitary and supplied with as many of the "comforts of home" as ingenuity and foresight could contrive.

Like so many engineers who have blazed wilderness trails, William Driscoll for years looked forward with deep longing to the possession of a farm and a home. His habit of carefully planning ahead showed again in planning his retirement. About the time he had completed his last field assignment in 1927, in connection with the International Railways of Central America, he bought a farm near St. Inigoes, Md., and lived there. He died at St. Inigoes on December 6, 1935. His friends and former co-workers in many countries remember him with affection. He always gave his best to the task in hand. He was a good friend with whom to live and work.

He had three sisters and one brother, and is survived by one sister, Mrs. Catherine Sullivan, of Middletown, Conn., and by his brother, Mr. J. E. Driscoll, of Savannah, Ga.

Mr. Driscoll was elected an Associate Member of the American Society of Civil Engineers on September 12, 1916.

HARRY HENRY FROST, Assoc. M. Am. Soc. C. E.[1]

DIED JANUARY 26, 1922

Harry Henry Frost was born in Bay City, Mich., on November 27, 1886. He was the son of Herman Charles Frost and Dorothea (Small) Frost. His father came to Michigan from New York, N. Y., about 1870; his mother's parents were pioneers in Michigan, in the vicinity of Detroit. He was a graduate of the Bay City High School in 1904, and of the Civil Engineering Department of the University of Michigan, Ann Arbor, Mich., in 1908. In recognition of his scholastic attainments he was elected, in his Senior year, to Sigma Xi Honorary Fraternity.

Mr. Frost began the practice of his profession, immediately upon his graduation, as a Surveyor in connection with coal mines in the Saginaw Valley, in Michigan. On August 26, 1908, he was employed as an Assistant Civil Engineer with the Department of Water Supply, at Detroit, Mich., but on May 7, 1910, he resigned to become Chief Civil Engineer to the Department of Parks and Boulevards, of Detroit. In January, 1911, he accepted the position of Superintendent of the City Water-Works Company at Akron, Ohio; and, after the acquisition of the property of the Water Company by the City of Akron on April 1, 1912, he retained his position as Superintendent, through five administrations, until his death. He also acted as Superintendent of the Akron Garbage Disposal Plant during 1915-16, while that plant was under construction and until it was in successful operation.

Mr. Frost possessed an unusually pleasing personality. Endowed with a jovial spirit and a natural kindliness, he "had fine capacity for friendship and was generally beloved." He was popularly known as "Brakie" and "Jack." He was President of his High School Class and of his Senior Class at the University of Michigan. A former employer writes: "I was very fond of Harry Frost;" and a former associate relates of "Jack" that: "On one occasion, late on a cold night, he and the trouble foreman crawled through water, curb deep, in a low spot on a down-town street, fumbling for the valve-box, to shut off a break. That was his style and the men loved it." In a spirit of "service" Mr. Frost took a personal interest "in each of his fellow workers" which strengthened their attachment to him.

He was an excellent administrator in public office. He had the "knack" of handling his employees, the public, and the politician. From 1910 to 1920, the population of Akron increased from 69 000 to 208 000, and Mr. Frost was successful in his efforts to meet the demands for increased water-works facilities required by this remarkable growth. The following is quoted from the Akron Rotary publication of February 7, 1922:

"Through the change from private to municipal ownership of the City Water Plant, and through all political and partisan changes that have taken

[1] Memoir prepared by Louis E. Ayres, M. Am. Soc. C. E.

place in the decade, there was never any question as to who should head this important branch of our municipal government. And his retention was based solely on merit and proved achievement."

* * * * *

"During a period when the tremendous growth of the City required public officials to do miracles in engineering accomplishment, Harry Frost measured up fully to the necessities of the day."

For three years prior to his death, Mr. Frost suffered from diabetes. He knew the implications in a young man, but he never let the shadow affect him, other than to put his affairs into the best order possible. He had an optimistic philosophy which he expressed in the words: "You may be disappointed, but never discouraged." To the end he replied to many solicitous inquiries regarding his health that he "was getting along just fine." Death came suddenly from a throat infection which could not be corrected because of the diabetic condition.

Mr. Frost was active in the civic and business affairs of Akron. He was interested in banking, real estate development, and automobile manufacturing. He was a member of the Akron City Club, University Club, Rotary Club, and the Masonic Order.

On June 24, 1915, he was married to Mareta Lyon, daughter of Dr. O. A. Lyon, of Akron. He is survived by his widow and a daughter, Betsy Jane Frost.

Mr. Frost was elected an Associate Member of the American Society of Civil Engineers on June 4, 1913.

CONWAY ROBINSON HOWARD, Assoc. M. Am. Soc. C. E.[1]

Died August 26, 1936

Conway Robinson Howard was born in Richmond, Va., on March 27, 1881, the son of Major Conway Robinson Howard, a distinguished Civil Engineer, and Jane (Colston) Howard.

Mr. Howard came of an old Virginia family, prominent in the State since Colonial days. His early youth was spent in the city of his birth, where he attended a school conducted by his Aunt, Mrs. A. B. Camm, and another conducted by a Mr. Nolley. During the session of 1895–1896, he was a student at the Baylor School, in Chattanooga, Tenn. In the fall of 1896 he matriculated at the Virginia Military Institute, at Lexington, Va., and was graduated therefrom in the Class of 1900 in Civil Engineering.

After his graduation, Mr. Howard entered the service of The Chesapeake and Ohio Railway Company in the Engineering Department. He served that Company and the Lexington and Eastern Railway Company as Assistant and Resident Engineer in charge of heavy construction work.

[1] Memoir prepared by a Committee of the Virginia Section, consisting of C. W. Johns and Fontaine Jones, Members, Am. Soc. C. E.

In 1908 he became associated with the City of Richmond, on cadastral topographical surveys of territory which had become annexed to that City in December, 1906. Mr. Howard was engaged in this work until 1910, when he was tendered a position with the Great Southern Lumber Company and the New Orleans Great Northern Railroad Company, at Bogalusa, La. In 1911, he was appointed Chief Engineer of the Great Southern Lumber Company, in which capacity he served until 1917.

Mr. Howard joined the 17th Engineers (Railway) in June, 1917, with the rank of First Lieutenant. The regiment sailed for France on July 28, 1917, landing first in England, and was included in the first contingent of volunteers sent overseas. From England the regiment went to France and was stationed at St. Nazaire for the duration of the World War.

Among other works, Lieutenant Howard had charge of the construction of the junction yard and the flying connection of the main line of the Paris-Orleans Railroad and the line from Bordeaux to Samur. There was about 15 miles of track in the yard with engine-terminal facilities, etc., as well as an overhead crossing of the main line. He reported directly to the late Lieut.-Col. William Bowdoin Causey, M. Am. Soc. C. E., who had charge of the work in the eastern part of Base Section No. 1. Lieutenant Howard was promoted to the rank of Captain in 1918 and, after the Armistice, was detached from his regiment and assigned to the transportation rehabilitation of Central Europe under Colonel Causey, with station in Vienna, Austria. This work was under the direction of Col. William G. Atwood, M. Am. Soc. C. E., American Transportation Representative on the Supreme Economic Council and the American Relief Administration, under Herbert Hoover, Hon. M. Am. Soc. C. E.

Captain Howard was discharged from the Army in Europe and remained with Colonel Causey for several years while the latter was Technical Adviser to the Austrian Republic.

Before going to Vienna, Captain Howard was first sent to Serbia, with headquarters at Zagreb. He remained there for about nine months, most of which time he was the only American in the town. The efficiency of his work in connection with railway rehabilitation and the administration of relief was attested by two decorations, the Order of St. Save (Fourth Class) from the Serbian Government and the Cross of the Serbian Red Cross.

Mr. Howard returned to the United States in 1921 on account of the illness of his mother. In 1922, he went back to Europe with the American Relief Administration in Russia, being stationed chiefly near the Siberian border, first at Ufa during the typhus epidemic, and, later, in Ekaterinburg, the town where the Czar and his family were murdered.

Returning to America in 1923, Mr. Howard again entered the service of The Chesapeake and Ohio Railway Company and from 1923 to 1926 was assigned to special duties in the Chief Engineer's Office, in Richmond.

In 1926, Mr. Howard became associated with a concern in Louisiana making mattresses out of a moss grown in that section. This venture, however, did not prove a success, and he returned to Richmond late in 1927. He returned to The Chesapeake and Ohio Railway Company in 1927, serv-

ing in various engineering capacities and reporting to the Chief Engineer at Richmond. From 1932 to 1934, Mr. Howard was variously employed. For a short time he was connected with the Department of Public Utilities, City of Richmond, preparing maps of the gas and water distribution system. In the latter part of 1934, he was engaged as Resident Engineer-Inspector with the Public Works Administration, in charge of building construction at the Virginia Polytechnic Institute, at Blacksburg, Va.

He was a member of the Commonwealth Club of Richmond; a Knight Templar, York Rite, and member of the Ancient Arabic Order of Nobles of the Mystic Shrine, Jerusalem Temple, of New Orleans.

During 1935, Mr. Howard suffered a nervous breakdown and, after making a trip to South America in the hope of regaining his health, found it necessary to retire from active practice. He died at Ambler Heights Sanatorium, Asheville, N. C., on August 26, 1936, and was buried in Hollywood Cemetery, in Richmond.

He is survived by three sisters, Mrs. Vance C. McCormick, of Harrisburg, Pa., Mrs. Frank Shoup, of Dallas, Tex., and Jane Howard, of Richmond, Va.

Mr. Howard was elected an Associate Member of the American Society of Civil Engineers on December 5, 1906.

GILES MATTHEW JOWERS, Assoc. M. Am. Soc. C. E.[1]

DIED MARCH 24, 1936

Giles Matthew Jowers was born at Thomasville, Ala., on September 19, 1869. When four years of age he lost his father, Wilson Jowers, a Professor of Mathematics and a Civil Engineer whose analytical mind was a natural heritage of the son. Giles Matthew Jowers received his education in the public schools in Thomasville and Mobile, Ala., and was graduated from the Springhill Academy, at Mobile, in 1885. In 1904, he completed a course of study in Railroad Engineering at the Armour School of Technology, at Chicago, Ill.

In 1888, Mr. Jowers moved to Texas where, in 1906, he surveyed and subdivided the old Circle S Ranch, laying out the now prosperous Winter Garden City of Crystal City, Tex. Employed as Location Engineer and, later, as Division Engineer by the San Antonio, Uvalde and Gulf Railroad Company from 1908 until 1913, he located and supervised the construction of 300 miles of railroad which opened a vast section of Texas to development. In 1914, he was in charge of the construction of the irrigation system of the Winter Garden Irrigation Company in Zavala and Dimmit Counties, Texas. He returned to this work in 1925 and 1926 to extend and complete the system.

[1] Memoir prepared by H. P. Stockton, Jr., Assoc. M. Am. Soc. C. E.

In private practice, with headquarters in San Antonio, Tex., in 1915 and 1916, Mr. Jowers was engaged in surveying, irrigation, and municipal work. In 1917, he was employed by the United States Government in laying out and constructing railway facilities, streets, and sewers in the several training camps and flying fields then being expanded and developed in the San Antonio Area. In 1918 and 1919, he was employed as Special Engineer by the International Boundary Commission in locating and marking the border and determining the division of irrigational waters between the United States and Mexico from Del Rio to the Gulf of Mexico. With Val Verde County, Texas, from 1920 to 1925, he located and supervised the construction of 150 miles of State and Federal highways.

From 1926 until his death, Mr. Jowers was employed by the Texas State Highway Department as Resident Engineer on the location, design, and construction of highways. In this capacity he located several hundred miles and designed and supervised the construction of more than 100 miles of highways of the Texas System in Zavala, Kerr, Kendall, Bexar, Bandera, Bell, Coryell, and Hamilton Counties.

Possessed of a keen and inquiring mind and of remarkable strength and energy, Mr. Jowers gave to his work that character which makes it an outstanding monument to his ability. He had a large part in the development of the Winter Garden District and of the highway system of Texas.

The respect of all with whom he came in contact and the firm friends he left are evidences of his pleasing personality, earnest endeavor, and fidelity. The admiration of his colleagues gauges his professional standing.

He is survived by his widow, Margaret M. Jowers, and a son, Thomas Giles Jowers, of San Antonio; his daughter, Mrs. Lucy (Jowers) Storck, of Bronxville, N. Y.; a sister, Mrs. Stella Ford, of Thomasville, Ala.; and two brothers, V. E. and Albert W. Jowers, of Buffalo, Tex.

Mr. Jowers was elected an Associate Member of the American Society of Civil Engineers on March 9, 1920.

RALPH LONG KELL, Assoc. M. Am. Soc. C. E.[1]

DIED MAY 24, 1936

Ralph Long Kell was born on September 8, 1881, in Loysville, Perry County, Pa., the son of Peter G. and Ella (Long) Kell. Following the completion of his preparatory schooling at the New Bloomfield Academy, Mr. Kell entered Pennsylvania State College, at State College, Pa., from which he was graduated with the degree of Bachelor of Science in Civil Engineering in 1905.

His first engineering work was with the Maintenance-of-Way Department of the Pennsylvania Railroad Company, and he served with this Company from 1905 to 1917 as Rodman, Transitman, and Assistant Supervisor of Track. His work included plans, surveys, estimates, examinations, and reports in con-

[1] Memoir prepared by John H. Wickersham, M. Am. Soc. C. E.

nection with railroad maintenance and construction. During this period, Mr. Kell was located at various times at Altoona, Harrisburg, Freeport, and Chester, Pa

In 1917, Mr. Kell accepted a position with Frank H. Shaw, M. Am. Soc. C. E., Consulting Engineer, of Lancaster, Pa., as Principal Engineer in charge of the Lancaster Office and served in this capacity until 1918. The work of this office embraced designs, plans, specifications, and the supervision of construction on highway bridges and water-works.

From 1918 to 1919, he was with the Water Supply Commission of Pennsylvania, as Engineer on surveys, examinations, and reports on flood control, stream encroachments, and stability and construction of dams. In 1919, Mr. Kell returned to Lancaster, and was engaged as Engineer with John H. Wickersham, M. Am. Soc. C. E., Engineer and Contractor, until 1924. His services with this firm were extremely valuable and included the design, plans and specifications, and the management of general building construction for numerous projects throughout Eastern and Central Pennsylvania.

In 1924, his health required him to engage in less confining work, and he accepted a position as Construction Supervisor for Franklin and Marshall College, Lancaster, on an extensive building program. His work with the College covered a period of two years. Following its completion, Mr. Kell served, during 1927, as Construction Supervisor for Charles H. Bear and Company, York, Pa., on alterations and addition to its Department Store.

Mr. Kell was also engaged as Construction Supervisor for the School District of Lancaster, during the period, 1927 and 1928, on the erection of two Junior High Schools and two Grade Schools. He served in the same capacity for the York Hospital, at York, on the erection of a new building, a Nurses Home, and a power plant, during 1929 and 1930.

In January, 1934, he was appointed City Engineer of Lancaster and served with distinction in this office until the time of his death. He was stricken while marching with the Knights Templars to attend the annual Ascension Day services, and died shortly afterward.

Although modest and unassuming, Ralph Kell was a man of high ideals and integrity. A conscientious and capable engineer, he left behind him a record of many accomplishments which will be remembered by his associates, who held him in great esteem.

He was married on April 30, 1910, to Rowena Millar, of Harrisburg, Pa., who survives him. He is also survived by a sister, Mrs. Mary Kell Fry, of York, Pa., and a brother, Harry, of Huntingdon, Pa.

He was a member of the Torch Club and the Penn State Alumni Club, of Lancaster. His fraternal affiliations in the Masonic Order, included: Lamberton Lodge, No. 476, F. and A. M.; Royal Arch Chapter, No. 43, of which he was Past High Priest and District Deputy Grand High Priest; Goodwin Council, No. 19, of which he was Past Thrice Illustrious Master; Lancaster Commandery, No. 13, Knights Templars; and Lancaster Forest, No. 27, Tall Cedars of Lebanon.

Mr. Kell was elected an Associate Member of the American Society of Civil Engineers on March 14, 1916.

JOHN BIGGER LEEPER, Assoc. M. Am. Soc. C. E.[1]

Died December 3, 1936

John Bigger Leeper was born at Hookstown, Pa., on February 1, 1868, the son of Robert and Elizabeth (Dallas) Leeper. In 1892, he was graduated from Lafayette College at Easton, Pa., with the degree of Bachelor of Science.

Between July, 1892, and February, 1893, he was Draftsman for the Boston Bridge Works; from February, to July, 1893, he served as Draftsman with the McMyler Manufacturing Company, at Cleveland, Ohio; from July, 1893, to February, 1895, he was Rodman, Leveler, Draftsman, and Masonry Inspector with the Lake Shore and Michigan Southern Railway Company; and from February, 1895, to September, 1897, he was in the employ of Lewis and Daily, at Cleveland, as Designer, Estimator, Inspector, and Superintendent of Structural Work.

On September 1, 1897, Mr. Leeper became affiliated with the Keystone Bridge Works, at Pittsburgh, Pa., as Estimator and Draftsman. The Keystone Bridge Works was merged into the American Bridge Company in 1900, and he was transferred to the Engineering Department, Pittsburgh Division, as Estimator, and, after 1904, was in charge of the estimating forces of the Pittsburgh Division.

Mr. Leeper did not confine his thoughts to his work at hand. In 1904, he instigated an experimentation in the manufacture of spelter pans with no riveted joints (pressed from a single plate), which finally led to an extensive development of pressed spelter pans, such as are now in extensive use.

In 1908, he began work in connection with high-tension transmission towers, and soon gave up his post as Chief of the Estimating Department. He then became Manager and Engineer of a Tower Department that was organized by the American Bridge Company, his duties including design, detail, and sales. His influence was soon felt throughout the power industry. He developed several patents on power-transmission equipment, and his unremitting efforts developed a distinctive advancement in the design and detail of transmission towers and transformer stations. He retired from active service on May 31, 1933.

He was the author of a Hand Book on Transmission Towers that was published in 1925 and which became an authoritative reference book for engineers and engineering schools.

Mr. Leeper made an outstanding reputation as a Designer and Salesman. His methods were original and in conformity with a strict code of honorable dealing which was exemplified in his social contacts with all men. He was a most lovable character. Friendliness and serenity were the keynotes of his personality, but he had an active mentality that was awake to every opportunity. However, he carefully analyzed every opportunity to assure himself that it corresponded with his code in every respect. He enjoyed a wide circle

[1] Memoir prepared by Marshall Williams, M. Am. Soc. C. E.

of friends, whose confidence was never violated and that confidence extended to the people with whom he had business dealings, as well as among those with whom he labored, and among his neighbors and acquaintances from all stations of life. Pomp and circumstance had no place in his plan of life. The finger of scorn and the darts of criticism were never aimed at him during the course of a life that was well-nigh blameless, and he will be fondly remembered as a distinctive character, a capable Engineer, and an honorable gentleman.

Mr. Leeper was a devotee of outdoor life. His home in the hills back of Glenfield, Pa., was an open house to his friends, who shared his enjoyment of a home that was removed from the busy lines of traffic and where he gave full swing to his love for communion with Nature. He also maintained a lodge on an island in Hollow Lake, Ontario, Canada, where he spent his summers in a fisherman's Paradise, and enjoyed the labor of improvement in the living quarters and equipment of the place.

On November 29, 1899, Mr. Leeper was married to Margaret Campbell, of Pittsburgh, who, with a daughter, Mildred, survives him to mourn the loss of a devoted husband and father.

He was an Associate Member of the Engineers' Society of Western Pennsylvania, and from 1914 to 1934, a Member of the American Institute of Electrical Engineers.

Mr. Leeper was elected an Associate Member of the American Society of Civil Engineers on January 3, 1900.

JAMES WILLIAM NORTON, Assoc. M. Am. Soc. C. E.[1]

DIED MAY 27, 1936

James William Norton was born in Nicholas County, Kentucky, on May 16, 1889, the only child of Jesse H. and Mary (Huffstetter) Norton. His early education was received in the public schools of Carlisle, Ky., followed by preparatory training in the Millersburg Military Institute, at Millersburg, Ky., and, finally, entry into the University of Kentucky, at Lexington, where he enrolled as a student in Mining Engineering.

About 1905, Mr. Norton left the University before completing his course and went to work for the Tennessee Coal, Iron, and Railroad Company, at Birmingham, Ala., and, later, at Ensley, Ala. At the latter place an accident happened that had much to do with shaping his future. While attempting to catch a moving yard engine, his foot slipped, and he was caught by a drive-wheel and carried around by it, striking the hard road-bed many times before the locomotive could be stopped. The resulting nervous shock and the loss of one foot caused him much suffering throughout the remainder of his life; and often made it necessary for him to have either medical attention, or care in a hospital, for periods of several weeks at a time.

[1] Memoir prepared by J. T. Madison, M. Am. Soc. C. E.

While living in the South Mr. Norton served as Engineer for one or more municipalities; and, for a time, was engaged in the business of contracting. After returning to Kentucky, he was Road Engineer for Nicholas County, from 1915 to 1920; he then engaged in private practice for about a year at Carlisle.

In 1921, Mr. Norton was appointed Assistant District Engineer for the Kentucky Highway Department at its Covington Office, where he served until 1922. Then, acting on the recommendation for a change of climate made by his medical advisers, he moved to Lakeland, Fla., in 1923, where he was employed as Designer of Sewers and Streets in the City Engineering Department until the close of 1924.

In January, 1925, he, with several associates, entered private practice in Lakeland to specialize in municipal and highway work. For about four months of the same year, Mr. Norton served as City Engineer of Lakeland. He continued in private practice at Lakeland until 1933, when he returned to Kentucky.

For several years following his return, Mr. Norton was associated with highway contractors, as Superintendent of Construction on projects in Central Kentucky. Subsequently, he had been engaged on Federal projects in a number of counties in Kentucky. The last assignment was at Noble, Ky.

Mr. Norton had many friends and acquaintances who were attracted by his pleasing personality and good sense of humor. His manner was mild, but his arguments forceful. One of his outstanding qualities was an ability to impress the members of governing bodies and convert them to his views. The great handicap resulting from the physical injuries received at Ensley often bore heavily upon him; this, however, was admitted only to his most intimate friends who understood how he suffered.

He entered the Masonic Lodge in 1910, and at the time of his death was affiliated with Daugherty Lodge F. and A. M., at Carlisle.

Mr. Norton was elected an Associate Member of the American Society of Civil Engineers on March 9, 1920.

GEORGE PAUL O'CONNELL, Assoc. M. Am. Soc. C. E.[1]

Died January 3, 1936

George Paul O'Connell, one of six sons of Daniel and Johanna (Brassil) O'Connell, was born in Holyoke, Mass., on January 4, 1881. His father was a prominent contractor in Western Massachusetts and an influence in Holyoke from the period following shortly after the Civil War. After the father's death, the contracting business was continued by his sons, Daniel, Charles, and John, under the name of Daniel O'Connell's Sons, Inc.

[1] Memoir prepared by James L. Tighe, M. Am. Soc. C. E.

George Paul O'Connell received his elementary education in Holyoke, and was graduated from the Holyoke High School, in the Class of 1898. He then entered the Massachusetts Institute of Technology, at Boston, Mass., from which he was graduated in 1902, receiving the degree of Bachelor of Science in Civil Engineering. His early engineering experience included work as Assistant Engineer with the firm of Ellsworth and Kirkpatrick, of Holyoke, the Burr-Hering-Freeman Commission, of New York, N. Y., the Passaic Water Company, of Paterson, N. J., and the Aqueduct Commission of New York City.

From 1906 to 1913, Mr. O'Connell was an Assistant Engineer with the New York City Board of Water Supply, and was engaged on the construction of the Catskill Supply System, including surveys for the Ashokan Reservoir, surveys and studies for the proposed Prattsville Reservoir, and the construction of the Ashokan Reservoir and the East Dike and Waste Weir, at Brown Station, N. Y.

Toward the end of 1913, he returned to Holyoke to become Engineer of Daniel O'Connell's Sons, Inc., General Contractors, of which Company he was also Vice-President at the time of his death. While associated with this Corporation, he directed the construction of many engineering projects, including the building of dams, bridges, water supply pipe lines, sewerage systems, State and county highways, city streets, churches, mills, and other industrial establishments.

For several years before, and until the time of, his death, Mr. O'Connell was a member of the Planning Board of the City of Holyoke. During the World War, he served as a Captain in the Engineer Corps, being stationed for the most part at Camp Humphreys, Virginia. He was a member of the Holyoke Post, American Legion, and the Holyoke Lodge of the Benevolent and Protective Order of Elks.

He was not married, and is survived by two brothers, Daniel and John, and by several nephews and nieces.

Mr. O'Connell was elected an Associate Member of the American Society of Civil Engineers on September 6, 1910.

RODERIC PEARSON, Assoc. M. Am. Soc. C. E.[1]

DIED FEBRUARY 4, 1937

Roderic Pearson, the son of the late L. K. Pearson and Minnie G. Pearson, was born at Portland, Ore., on October 1, 1893. He was educated in the local schools and at Oregon State Agricultural College, at Corvallis, where he was a member of the local fraternity, Gamma Tau Beta, and from which he was graduated with the degree of Civil Engineer in 1916.

After his graduation from college, Mr. Pearson spent a season with the United States Geological Survey, and several months with the firm

[1] Memoir prepared by George D. Whittle, M. Am. Soc. C. E.

of Meese and Godfried, on the design of conveying machinery. In January, 1918, he was employed as Draftsman for the United States Bureau of Public Roads, at Portland. He left the service of the Bureau in October of the same year to enlist in the Army, being assigned to the 17th Recruit Company, at Fort McDowell, California. He was honorably discharged the month after the Armistice, and returned to the employ of the Bureau of Roads, at Portland. He remained with this organization until his death, serving 2 yr, at Portland; 2 yr, at Helena, Mont.; 2½ yr, at Ogden, Utah; and the last 12½ yr, at San Francisco, Calif. During all this time, Mr. Pearson was engaged on bridge work, advancing through the grades to the position of Highway Bridge Engineer. For a period he was also Materials Engineer in the San Francisco District, and during the heavy program of grade separation, in 1936, he had charge of this work in Nevada.

Mr. Pearson was at his best when engaged on some difficult problem of structural design, mathematical analysis, or the cost of construction materials.

For several years he suffered from anemia and despite continual medical care, his condition gradually became worse. He was confined to his bed for three months preceding his death, at Letterman General Hospital, in San Francisco. He was buried in the National Cemetery at the Presidio on a protected slope overlooking the Golden Gate.

He was not married, and is survived by his mother and one brother, L. K. Pearson, Jr.

Mr. Pearson's chief hobby was photography and he did some very creditable work therein as a member of the San Francisco Camera Club. He also made a hobby of his engineering library and equipment, as evidenced by the fact that at the time of his death he possessed eleven different slide-rules.

He was made a Mason in Portland, in 1918, and was a member of Oregon Lodge No. 101 and Al Kader Temple of the Mystic Shrine.

Mr. Pearson was elected an Associate Member of the American Society of Civil Engineers on August 28, 1922.

JOHN MELVIN REARDON, Assoc. M. Am. Soc. C. E.[1]

DIED SEPTEMBER 29, 1936

John Melvin Reardon was born on March 10, 1900, in St. Paul, Minn., the son of Michael Joseph and Alice (McGorry) Reardon. He received his early education in the public schools of St. Paul. He afterward attended, and was graduated from, St. Thomas College, at St. Paul, in 1915. He then enrolled in the Civil Engineering College of the University of Minnesota, at Minneapolis, Minn., from which he was graduated in 1919 with a degree of Bachelor of Science in Civil Engineering. The United States entered the

[1] Memoir prepared by William N. Carey, M. Am. Soc. C. E.

World War before Mr. Reardon was graduated from the University, but at the outbreak of the war he enlisted in the United States Army and served in the University Training Corps until November 26, 1918, when he was honorably discharged.

After his graduation from the University, and until December, 1923, Mr. Reardon was employed as Surveyor and as Construction Engineer, principally on highway paving construction in Minnesota.

In December, 1923, he joined the forces of the Department of Public Works, in St. Paul, where he served until his death. As Assistant Superintendent of the Bureau of Construction and Repair, Department of Public Works, City of St. Paul and, later, as Superintendent of the Bureau and Assistant City Engineer, Mr. Reardon was responsible for supervising much of the paving and sewer construction carried on by the City. This work extended over a 12-yr period and involved a construction expenditure of more than $11 000 000. Although principally concerned with the construction of sewers, pavement, and similar improvements, Mr. Reardon was keenly interested in the specifications and the design of Public Works Department improvements in his city. The plans and specifications originating in that Department showed the influence of his sound and practical construction judgment.

In the field, on the supervision of contract construction, Mr. Reardon displayed the unusually happy faculty of combining firmness of purpose with a natural warm-hearted geniality. He was able thereby to enforce contract compliance with the absolute minimum of disagreement as between Engineer and Contractor. His immediate associates as well as the contractors and job superintendents with whom he came in contact in his work, held him in the highest respect both as a man and as an Engineer.

He was married on October 6, 1925, to Helen Albeck, who, with a son and a daughter, survives him.

Mr. Reardon was elected an Associate Member of the American Society of Civil Engineers on March 5, 1928.

CLARENCE HORACE SCHWARTZ, Assoc. M. Am. Soc. C. E.[1]

Died June 28, 1936

Clarence Horace Schwartz, known to his many friends as "Charley", was born near Carbondale, Ill., on December 22, 1893, to William and Etta (Thomas) Schwartz. His ancestry was a mixed lineage with English, Irish, and German predominating. Two of his ancestors most worthy of mention were General James Wolfe, conqueror of Quebec, and Thomas Parr, who was noted for his longevity, and who is buried in Westminster Abbey, in London, England.

[1] Memoir prepared by Lieut. Col. E. Reybold, Corps of Engrs., U. S. Army; Dist. Engr., Memphis, Tenn.

Mr. Schwartz's early education was received in the public schools at Wickliffe, Ky., where he was graduated from the High School in 1910. He entered the University of Kentucky, at Lexington, Ky., in the same year, and was graduated in 1914, Cum Laude, receiving the degree of Bachelor of Science in Civil Engineering. He was a member of Tau Beta Pi Fraternity.

Mr. Schwartz obtained his elementary engineering experience after graduation, with the Delaware, Lackawanna and Western Railroad Company, working on physical evaluation appraisals; with the Kentucky State Highway Department as an Inspector; and with the Morgan Engineering Company on plans for flood-control improvements for the Miami Conservancy District, at Dayton, Ohio. With the Morgan Engineering Company, Mr. Schwartz received his first flood-control and hydraulic engineering experience, which he was later to use in his most important works.

A heart ailment of long standing, which was eventually the cause of his death, almost prevented Mr. Schwartz from joining the Army when the United States entered the World War, but his persistence and refusal to accept the first rejection, finally won for him entrance to the Second Officers' Training School. He was commissioned Second Lieutenant in the Engineering Corps on October 4, 1917, and promoted to the rank of First Lieutenant on August 24, 1918. He was discharged from the Army on February 4, 1919.

The Miami Conservancy District employed Mr. Schwartz after the war and put him in charge of the flood-control works at West Carrollton, Ohio. On the completion of this work, F. G. Mueller, Architect, placed him in charge of construction of the hydro-electric power plant at Hamilton, Ohio, for the Ford Motor Company. After the hydro-electric plant was completed, the Miami Conservancy District re-employed Mr. Schwartz, giving him full responsibility for its Division Office, which position he held until these flood-control works were completed. He then joined the forces of the Lloyd Construction Company, of Willoughby, Ohio, in the building of filtration and sewage disposal plants. In 1927, the U. S. Engineer Office at New Orleans, La., engaged him to make hydraulic studies on flood-control works on the Mississippi River. The Portland Cement Association at New York, N. Y., employed him next as Contact Engineer to meet engineers, architects, and contractors. After two years, friends who knew of his ability on flood-control studies induced him to join the forces in the District Office of the United States Engineers, at Memphis, Tenn., where he remained until his death. The last five years of his service were in cost accounting, which work he conducted in a highly efficient manner, and for which he received official commendation.

Having made a success of engineering, Mr. Schwartz took up the study of law and was admitted to the Bar in Tennessee in 1932. He was graduated from the University of Memphis Law School, in 1933. Immediately upon his graduation, Mr. Schwartz formed a partnership law firm with Mr. Milton Picard, but was prevented from taking an active part in the firm's affairs because of ill health.

He spent five months in the hospital from January to June, 1934, and although the doctors gave him no encouragement, he recovered sufficiently to

resume his work, which he carried on for two years until his passing on June 28, 1936.

He was a Mason, and a member of the Memphis University Club, and the Memphis Engineers' Club. He served as Secretary of the Mid-South Section of the Society for the year 1933 and 1934.

Mr. Schwartz was a constant student and a reader of diversified subjects. He was a pleasing conversationalist because of his breadth of knowledge, which, coupled with his interest in and his desire to help his fellow companions and his unfailingly cheerful disposition, earned for him the friendship of all with whom he came in contact. His brilliant mind would have carried him much farther in his chosen career; his passing was a distinct loss to his friends and to his profession.

He was never married, and is survived by his parents, two sisters, Mrs. Ruth Spalding and Mrs. Grace G. Carter, and one brother, John, all of Chicago, Ill., and vicinity.

Mr. Schwartz was elected an Associate Member of the American Society of Civil Engineers on November 9, 1920.

EDWARD RALPH TAYLOR, Assoc. M. Am. Soc. C. E.[1]

Died June 4, 1935

Edward Ralph Taylor was born in Trenton, N. J., on June 3, 1898, the son of Edward Watson and Ida Frances (Skillman) Taylor. He received his Grammar School and High School education at the local schools.

After leaving High School, Mr. Taylor was employed in the Distribution Department of the Public Service Electric Company, at Trenton, as a Draftsman. In June, 1916, he became Chief Draftsman, which position he held until July, 1918. During this time, he attended Drexel Institute, in Philadelphia, Pa., and was graduated from its Evening Course in Electrical Engineering. While with the Public Service Electric Company, he had not only experience in special transmission-line design, but he had considerable field work as Instrumentman and Chief of Party on the survey of the transmission line which had to be run from Mt. Holly, N. J., to the Army Cantonment at Camp Dix, New Jersey.

Directly after this, and until October, 1918, Mr. Taylor served as Electrical Draftsman and Designer of Industrial Wiring and Sub-Stations for the Plant Engineer at the Harriman, Pa., Ship Yards. At this time, he joined the Student Army Training Corps at Lafayette College, at Easton, Pa., pursuing further his study of Electrical Engineering.

The need for the Student Corps being over by the end of 1918, Mr. Taylor returned to Trenton and became a member of the Tramway and Bridge Engineering Department of the John A. Roebling's Sons Company,

[1] Memoir prepared by A. J. Morgan, Esq., Trenton, N. J.

in January, 1919. He was engaged on the study and design of suspension bridges, cableways, tramways, and various wire-rope applications. Later, he was placed in charge of construction in the field. He also made engineering studies and surveys of the use of wire rope for mines, oil fields, logging, and coal and ore-handling equipment.

In furthering his study of bridges, Mr. Taylor was employed on the field work during the erection of the cables for the Bear Mountain Bridge over the Hudson River, and for the Philadelphia-Camden Bridge. About that time, he was instrumental in introducing the new parallel-strand type of bridge cable on the Grand 'Mere Bridge, in Canada.

In January, 1928, he became Assistant Resident Engineer for the John A. Roebling's Sons Company, on the New Jersey side of the George Washington Bridge over the Hudson River at New York City, and continued in this position until about the end of that year, when he was made Assistant Chief Engineer of the Wire Rope Department of the Company. He then continued his engineering study of wire rope and its proper application to all types of installations in the field.

In September, 1934, he was appointed Mill Representative for the Sales Department, which position he held at the time of the unfortunate accident which caused his death. He died on June 4, 1935, at Honolulu, Hawaii, due to a broken vertebra, the result of a so-called shallow dive the day before. His body was brought to Trenton for burial.

Mr. Taylor was well known throughout the wire rope industry and the trade, and his personality and engineering ability made many friends among bridge builders and industries using wire rope.

He was a Licensed Professional Engineer and Land Surveyor of the State of New Jersey. He was a member of Column Lodge, F. and A. M. of Trenton, a Thirty-second Degree Scottish Rite Mason, and a member of Crescent Temple.

He was married at Trenton, on June 23, 1920, to Mabel Randall Towers of that city, who survives him.

Mr. Taylor was elected an Associate Member of the American Society of Civil Engineers on December 3, 1928.

WILLIAM JOHN UBBINK, Assoc. M. Am. Soc. C. E.[1]

DIED FEBRUARY 8, 1937

William John Ubbink was born in Port Washington, Wis., on August 10, 1890, the son of Joseph and Susan (Weyker) Ubbink, both of whom were natives of Ozaukee County, Wisconsin. His paternal grandparents emigrated from Holland to the United States in 1840, and at about the same time his maternal grandparents came to this country from Germany, both families settling in Ozaukee County.

[1] Memoir prepared by Joe J. Ubbink, Esq., Port Washington, Wis.

His grandfather, Bernard Ubbink, established a masonry contracting business, in Port Washington, in 1848, and, in 1876, was joined in that enterprise by his son, Joseph, with whom he carried it forward until his death in 1890. Joseph Ubbink thereafter conducted the business alone until 1908, when he was joined by his son, William. Five years later, in 1913, Joseph and Arnold Ubbink, the two other sons of the family, likewise associated themselves with the firm. The Company was continued until the death of the father, which occurred in 1929. The family still has the continuous set of books, covering the details of the business over a period of more than eighty years. Among the many important structures erected by the Ubbinks may be mentioned three of the leading hotels in Port Washington; the plants of the Wisconsin Chair Company and the Gilson Manufacturing Company, both of Port Washington; the Port Washington malt-house; oil-burning lime kilns, at Dubuque, Iowa; the Lower Wisconsin Avenue Viaduct, in Milwaukee, Wis.; the Wisconsin Street School Building, in Port Washington; St. Mary's Roman Catholic Church and School; and many bridges, large and small, throughout the State.

William John Ubbink received his early education in the parochial schools of Port Washington and in the local High School. He attended the Rheude Architectural School, in Milwaukee, until that institution was discontinued on the death of Mr. Rheude, and afterward entered the Chicago Technical College, at Chicago, Ill., where he completed a course in Civil Engineering in 1909.

On his return to Port Washington, Mr. Ubbink became associated, as stated, with his father in the contracting business, to which he devoted his attention until 1917, when he enlisted for service in the World War. He was on active duty with the 42d United States Engineers—a road and bridge building regiment—in the Lorraine Sector, France, and was honorably discharged on July 1, 1919.

On his return to Port Washington, he rejoined his father, with whom he was associated in business until January 1, 1921, when he was made Highway Commissioner of Ozaukee County, which position he held until his death.

During his term of office the County floated a bond issue of \$1 750 000 for the construction of roads and bridges, all of which has been completed, together with the new Highway Office Building into which the Highway Department had just moved. Mr. Ubbink's administration of the office held by him was marked by conscientious regard for the interests of the taxpayers of the County and he earned high praise for the marked improvement in the condition of the streets and highways.

At Lake Church, Wis., on June 23, 1922, Mr. Ubbink was married to May Johann, the daughter of Carl and Mary (Frantz) Johann, natives of Germany. Afflicted by a chronic heart ailment, Mr. Ubbink died on February 8, 1937, and is survived by his widow and a daughter, Mary Ruth, and by two brothers and three sisters.

He was a member of Port Washington Post No. 82, of the American Legion; the Knights of Columbus, Fourth Degree; the Rotary Club, of

Port Washington; the County Highway Commissioners Association of Wisconsin; the Engineering Society of Wisconsin; and the Port Washington Chamber of Commerce, of which he was President. He was also Vice-President of the First National Bank; Vice-President of The Ubbink Fuel and Dock Company; and President of the Port Development Company. He was very highly regarded as a civil engineer; in private life, he was a loyal citizen, and a dependable friend and neighbor.

Mr. Ubbink was elected an Associate Member of the American Society of Civil Engineers on August 12, 1935.

REENEN JACOB VAN REENEN, Assoc. M. Am. Soc. C. E.[1]

DIED OCTOBER 19, 1935

Reenen Jacob van Reenen was born at Calvinia, Union of South Africa, on April 15, 1884. He was the son of Albert Johannes van Reenen, a prominent attorney at Calvinia, and Susanna (de Villiers) van Reenen. His education was received principally at the South African College, at Cape Town, Union of South Africa, from which he took his Bachelor's Degree and won the Victoria Scholarship.

In 1903, he came to the United States and entered the Civil Engineering Department at Lehigh University, at South Bethlehem, Pa., from which he was graduated in 1906. During this period, he became a member of Kappa Sigma and Tau Beta Pi, and played on the University football team.

On the completion of his studies in 1906, Mr. van Reenen became Resident Engineer to the Tri-State Land and Irrigation Company, in Nebraska, and it is interesting to note that the writer, during a visit to the United States in 1934, met several members of the Society who remembered Mr. van Reenen on this particular work.

Toward the end of 1907 Mr. van Reenen returned to his native land, where he became associated with the construction of the Reservoir and Irrigation Distribution Works of the Smartt Syndicate, at Britstown, in the Cape Province, Union of South Africa. On the completion of this work, in the middle of 1909, he entered the Government Civil Service and was occupied in the design and construction of several irrigation projects on the Gamtoos River—one of which was named for him.

In May, 1912, he was appointed Superintendent of Roads and Local Works in the Orange Free State Province, Union of South Africa, which position he retained until 1926. The excellent highway system which that Province enjoys, bears eloquent testimony to his ability. During this period, Mr. van Reenen was appointed a member of the Drought Investigation Commission (1920–24), and, later, Chairman of the Drought Investigation Commission of the mandated territory of South West Africa (1923–24). In

[1] Memoir prepared by Philip R. R. Bisschop, Assoc. M. Am. Soc. C. E.

October, 1924, he was appointed a member of the Irrigation Finance Commission and, on the completion of that work, he was appointed Chairman of the Special Irrigation Commission. During this latter period, he also served as a member of the Angola Boundary Commission, which was detailed to determine the boundary between the Portuguese territory of Angola and that of South West Africa. In August, 1926, he was appointed Chairman of the Permanent Irrigation Commission which position he held with great distinction until his death. Apart from these duties, Mr. van Reenen was called upon to serve first as a member and, later, as Chairman of the National and Historical Monuments Commission. In 1933, he served as Chairman of the Low Grade Ore Commission, appointed by the Government to report on the life of the low-grade gold mines of the Witwatersrand. In 1934, he was appointed Chairman of the Industrial Legislation Commission the report of which was issued shortly before his untimely death.

In addition to these many Government appointments, Mr. van Reenen was a recognized authority on ancient Bushman culture and paintings, educational matters, and Afrikaans literature. Besides giving numerous lectures on these subjects before scientific and academic bodies, he published a number of volumes in Afrikaans and had just completed writing a book entitled, "Resisting Drought." His book on "Die Agterste Voortrekker", can be found on the shelves of the Library of his American Alma Mater, Lehigh University. Mr. van Reenen was a member of the Afrikaner Kring, Die Suid Afrikaanse Akademie vir Lettere, the South African Society for the Advancement of Science, the South African Society of Civil Engineers, and the Ramblers Club, at Bloemfontein, Union of South Africa.

In 1908, Mr. van Reenen was married to Elizabeth Lilian Roos, a member of a well-known Cape Town family, and the sister of the late South African statesman, the Hon. Tielman Roos. Of this union there are two daughters and a son, who, with Mrs. van Reenen, survive him.

Known among his intimates as "Voorsitter" (that is, "Chairman"), he was a hard worker, a brilliant man, generous and kind, diplomatic, loyal, and straight. Full of humor, appreciative of, and a narrator of, a good story, in short, a lovable fellow. Chief among his many hobbies were sketching, cabinet-making, and photography. All that he produced along these lines was of exceptional merit. When visiting in New York City in 1932, he obtained a number of camera studies, and was particularly proud of the photographs that he took at night from the top of the Empire State Building.

As a public servant, Mr. van Reenen served his country well. There are no brass tablets to record his deeds, but his findings on the many Government bodies upon which he served, will benefit his country, farmers, and townsmen. South Africa, the Government Service, and his friends have lost one of the best, and are the poorer for his departure.

"Pass, Friend, 'Totsiens, Voorsitter'."

Mr. van Reenen was elected an Associate Member of the American Society of Civil Engineers on October 3, 1911.

JOHN JUNIOR WILSON, Assoc. M. Am. Soc. C. E.[1]

Died November 21, 1936

John Junior Wilson was born at Georgetown, Colo., on September 2, 1878. He was the son of the Rev. John Wilson, a noted pioneer minister in Colorado and New Mexico, and Elizabeth (Boyce) Wilson. John Junior Wilson was educated in the public schools of Longmont, Colo., and the State Preparatory School, at Boulder, Colo., and took his engineering course in the University of Colorado, at Boulder. He was interested in athletics and was a member of the University football team. He served as a Sergeant of the Signal Corps of the Colorado National Guard during the strike at Cripple Creek.

After leaving the University, Mr. Wilson began his career with the Hill's Engineering Company, of Cripple Creek, Colo. Although subsequently he was engaged in other lines of engineering work, especially in the construction of dams, Mining Engineering was his specialty and his last active work was in that branch of service.

In 1907, he accepted a position with the Teziutlan Copper Company, of LaAurora, Pueblo, Mexico, and was with that Company for a considerable length of time. Returning to the United States he became Engineer for the construction of a large earthwork dam for irrigation purposes, at Two Buttes, near Lamar, Colo.

When construction was begun on the Barker Meadows Dam, near Nederland, Colo., Mr. Wilson was assigned to check the work as Deputy State Inspector and remained in that position until the dam was completed. He then went to Minnesota and became a Bridge Engineer for the Great Northern Railroad Company. He was afterward elected a member of the Faculty of the Agricultural Engineering Department of the University of Minnesota, Minneapolis, Minn.

In 1915, his chosen work as Mining Engineer lured him back and he took a position with the Ray Consolidated Copper Company, at Ray, Ariz. He later returned to Colorado and took charge of the construction work at the Silver Lake and Albion Dams, for the water supply of the City of Boulder. He then became Engineer in charge at the tungsten mines of the Primos Mining Company, at Lakewood, Colo.

While superintending some underground work in those mines, Mr. Wilson met with a serious accident, and for the last twenty years of his life he was incapacitated from active service. He made his home at Boulder, where he died on November 21, 1936. He was never married, and is survived by four sisters, Mrs. Jessie W. Dwyer, and Mrs. Agnes W. Morris, of Boulder; Mrs. Jennie B. Brown, of Longmont, Colo.; Mrs. Irvin E. Keeler, of Long Beach, Calif., and one brother, the Rev. Harry Noble Wilson, D.D., of St. Paul, Minn.

[1] Memoir prepared by the Rev. Harry Noble Wilson, D.D., St. Paul, Minn.

John Junior Wilson was a man of fine intellectual gifts, a stalwart character, and possessed of a pleasing personality. During the years when he was laid aside from his regular calling, he never lost his courage or cheerfulness, and he continued to pursue his studies and kept in touch with modern research. He was always greatly interested in the Society and always wore his badge of membership. Although he was a member of other organizations, the pin of the Society, at his request, was the only insignia that was buried with him. His calling away is a source of real sorrow to his many friends.

Mr. Wilson was elected an Associate Member of the American Society of Civil Engineers on February 4, 1913.

LEONARD JOHN BUTLER, Jun. Am. Soc. C. E.[1]

Died April 7, 1936

Leonard John Butler was born in Flagstaff, Ariz., on May 21, 1912, the son of the Rev. and Mrs. John Butler, who, for many years, have served as missionaries to the Navajo tribe of Indians of Northern Arizona. After completing his studies in the graded school on the Indian Reservation, he attended High School, at Tucson, Ariz. On the completion of his four years' High School Course, he entered the University of Arizona at Tucson, selecting the Civil Engineering Course, and was graduated in May, 1935, with the degree of Bachelor of Science in Civil Engineering.

Soon after his graduation, Mr. Butler entered the employ of the Government, as a Civil Engineer in the Soil Conservation Service of the United States Department of Agriculture. He continued in this work until his tragic death on April 7, 1936, at Santa Barbara, Calif., caused by an accidental 150-ft fall from the top of the large Gibraltar Dam, on the Santa Ynez River, to the rocks below. He had been assigned to that location temporarily to make silt tests.

During the brief period of his professional work, which began at Elephant Butte Dam, in New Mexico, Mr. Butler served on various similar projects, in soil and erosion work in that State as well as in Arizona and California. Although yet quite young (being only twenty-three at the time of his death), his potential possibilities in his particular profession seemed rapidly coming to the fore, assuring a possible brilliant future. His engineering associates who contacted him most in his professional work and social life paid lavish tribute to the high qualities of his character, his exceptional ability and keenness as a young engineer, and his conscientious disposition to do his work with an interest, skill, and thoroughness, which, in due time, would undoubtedly have commanded attention and given to him the advancement in his chosen profession which his fitness deserved.

---

[1] Memoir prepared by the Rev. John Butler, Tuba City, Ariz.

Mr. Butler was of a strong and robust constitution, with a splendid physique and high ideals of life. Although generous in a quiet and unpretentious way, he was also prudent in all his affairs, as the adjustment of his business after his death so satisfactorily disclosed. His exceptionally fine spirit, his quiet, earnest, yet modest and unassuming ways, with his other fine qualities, quickly won for him the warm friendships which bore valid witness to his intrinsic worth. None but an All-Wise Providence can satisfactorily account for the sudden and tragic taking of this young and promising life, so early in the morning of what seemed a worthy career, for which he had been well trained, and which seemed fraught with such happy and splendid possibilities.

His mother, Mrs. Sue Woodward Butler, died when he was only six years of age. He is survived by his father, his sisters, Florence M. Butler, and Mrs. Grace W. Wells, the wife of the Rev. Lloyd D. Wells, of Yuma, Ariz., and by his older brother, Warren W. Butler.

Mr. Butler was elected a Junior of the American Society of Civil Engineers on January 13, 1936.

MARSHALL HUDSON REESE, Jun. Am. Soc. C. E.[1]

DIED SEPTEMBER 26, 1936

Marshall Hudson Reese, the son of Hilliard H. and Claudia (Coyle) Reese, was born at Arcadia, La., on October 5, 1904. He acquired his early education at the Grade and High Schools, at Baskin, La. In 1928, he received the degree of Bachelor of Science in Civil Engineering, at the College of Engineering, Louisiana State University, at Baton Rouge, La., entering the service of the United States Coast and Geodetic Survey on September 1, 1928. In 1935, he received the Professional Degree of Civil Engineer from Louisiana State University, for a graduate thesis entitled "The Development of Aerial Surveying in the U. S. Coast and Geodetic Survey."

Lieutenant Reese served as a junior officer on the U. S. Coast and Geodetic Survey Ships, *Lydonia* and *Natoma*, and, at the time of his death, was attached to the *Surveyor*. He was one of the first assigned to the duty of flight checking the sectional airway maps, and also spent time in the Washington Office of the U. S. Coast and Geodetic Survey in compiling aerial photographs.

Lieutenant Reese was lost on September 26, 1936, when a dory, in which he and Quartermaster McLees were leaving camp near Wislow Island, Aleutian Islands, Alaska, capsized in the outer line of breakers. A strong offshore gale carried the men and the overturned boat out into Bering Sea. All efforts to reach them by their comrades on shore were unsuccessful, and the men were last seen clinging to the overturned boat, drifting seaward in a strong offshore wind.

[1] Memoir prepared by Paul Albert Smith, Assoc. M. Am. Soc. C. E.

The party had been encamped on an isolated section of the north coast of Unalaska, and news of the accident was carried to Dutch Harbor by two of his men, who arrived at the Coast Guard Station thirty hours after the accident. The Coast Guard Cutter, *Alert*, and the U. S. Coast and Geodetic Survey Ship, *Surveyor*, searched a wide area and the coasts in the vicinity of Wislow Island without finding any trace of the men or the boat.

Lieutenant Reese was efficient and unusually well liked, and his many friends and associates feel the loss of a real friend. He was outstanding in his profession, and, in his death, the U. S. Coast and Geodetic Survey has lost a most promising young officer.

He was a member of Delta Sigma Phi; Sigma Tau Sigma; Scabbard and Blade; and the Society of American Military Engineers.

On December 14, 1935, he was married to Doris Anderson, of Pensacola, Fla., who survives him.

Lieutenant Reese was elected a Junior of the American Society of Civil Engineers on January 14, 1929.

ALBERT FARWELL BEMIS, Affiliate, Am. Soc. C. E.[1]

Died April 11, 1936

Albert Farwell Bemis was born in Boston, Mass., on November 11, 1870, the son of Judson Moss and Alice (Cogswell) Bemis. He received his primary education at schools in Newton, Mass., until 1882 when he went to Colorado. He was a student at Cutler Academy, Colorado Springs, and at Colorado College, until 1889 when he returned to Boston. He then entered for the course in Civil Engineering at the Massachusetts Institute of Technology from which he was graduated in 1893 with the degree of Bachelor of Science.

After his graduation from college, Mr. Bemis became associated with the Bemis Bro. Bag Company. This Company operates bag factories, cotton mills, a bleachery, paper mill, machine shop, and ink factory, and Mr. Bemis had supervision of the design and plans of all new construction for the Company from 1894 to 1922. In 1897 he became Secretary, and in 1909 President, of the Company, continuing in the latter position until 1925 when he was made Chairman of the Board of Directors. He held the latter office until his retirement in 1934.

Mr. Bemis was also a Director of the Boott Mills, of Lowell, Mass., from 1905 to 1934, and in 1912 he organized the Angus Jute Company, Limited, of Calcutta, India, which operates a jute mill and jute machinery works in India. Mr. Bemis also served as a Director of this Company until 1934. Included in his business interests were his Directorships of the Second National Bank of Boston from 1916 to 1926 and of the Federal Reserve Bank of Boston from 1928 to 1932.

---

[1] Memoir prepared from information supplied by Milton Brooks, Esq., of Boston, Mass., and on file at the Headquarters of the Society.

He was deeply interested in research and economics. This interest led him to become associated with the work of the National Industrial Conference Board of which he was a member from its organization in 1916. In 1928 he was appointed a member of its Executive Committee and served as such until 1932. In 1934 he accepted a re-appointment to the Executive Committee and at the time of his death he was, in addition, Chairman of the Advisory Council on Research. He had been for many years a member of the International Chamber of Commerce and of the Royal Economic Society of London, England.

As an active and constant supporter of housing research, Mr. Bemis became a nationally known authority on the theory of building and the improvement of construction methods. He was largely responsible for the newer dormitory construction at the Massachusetts Institute of Technology to which he was a large contributor and he assisted in making possible the restoration of Lincoln Cathedral in England, both by large financial contributions and also co-operation with the authorities in charge of the restoration. In 1918 he organized the Housing Company in Boston, which Company was responsible for many group housing developments in New England and elsewhere. He also founded the course in building at Hampton Institute in Virginia. He was an active supporter of the production of better housing for the lower service groups and in connection with this interest he published a three-volume work under the title of "The Evolving House." The first two volumes of this work were "A History of the Home", and "The Economics of Shelter" and the third volume, published just prior to his death, was entitled "Rational Design."

Mr. Bemis was actively interested in his Alma Mater, the Massachusetts Institute of Technology. He served as President of its Alumni Association in 1910, and had been a Life Member of the Corporation since 1914. He also served at various times as a member or Chairman of Visiting Committees of the Departments of Civil Engineering, Architecture, and Naval Architecture, as well as the Division of Industrial Co-Operation and Research. The younger graduates of the Institute were always of great interest to Mr. Bemis and many of them are indebted to him for placing them in positions from which they rose to prominence.

He was a frequent traveler and had visited many countries of the world. The promotion of Anglo-American relations was one of his major interests. He held a Life Governorship in the English Speaking Union, of London, and was also a Fellow of the Royal Society of Arts. He was a member of the Club International, of Geneva, Switzerland.

As a member of the Commission on Foreign Inquiry of the National Civic Federation, Mr. Bemis contributed the sections of its report published in 1919 on "Social and Industrial Relations" and "Housing and Agricultural Reconstruction" in Great Britain and France. In 1927 he visited Russia and afterward prepared a paper on his observations which was published[2] by the American Academy of Political and Social Science. He also visited the Orient and in connection with the operations of his Company, the Angus

[2] *Annals*, Am. Academy of Political and Social Science, July, 1928.

Jute Company, Limited, at Calcutta, India, he framed policies which did much to improve living conditions for its employees and for the public residing in its vicinity, from the point of view of health and sanitation. The medical work conducted by the Company was highly commended by the Royal Commission on Labor in India in a report to the British Parliament.

Mr. Bemis was a member and Past-President of the National Association of Cotton Manufacturers and a member of the American Cotton Manufacturers Association and, in 1911 prepared a report on "Co-Operation Between Departments of the Federal Government and Textile Manufacturers" for the former as well as a report, in 1910, on "Cotton Goods Sale Note."

He served as Alderman of the City of Newton, Mass., from 1911 to 1914; was a Director of the Boston Chamber of Commerce from 1914 to 1916; a Trustee of the Newton Young Men's Christian Association from 1923 to 1926; a Trustee of the Cambridge School of Architecture from 1927 to his death; and Chairman of the Trustees for Real Estate of the Boston Young Men's Christian Association in 1935.

Mr. Bemis was also a member of the Bostonian Society, the Ipswich Historical Society the New England Historic Genealogical Society, and the Boston Athenæum. He had been a member of the Old South Church, in Boston, since 1908.

His social clubs included the City, Union, Commercial, Technology, Exchange, University, and Engineers Clubs, of Boston; the Longwood Cricket Club, the Brookline Country Club, Cohasset Golf Club, and the Manchester Yacht Club. He was also a member of the Engineers and Technology Clubs, of New York, N. Y.

As stated by a friend of long standing the attributes for which Mr. Bemis will be remembered were "his kindliness and humor, his humanity and sympathy, and his self-sacrificing effort to render the greatest possible service to his fellow man."

On December 30, 1899, he was married to Faith Gregg, of Colorado Springs, Colo., and is survived by his widow, four sons, and three daughters.

Mr. Bemis was elected an Affiliate of the American Society of Civil Engineers on September 12, 1916.

THANE ROSS BROWN, Affiliate, Am. Soc. C. E.[1]

DIED JUNE 30, 1934

Thane Ross Brown (or "T.R.", as he was called by those who were intimate with him) was born at Oxford, Ohio, on June 21, 1870, the son of Edwin W. and Harriet (Ross) Brown. Soon after his birth the family moved to Kansas and, after a short stay, returned to Oxford and then moved to Indian-

[1] Memoir prepared by E. D. Coddington, Esq., New York, N. Y.

apolis, Ind., where Mrs. Brown died in 1878. This broke up the family, and an aunt at Oxford assumed the care of the children—three boys, Thane, his twin brother, and a younger brother.

In 1882, the father succeeded in getting his boys together again on a farm near Topeka, Kans., and here Thane Ross Brown grew from boyhood to manhood, getting his first college work at Washburn College, at Topeka. From Washburn, he went to the University of Wisconsin, at Madison, Wis., from which he was graduated, from the College of Engineering, in 1895.

Mr. Brown immediately began work relating to the profession for which he had been training and, from June to August, 1895, he was engaged in surveying in University Heights, Madison, and from August 1 to November 25 of the same year, he held the position of Levelman with the Field Engineering Force supervising the construction and erection of a bridge for the Pacific Short Line Railroad Company, at Sioux City, Iowa, Lee Treadwell, M. Am. Soc. C. E., being the Engineer in Charge.

Mr. Brown's experience during the construction of this bridge undoubtedly had a great influence in leading him to decide on specializing in bridge construction, and after completing his work at Sioux City in the fall of 1895, he entered, in November, the service of the Wisconsin Bridge and Iron Company, at Milwaukee, Wis.

In this Company, which Mr. Brown served so faithfully for many years, when designs are made, contracts taken, and working drawings begun, it is upon the engineers and draftsmen of the Shop Drafting Room that the task of putting the designer's ideas into practical shape for actual construction falls, and, in this work, Mr. Brown was a main stand-by for many years.

Few engineers have handled a greater variety of work than did Mr. Brown during his connection with the Wisconsin Bridge and Iron Company. From small highway spans to heavy cantilever bridges across such rivers as the Ohio and the Mississippi, from the simplest types of lift and draw-bridges to heavy double-track railroad lift spans with their machinery; from small factory buildings to the largest types of industrial plants; from small storage bins to immense ore docks—Mr. Brown was engaged in all this work doing as much of it as it was possible for one engineer. If difficult counterweight calculations or deflections diagrams for long spans were required, where willingness to work, and where much patience and mathematical ability were necessary, Mr. Brown was the man. He was the very personification of steadiness and reliability and was held in highest respect by all who worked with him.

Mr. Brown's father served his country during the Civil War and showed his patriotism as a soldier in doing his part in some of the most difficult campaigns and battles of that struggle. His patriotism and loyalty to duty found expression again in his son, Thane, who identified himself in the community in which he lived by always answering unselfishly any call from either Church or public, and whatever he undertook he could be depended upon to finish.

Mr. Brown's services with the Wisconsin Bridge and Iron Company covered a period of more than thirty-seven years and when failing physical powers, finally ending in death on June 30, 1934, compelled him to lay down

his tools, his loss was felt by all who knew him and most keenly by those in closest touch with him.

On July 6, 1904, he was married to Cora Treadwell, of Kilbourn, Wis., who died in January, 1914. Their union was blessed by two children, Helen and Thane B. Brown, who survive them.

Although he had very definite beliefs and set for himself the strictest rules of conduct toward his fellow men, he was always very tolerant toward the beliefs and actions of others. Although his life was not of the spectacular kind, his was one of the finest examples of American manhood, and truly it can be said of him that he served his day and generation faithfully and well.

Mr. Brown was elected a Junior of the American Society of Civil Engineers on March 31, 1896, and an Affiliate, on October 2, 1900.

ROBERT WHITMAN LESLEY, Affiliate, Am. Soc. C. E.[1]

Died November 10, 1935

Robert Whitman Lesley was born in Philadelphia, Pa., on July 3, 1853, the son of James Lesley, Jr., and Elizabeth (Thomson) Lesley. His ancestors on both sides were Scotch, his grandfather, Judge Thomson, of Chambersburg, Pa., who had served as a member of Congress, having married a Graham, or in the old spelling, Graeme. His father was a literary man, a student of poetry, and a linguist. His mother was a sister of the eminent oculist, the late Dr. William Thomson, and of the late Frank Thomson, President of the Pennsylvania Railroad Company. A few years after his birth, his father was appointed American Consul to Lyons, and, later, to Nice, France, where he died in 1865.

Robert Whitman Lesley received his preparatory education in France and at the Langdon School, in Philadelphia. In 1867, he entered the University of Pennsylvania, but left college before he was graduated to enter the office of the Philadelphia *Public Ledger*, then owned by George W. Childs and Anthony J. Drexel. Mr. Lesley served in the Business Department of the newspaper and, later, became Assistant Editor. He afterward studied law in the office of Benjamin Harris Brewster, United States Attorney General, and was admitted to the Philadelphia Bar in 1879. In 1908 he was granted the degree of Master of Arts by the University of Pennsylvania as of the Class of 1871.

In 1874, Mr. Lesley organized the firm of Lesley and Trinkle in connection with the importation and distribution of cement. In 1876, he became associated with the late David O. Saylor, of Allentown, Pa., in the introduction of Saylor's Portland cement. From 1880 to 1883, Mr. Lesley was interested in the manufacture of natural cement in Maryland, and with Professor E. J. De Smedt, United States Chemist, of Washington, D. C., he carried

[1] Prepared from information on file at the Headquarters of the Society.

on a series of experiments and tests looking to the economical and commercial manufacture and distribution of Portland cement. This work resulted in a series of patents granted to them for improvement in the art, especially in the preparation of the "slurry" for the kilns by the use of gas tar pitch at that time a waste product.

Under these inventions Mr. Lesley and others, in 1883–84, organized the American Improvement Cement Company, of which he served as Treasurer and a Director. The Company had three plants at Egypt, Pa., and one at Jordan, N. Y., and was at that time the largest manufacturer of Portland cement in the United States. Subsequently, the Company was re-organized as the American Cement Company, and Mr. Lesley was its first President, also serving as Treasurer and Director. It is now operated as the Giant Portland Cement Company, of which Mr. Lesley was a Director at the time of his death. In 1924, jointly with Mr. George S. Bartlett, he wrote and published a history of the Portland Cement Industry, and, in 1925, he laid the cornerstone of the Portland Cement Association Building, in Chicago, Ill.

In addition to his cement interests, Mr. Lesley was also a Director of the Surface Combustion Corporation, The Philadelphia and Camden Ferry Company, the Bearings Company of America, Bonzano Rail Joint Company, Jackson Mills Emery Company, Incorporated, The Tidewater Land Company and the Concrete Cement Age Publishing Company. He also served as Consulting Editor of *Concrete*, published in Chicago.

Mr. Lesley was always interested in science and was connected with the Clarke Thomson Research Fund. The Company was organized just before the World War to develop new inventions in the field of aviation, and was associated with the National Advisory Committee for Aeronautics. During Mr. Thomson's absence in the Army, Mr. Lesley took over the management of the Company. He also presented a Cement Laboratory to the University of Pennsylvania.

During the World War, Mr Lesley assisted in the organization of the Philadelphia War Chest and served as Captain of teams appointed to secure money for the various Liberty Loans, War Savings Stamps, and the Red Cross.

Mr. Lesley was an Honorary Member and Past Vice-President of the American Society for Testing Materials; Honorary Member and Past-President of the Portland Cement Association; a member of the American Concrete Institute; The American Chemical Society; British Chemical Society; the Franklin Institute; and the Philadelphia Chamber of Commerce. He had also served as a member of the Special Committee of the American Society of Civil Engineers on Concrete and Reinforced Concrete; and as Chairman of the Sub-Committee on Ways and Means of the Joint Committee on Concrete and Reinforced Concrete; on Committee C–1 of the Committee of the American Society for Testing Materials on Cement Specifications; Presiding Officer of the Cement Section of the International Congress of the Association for Testing Materials, in New York, N. Y., in 1924; and as a member of the Government Board for Testing Fuels and Materials.

In addition to his commercial and financial interests, Mr. Lesley found time to devote to other interests, of which golf was one of his particular

hobbies. He served as a Director of the Philadelphia Golf Association, and as President of the United States Senior Golf Association, in 1924. From 1923 until his death, he also served as President of the Merion Cricket Cub. He was the donor of the Lesley Cup, for competition between golf teams from New York State, Pennsylvania, Massachusetts, and Eastern Canada. It was his endeavor always to establish all forms of sport on the highest plane.

His social clubs included the Rittenhouse, Midday, Pine Valley, Radnor Hunt, Bryn Mawr Polo, and the Engineers Clubs of New York and Philadelphia, as well as the Railroad Club of New York.

As a resident on the "Main Line", Mr. Lesley was interested in civic and charitable matters. He was also a Director of the Main Line Citizens Association for many years, and it was during his administration that it was re-organized as the Community Health and Civic Association with its various fields of nursing, zoning, roads, and other local matters. In addition, he was in charge of the Welfare Federation Drive for the Main Line territory, and was interested as a Director of Regional Planning in beautifying the Creek Valleys on the Main Line.

Although brought up a Unitarian in religion, he joined the Roman Catholic Church some years before his death, and found great happiness in the practice of that faith.

Mr. Lesley was a man of wide experience and his charming personality, sympathy, generosity, sense of humor, and joy of life endeared him to his many friends. He was interested in and acquainted with all current events and was well versed in history, art, and literature, and read and spoke both French and German. Although he was eighty-three years of age when he died, Mr. Lesley was active both mentally and physically until shortly before the end. He had established a health program many years before to which he adhered rigidly and to which he attributed his splendid physical condition.

He was married on October 23, 1879, to Eulalia Willcox, of Glen Mills, Pa., and Philadelphia, whose ancestors at the old Ivy Mills, and, later, at the Glen Mills, made the Colonial and Continental Currency paper; they also made the paper for the currency used in the North during the Civil War. Mr. Lesley is survived by his widow and by an only daughter, Mrs. Richard Berridge, of London, England, and Screebe Lodge, County Galway, Ireland. He is also survived by several grand-children and great-grandchildren.

Possessed of a buoyant personality, a sparkling humor, a keen sense of responsibility, and a priceless reservoir of enthusiasm and good cheer, Robert Whitman Lesley will be missed as a man, a loyal friend, and a co-worker in the Cement Industry. He will also be remembered widely, for his presence made the world a somewhat better place in which to live.

Mr. Lesley was elected an Affiliate of the American Society of Civil Engineers on January 31, 1893.
